RFLP type 1-0-4 was associated with increased probability of abortion, sows off-feed, stillbirths, weak-born pigs, sow/boar mortality, and preweaning mortality. RFLP type 1-0-2, was associated with clinical disease in the farrowing phase of production and type 184 was significantly associated with increased abortions.

The GAM models indicated a significant association between PRRSV sequence similarity and similarity of both abortions and stillbirths and that the chance of similarity of these clinical signs was significantly increased when sequences were >92% similar (Fig 1). Including vaccine like viruses in the analyses caused similar model to decline at the upper end of homology.

Discussion
These results indicate that variation in clinical signs of PRRS is caused in part by variation in the PRRSV. For abortions and stillbirths, PRRSV isolates of >92% homology of the ORF5 gene are associated with similar clinical signs. This is in contrast to the benchmark where viruses of <98% ORF5 sequence similarity are considered different (3). Presence of vaccine type virus in a population can have an impact on the interpretation of PRRSV epidemiology. Removal of vaccine type observations before analysis may be necessary to interpret studies such as this because vaccine isolates are genetically similar but are not expected to be associated with similar clinical signs of disease.

References
Introduction

Porcine Reproductive and Respiratory Syndrome (PRRS) is a swine disease produced by PRRS virus (PRRSV), which is antigenically and genetically heterogeneous (1). PRRSV variability extends also to pathogenicity and highly and moderately virulent isolates have been described within the American genotype (2). The infection by highly virulent isolates produces severe clinical signs, significant gross lung lesions and high levels of viremia (2, 3). In a previous study, we characterized the pathogenicity of seven European-type isolates including one isolate which virulence was comparable to that described for American type isolates (4). The aim of this study was to compare the pathogenic properties of this isolate with that exhibited by a European type isolate of remarkable low virulence.

Materials and Methods

Two European-type isolates were used in this study. Additionally a modified live vaccine strain, Ingelvac PRRS, was used as an attenuated control. European isolates were propagated in porcine alveolar macrophages (PAM) and the fifth passage was used for pig inoculation. Vaccine strain was used directly from the bottle. For pig inoculation, a total of 45 3-week old piglets seronegative to PRRSV were divided into 3 groups. On Day 0 of the experiment piglets of groups A, B and C were inoculated intranasally (IN) with 5 x 105 TCID50 of highly virulent isolate, low virulent isolate and vaccine strain, respectively. All pigs were examined daily for clinical signs and rectal temperatures were recorded until the end of the experiment. Biological samples, including serum, nasal and rectal swabs were collected every three days. Five piglets per group were sacrificed on days 7, 14 and 21 post-infection (p.i.) and different tissue samples were collected. At necropsy macroscopic lung lesions were evaluated. Determination of viremia and organic distribution were carried out by virus isolation as previously described (5) on cultures of PAM in the case of field isolates and MARC 145 in the case of vaccine strain. Clinical and viremic results for each pig were converted to an approximate area under the curve (AUC) and different statistical analysis was performed. Finally, a cluster analysis of clinical and virological parameters was performed.

Results

After inoculation, severe clinical signs were observed in pigs exposed to highly virulent isolate, leading to a AUC values of 5.13, 8.0 and 0.4 on the first, second and third week p.i. On the contrary, pigs infected with low virulent isolate and vaccine strain remained clinically normal throughout the experiment, reflected in AUC values that never exceeded 0.5. Seemingly, fever was only recorded in pigs exposed to highly virulent isolate, namely from day 2 p.i. to day 10 p.i. Consistently with the clinical score macroscopic lung lesions were more severe in pigs inoculated with the highly virulent isolate.

Looking at the virological parameters, viremia was more intense with statistically significant differences in those pigs inoculate with highly virulent isolate. Additionally, highly virulent virus was isolated more frequently from tissue samples than low virulent or vaccine strain, being viral load also higher in the former group. Finally, remarkably low virulent isolate was never detected in any swab, indicating a very low shedding rate.

The apathogenic phenotype of the low virulent isolate was confirmed by the grouping of pigs of this group with those infected with the vaccine strain in the cluster analysis.

Discussion

This is the first description of the existence of highly pathogenic and apathogenic PRRSV isolates within the European type. The ultimate causes of the differences in pathogenicity between these two isolates were not elucidated in our study. However, there are strong indications that the replication rate of the isolates and the organic distribution in the pigs upon inoculation can determine their virulence.

Genetic variation and pathogenicity of the recently isolated PRRSV in Korea

Hyun Jang; Ji-Youl Jung; Sung-Su Park; Seong-cheol Moon
Komipharm International Co. LTD, Gyeonggi-do, Korea

Introduction
The porcine reproductive and respiratory syndrome virus (PRRSV) is the causative agent of porcine disease, which has respiratory failure in neonate and abortion in sow. The PRRS is one of the most serious endemic diseases to swine producing countries and heavy economic burden due to the high mortality rate in infected pig. PRRSV is a positive sense single stranded RNA virus of the family Arteriviridae. The genome of PRRSV consist nine ORFs. Among nine ORFs, ORF5 and Nsp2 gene show the highest genetic variations. Especially ORF5 gene encodes GP5 major surface protein, which is major inducer of neutralizing antibodies in vivo. GP5 protein is presumed to interact with sia-loadhesin. Recently isolated PRRSV show different glycosylation pattern in the GP5 protein and is also related with pathogenicity of PRRSV. The aims of this study are analyze genetic variation in the ORF5 gene and its relation to pathogenicity of recently isolated PRRSV in Korea

Materials and Methods
PRRSV isolated lung tissue samples from pig, which was show typical clinical signs of PRRSV infection in the field. Homogenate lung tissue clarified by centrifugation and supernatant filtered using 0.22 μm membrane filter and then inoculate into monolayer forming Marc145 cell. 3 to 5 days after inoculation, virus harvested and quantified virus concentration. GP5 protein gene amplified using PCR method and sequenced and then analyzed and compared with previous reported GP5 gene sequence. PRRS negative pigs were inoculated intratrachealy with isolated PRRSV (Komi-NA263, Komi-NA316 each virus titer adjusted 105.0 TCID50/ml) for pathogenicity test. After challenge clinical signs, body temperature and virus shedding observed every day and autopsy was performed for examination of pathological lesions.

Results
Two field isolated PRRSV Komi-NA263 and Komi-NA316 ORF5 gene sequence show 94 % and 87 % respectively. But both strains was show identical pathogenicity, such as high fever, virus shedding through nasal and respiratory distress. Grossly there was pulmonary edema and multifocal red spots in the lung. Enlargement of spleen and lymph nodes were also observed. Viral antigens in the lung also detected by immuno-histochemical staining. GP5 amino acid sequence at 34 and 35 of the both strains was asparagine and serine respectively. This positions were major glycosylation site at ectodomain of the GP5 protein.

Discussion
The major envelope protein GP5 is the most variable structural protein in PRRSV. In this study virulence of the PRRSV was related to specific amino acid sequence change by the accumulation of mutations rather than overall genetic variations

Reference
Introduction
The porcine reproductive and respiratory syndrome (PRRS) virus is widely distributed over the various pig production areas worldwide.

The diversity of the American PRRS strains has been well documented. That of the European strains has been described only recently (1, 2). The aim of this study was to describe the diversity of the PRRS strains present in a European pig production area that was contaminated in 1991 and has around 7000 pig farms.

Materials and Methods
The study carried out used the blood samples of piglets (9, 12 and 15 weeks of age) of breeder-fattener farms, taken over a period of 4 months (December 2004 to March 2005). The farms were known to be infected and had or had not observed signs that could be attributed to PRRS (in breeding animals and growing pigs). After screening the serum samples using a PCR kit allowing the detection of European and US strains of the PRRS Virus (Adiavet®PRRS), amplification and sequencing of ORF7 and ORF5 genes were carried out for each farm (one sample per farm). Sequence alignment and analysis was carried out using CLUSTALW (1.82), Lasergene (DNAStar) and PHYLIP 3.67 program packages. For the comparative analysis, selected sequences representing the full range of European genotype diversity were used.

Results
In total 51 ORF7 and 46 ORF5 were obtained. All sequences obtained were of the European genotype. The identity with the Lelystad strain was 91 to 100% for ORF7 and 82 to 98% for ORF5. These sequences were also highly similar to the FR/IV4A strain, isolated 14 years earlier at the time of the introduction of PRRSV in the region (Fig. 1).

No clusters were found in association with the clinical signs observed or with the geographical proximity of the farms.

Discussion
The results of this study underline the very high genetic identity, both between the isolated strains and compared to the Lelystad strain. This finding is rather unique considering the genetic diversity in many European countries (3,4), where the heterogeneity of the strains is much higher. In the region studied, the initial outbreak occurred in 1991 with a strain closely related to the Lelystad strain (5). It can be concluded that the great majority of the farms in this region were infected at the time of the original outbreak or later but with the strains originating from the original introduction. Only in 4 farms the strains were found to be unrelated. Since 1991, no new strains have been introduced and the original strains seem to have undergone a natural drift.

Genetic diversity and evolution of Porcine Reproductive and Respiratory Syndrome virus in a large sequence data set from Quebec swine herds

Benjamin Delisle; Carl A. Gagnon; Sylvie D’Allaire
Universite de Montreal, St-Hyacinthe, QC, Canada

Introduction
Porcine reproductive and respiratory syndrome virus (PRRSv) is known to be genetically highly variable; knowledge of this diversity within a geographical region may help to understand the epidemiology of the disease as well as the evolutionary drift in GP5 amino acid sequences. The purposes of our study were to classify the genetic diversity of PRRS in subgenotype clusters for various strains affecting herds in the Province of Quebec, and also to evaluate amino acid (a.a.) variation in vaccine-like strains found in the field.

Materials and Methods
As part of a PRRS surveillance project, samples were submitted by veterinarians over an 11-year period. Samples originated either from herds 1) experiencing reproductive or respiratory problems, 2) monitoring regularly their PRRS status, or 3) participating in a research project on risk factors for PRRS (see abstract by Lambert et al. in this IPVS proceeding). A total of 1345 ORF5 sequences from 659 production sites were obtained. RT-PCR and sequencing were done to obtain ORF5 gene. A dendrogram was made by phylogenetic analysis with the Neighbor-Joining algorithm in the Bionumerics software. Two different subsets were constructed and analyzed by phylogenetic alignment and selective evolutionary pressure by non-synonymous to synonymous rate, \( dN/dS \) (SNAP web utility and PAML 4.3).

Results
The first and largest dataset consisted of 520 sequences obtained after excluding redundant sequences, e.g. those with more than 98% of homology. Following a clustering analysis, 28 different groups were obtained. Half of the clusters were primarily composed of cases submitted in the earlier part of the surveillance project (2004-2006), whereas some others mainly included more recent cases (2007-2009), suggesting temporal variations in strain proliferation and consequently, its evolution. Some geographical clustering could also be observed. Amino acid non-synonymous substitution was generally high in the GP5 peptide signal region but also in two hypervariable regions (HVR) located between aminos 32-35 and 57-59 for all clusters. Very few amino substitutions were observed in the principal neutralizing epitope (PNE) between aminos 36-52, which is flanked by both HVR.

The second dataset extracted from the database focused on PRRS vaccine and vaccine-like strains. A total of 159 PRRS MLV-like and 46 PRRS ATP-like deduced a.a. sequences were obtained. A comparison of these strains found in the field with both vaccines and their parental strains (VR2332 and JA142) showed that a single amino, F101, was conserved when compared to actual and past wild-type field strains. Also, separate comparison of both vaccine-like field strains collected revealed that MLV-like had undergone very little a.a. variations in the last 2/3 of the GP5 amino acid sequence, as compared to ATP-like strains which had undergone more variation thru synonymous mutations (negative selection) and some non-synonymous mutations (positive selection). Positive selective pressure was statistically significant ([1-P] value was ≥98.5%) for 7 a.a. sites in MLV-like (3, 13, 32-34, 58 and 151) and 5 a.a. sites in ATP-like strains (32, 57-59 and 102).

Discussion
The interpretation of low or high PRRS subgenotype viral spread through time in affected regions can possibly help in predicting trends in emerging strain clusters. Even though some clusters could be attributed to temporal evolution or geographical area, the proportion or importance of each of these factors will have to be estimated. Further analysis of these clusters by SNAP showed PNE region to be relatively well conserved among clusters (1). This might indicate molecular constraints in possible viral receptor recognition site as seen for other RNA viruses (2,3).

The mutation found on almost all vaccine and vaccine-like strains can help distinguish field strains from vaccine derived field strains, therefore fulfilling a need for a typing tool, this is particularly important considering possible reversion to virulence by these vaccine like-strains (4). Analysis of these clusters by SNAP showed slightly different patterns of evolution. Position of sites under selective pressure might indicate a link between PNE (conserved region) and adjacent HVR. The factors implicated in selective pressure and evolution of vaccine derived strains remain to be clarified.

References
Introduction
Porcine reproductive and respiratory syndrome virus (PRRSV) is an emerging pathogen causing serious clinical problems in pig farms around the world. The viral genome is a positive-strand RNA and is evolutionary diverse. PRRSV exists in two genotypes: European (EU) genotype, type 1 (PRRSV-1) and North American (NA) genotype, type 2 (PRRSV-2). Based on nucleotide sequence variability, the EU genotype is genetically divided (Stadejek et al., 2006) forming three subtypes (Stadejek et al., 2008). The aim of this work was to contribute to genetic characterization of PRRSV isolates collected in Central Europe, namely in Slovakia, the Czech Republic, and Austria by their analysis in ORF5 and ORF7 regions.

Material and Methods
Ten viral samples (serum, lymph nodes, and lung) from pig farms in Slovakia, 10 viruses from the Czech Republic and 10 viral samples from Austria were collected in the period of last 5 years from clinically suspicious animals showing respiratory problems. The total RNA was extracted using Trizol reagent (Invitrogen) according to the manufacturer’s manual. The cDNA was prepared using gene-specific primer and SuperScript reverse transcriptase (Invitrogen). ORF5 and ORF7 fragments were prepared by nested RT-PCR using outer and inner primers according to Oleksiewicz et al. (1998) and Drew et al. (1997). Purified PCR products were sequenced using automatic sequencer ABI PRISM. Partial ORF5 sequences (432 nt) and entire ORF7 were assembled using SeqMan. The alignment was carried out and percentage of nucleotide identity were calculated using MegAlign (DNASTAR).

Results
All 30 PRRSV strains from Slovakia, the Czech Republic, and Austria were typed in both genomic regions, e.g. ORF5 and ORF7, as EU genotype (PRRSV-1), subtype 1. No geographic distribution of PRRSV isolates were observed in the phylogenetic trees. However, the grouping of viruses according to farms, especially with isolates from Slovakia was observed. Percentage of nucleotide sequence identity in ORF5 between Slovakian strains varied in the range 83.6-100 %, Czech strains – 82.6-100 % and Austrian strains – 84.5-98.1 %. Similar values were obtained when sequences were compared to the European genotype 1 prototype strain Lelystadt: 85.4-89.1 %, 85.0-98.6 %, 89.4-98.6 %. Corresponding values in ORF7 were as follows: 87.3-100 %, 87.6-100 % and 91.5-100 %, to Lelystadt strain: 90.7-93.3 %, 89.4-100 % and 94.6-98.7 %.

When compared amino acid sequence (aa) for entire ORF7 region, in all strains analyzed the size of this region was the same - 128 aa. However, the polymorphism in ORF7 size reaching 132 aa in two isolates from a pig farm in Slovakia was observed. The size was not the result of insertion/deletion of amino acids but longer ORF7 at C-terminus.

Discussion
Our work contributes to information on genetic characterization of PRRSV isolates in pig farms of Central Europe. The isolates belong to EU genotype, as it is prevalent in other western European strains (Fosberg et al., 2002) independently if they were analyzed in ORF5 or ORF7 genomic regions. On the other hand our results revealed new and the first time observed polymorphism on ORF7 size since two isolates had ORF7 size 132 aa differing from standard size – 128 aa for PRRSV-1, subtype 1 isolates. Recently it has been suggested that the ORF7 size 128 aa can be used as characteristic parameter for typing of EU genotype (PRRSV-1), subtype 1 strains (Stadejek et al., 2008). The results of our work indicate that two strains from Slovakia failed this criterion. Reason for ORF7 size polymorphism is not clear at present.

**Introduction**

A high degree of variability exists within European genotype of porcine reproductive and respiratory syndrome virus (EU-PRRSV). The EU-PRRSV strains can be grouped into several subtypes based on the sequence of the ORF7 gene coding for the capsid protein (2). While in majority of Europe relatively similar strains circulate, having ORF7 387 nucleotides long (subtype 1), the East European countries like Latvia, Lithuania, Belarus, Ukraine and Russian Federation harbor extremely diverse strains with ORF7 size from 375 to 393 nucleotides that belong to multiple genetic subtypes (2, 3). Exploring variability of the ORF7 is of major importance because it can influence the sensitivity and specificity of the PCR and serological diagnostic methods (1, 2). Here we determined the ORF7 sequences of PRRSV from recently obtained samples from Latvia, Lithuania, Belarus, Ukraine, Russia, Poland, Hungary, Croatia and Serbia.

**Materials and Methods**

Samples of serum, aborted fetuses or lungs were submitted for diagnosis to the authors’ laboratories. Total RNA was extracted, complete ORF7 sequences were amplified and sequenced with different methods used in the laboratories. The sequences were assembled and analysed using programs from the Lasergene program package, (DNASTAR) and the CLC Sequence Viewer (CLC Bio). As a reference, a set of 69 ORF7 sequences representing the full range of EU-PRRSV diversity was used.

**Results**

A total of 28 complete ORF7 sequences representing field PRRSV strains from, Latvia (1), Lithuania (3), Belarus (3), Ukraine (1), Poland (5), Hungary (8), Croatia (4) and Serbia (3) were obtained and all of them were classified to the European genotype. Their analysis showed that Polish, Hungarian, Croatian and Serbian strains were closely related and had ORF7 consisted of 387 nucleotides characteristic for subtype 1 strains. On the other hand, the new Latvian, Lithuanian, Belarusian and Ukrainian ORF7 sequences were distantly related to those from abovementioned countries and exhibited extensive but expected size polymorphism (375, 378 or 387 nucleotides) as it was shown before (2, 3).

**Discussion**

This collaborative report provides another evidence for already well documented extreme diversity of EU-PRRSV. The position of the most diverse strains in the countries formerly being part of the Soviet Union (Latvia, Lithuania, Belarus, Ukraine and Russia) indicates that the EU-PRRSV could have emerged there. Possibly only a single variant of the genotype diffused westward giving the origin to the presently globally spread subtype 1. The oldest serological evidence of PRRSV in Europe comes from East Germany from 1986. The first PRRS outbreak in Europe occurred also in Germany at the time of the country’s re-unification in 1989. These two pieces of evidence suggest that the source of virus for the first outbreak could be in East Germany. PRRS was recognized in Central Europe a few years later than in West Europe and several anecdotal reports pointed that the infection occurred after importation of pigs or contaminated semen from West Europe. However, it cannot be excluded that before the European epidemic PRRSV was present not only in East Germany but also in other countries of Central Europe. In summary, the presented data confirm that the strains from Central and Western Europe are closely related and have common origin while the strains from East Europe are much more diverse.

Broad cross protection against PRRS induced by chimeric viruses containing mixed structural gene fragments from distinct heterologous PRRSV viruses

Dong Sun¹ Wonil Kim² Yongil Cho¹ Sangho Cha³ Eunjin Choi³ Kyoung-Jin Yoon¹
¹. Iowa State University, Ames, IA, USA; 2. Chonbuk National University, Jeonju, Korea; 3. National Veterinary Research and Quarantine Service, Seoul, Korea

Introduction

PRRS virus (PRRSV) is one of the economically significant pathogens in the swine industry throughout the world. Vaccines can be an intervention tool, but a high degree of genetic variation among PRRSVs makes the protection induced by a monovalent vaccine limited to its homologous virus strains, impeding effective prevention of PRRS. Thus vaccines that can produce broad protection against heterologous viruses are highly desired for better control of the disease.

PRRSV GP5 is known to play a major role in the induction of anti-PRRSV neutralizing antibody. Yet, our recent study has demonstrated that GP3 and M also significantly contribute to cross-neutralization between different PRRSVs. Furthermore, GP3 was more critical than GP5 or M in overall virus neutralization against a PRRSV strain whose GP5 is highly glycosylated. Therefore, it was hypothesized that a chimeric virus of 2 distinctive PRRSVs can confer better cross-protection against those viruses if necessary genes from the 2 viruses are put together in a structured manner based on their prime role in virus neutralization.

Materials and Methods

To test the hypothesis, 3 chimeric viruses designated as JAP5, JAP56 and JAP2-6, respectively, were generated from the VR2332 infectious cDNA clone by replacing its ORF5, ORFs 5 and 6 or ORFs 2-6 with that/those of the JA142 strain that is genetically and antigenically distinct from the VR2332 strain. A total of 114, 3-week-old pigs were divided into 6 groups and each group was inoculated with one of the chimeric viruses, VR2332, JA142, or sham inoculum. At 44 days post inoculation (dpi), 8 pigs each within each group were randomly selected, housed separately and challenged intranasally with VR2332, JA142, or sham inoculum to determine if protective immunity was conferred by inoculation of the chimeric viruses. All pigs were bled periodically until 72 dpi and tested for viremia and antibody response. Half of the pigs in each room were necropsied at 14 days after the challenge and the remaining at 28 days for pathological evaluation.

To further assess the validity of chimeric virus strategy, 12 additional chimeric viruses randomly combining ORFs 2-4 and ORFs 5-6 of four antigenically and genetically distinct PRRSVs (1648-02, 17198-2, MN184 and SDSU73) were constructed using the VR2332-backbone infectious clone. Antisera against each donor virus were generated in 3-week-old pigs which were euthanized at 45 dpi. Neutralizing activity of each serum against each of the chimeric viruses was tested in vitro by a two-way fluorescent-foci neutralization assay.

Results

JAP56 was well neutralized in vitro by antisera raised against each of the donor strains whereas each donor strain was neutralized only by the homologous antisera. In pigs, the prior inoculation with JAP5 or JAP56 effectively protected the pigs from the challenge with VR2332 while the pigs inoculated with JAP56 or JAP2-6 demonstrated excellent protection against JA142 infection, suggesting that the JAP56 chimeric virus may be used as a vaccine candidate to induce broad cross-protection against both VR2332 and JA142.

As observed with the VR2332 and JA142 chimeric viruses, antisera generated against other donor viruses neutralized each of the chimeric viruses containing ORFs 2 to 4 from one strain and ORFs 5 and 6 from another as effectively as the homologous donor virus, while little cross neutralization was observed among the donor viruses.

Discussion

These observations suggest that the strategy of constructing chimeric viruses by combining structural genes from distinct heterologous strains in an organized manner can provide broad protection and can be widely applicable as a novel vaccine platform for PRRSV.

Lack of correlation between genetic and antigenic classification of European-type porcine reproductive and respiratory syndrome virus isolates

Francisco Javier Martínez-Lobo; Francisco Díez-Fuertes; Lidia Hornillos-Gumiel; Isabel Simarro; José María Castro; Cinta Prieto
Facultad de Veterinaria Universidad Complutense de Madrid, Madrid, Spain

Introduction
One of the main characteristics is its great variability. The extensive heterogeneity observed at the genomic level is likely to cause wide antigenic differences among the diverse PRRSV isolates and, in fact, significant differences have been reported between different isolates (1). However, current knowledge of antigenic variability of PRRSV is rather limited compared to the existing information on genomic diversity. Consequently, the main objective of the present study was to characterize European-type porcine reproductive and respiratory syndrome virus isolates by means of cross-neutralization assays, studying the possibility of the existence of serogroups, and to verify whether genotypic relationship reflect antigenic associations between PRRSV isolates.

Materials and Methods
Twenty nine PRRSV isolates were used in this study, of which one belonged to genotype II and was isolated in Denmark and 28 belonged to the European genotype. Of these 17 were Spanish isolates, 5 originated from Western Europe, 4 from Italy and 2 from Poland and Czech Republic, respectively. These isolates were adapted to replication in MARC-145. ORF5 of all isolates were amplified and sequenced and a phylogenetic tree was constructed. Monospecific antisera against these isolates were produced in 6-month-old PRRSV seronegative pigs and used in seroneutralization (SN) assays performed as described by Yoon et al (2). Homologous SN titers were adjusted to a titer of 1:128 either by dilution or concentration by antibodies precipitation using ammonium sulphate. All sera were used in cross neutralization assays, and heterologous titers were used to estimate antigenic similarity coefficients (R) that were used to construct a dendogram (3).

Results
The dendrogram obtained shows that the PRRSV isolates are antigenically diverse and are segregated into a considerable number of groups. When we use R values ≥ 25, which have been previously associated with significant antigenic differences (3), 19 different groups are defined, of which only 5 comprise more than one isolate. The comparison of antigenic and genomic dendograms indicates that there is no correlation between antigenic and genomic clustering of PRRSV isolates. Analysis of ORF5 and particularly of neutralizing epitope sequences or potential N-glycosilation sites is not predictive of antigenic similarity.

Discussion
The results of our study show that antigenic diversity among European isolates is significant and that no clear antigenic groups can be defined. Additionally the comparison of the antigenic and genomic dendograms indicated a lack of correlation between antigenic and genetic classification of PRRSV isolates.

Median infection dose (ID50) of PRRSV isolate MN-184 for young pigs via aerosol exposure

Tim D. Cutler1 Apisit Kittawornrat1 Steven J. Hoff2 Chong Wang2 Jeffery J. Zimmerman3
1. Iowa State University, Ames, IA, USA; 2. Iowa State University, Department of Statistics, Ames, IA, USA; 3. Iowa State University, Dept. of Vet Diagnostic and Production Animal Medicine, Ames, IA, USA

Introduction

The objective of this research was to quantify the likelihood of PRRSV transmission via aerosols as a function of exposure dose. This data is critical to understanding of airborne transmission of PRRSV between pigs, within herds, and between herds.

Materials and methods

The study used PRRSV isolate MN-184 (kindly provided by Dr. Scott Dee, UMN). All procedures were approved by the Iowa State University IACUC committee (#9-07-6429-S). All pigs were confirmed PRRSV negative prior to commencement of the experiment and were housed in HEPA-filtered isolation units throughout the experiment to avoid inadvertent transmission of pathogens.

The study was conducted in 10 replicates, 10 pigs per replicate, with pigs randomly assigned to treatment. One negative control pig and one positive control pig were included in each replicate. The negative control pig was used to validate biosecurity procedures, i.e., was present in the laboratory during the aerosol exposure treatments, was housed in the same room as pigs exposed to PRRSV aerosols, and was monitored throughout the observation period. The positive control pig was inoculated intramuscularly with 10 ml of fluid from the last air sample in each run to prove that infectious, airborne PRRSV was in the air to which pigs were exposed throughout the experiment.

Figure 1: Cartoon depiction of aerosol exposure. [A] Nebulizer with PRRSV, [B] Impinger for sampling cloud, [C] Aerosol reservoir, [D] Spirometer

To conduct the experiment (Figure 1), PRRSV MN-184 was aerosolized [A] into a dynamic aerosol toroid [C]. Pigs to be exposed to the PRRSV aerosol were anesthetized, fitted with a canine surgical mask attached to a pediatric spirometer [D]. Each pig respired 10 liters of virus aerosol. Air samples [B] were collected before and after each pig was used to estimate the exposure dose. Serum samples collected 5 and 10 days post-exposure (DPE) were tested for the presence of PRRSV to determine whether exposure resulted in infection. The dose-response curve for exposure to airborne PRRSV was derived from the proportion of pigs infected by dose.

Results

Three replicates were disqualified due to failure to meet quality criteria; therefore, the infectious dose 50 (ID50) estimate was based on 7 replicates. Initial analysis showed that the infective dose 50 (ID50) of MN-184 under the parameters of this study (pig body size and age, exposure dose and time) was <1 x 101 TCID50.

Discussion

Under comparable conditions, the ID50 estimate we report for MN-184 is lower than the ID50 estimate for isolate VR-2332 (Hermann et al., 2009). The data suggest that the ID50 for airborne PRRSV may vary among isolates and supports reports of transmission of PRRSV via aerosol (Dee et al., 2005).

Introduction
The FAO (1999) estimates that at least 25% of world grain and seed production is contaminated by fungi and their mycotoxins, and are considered as one of the greatest risks that affect human and animal health (1). The fumonisins have been associated with certain diseases in animals such as the leucocencefalomalacia in equines (ELEM) and pig lung edema (PLE) (3). The porcine reproductive and respiratory syndrome (vPRRS) has economically impacted the national and international swine industry, for 20 years

Material and Methods
The reference Strain ATCC 2332 of the PRRS virus was cultivated in MA-104 African Green monkey kidney cells, and the pigs were challenged with 104 TCFF50/ml. The FB1 used was a standard (SIGMA), in 5 mg and 10 mg vials with 98% purity. A stock solution was prepared at a concentration of 87ppm in distilled water. The FB1 was administered to weaned pigs in 12ppm (mg/kg live weight) by the oral route by means of a probe.

Experimental animals: Twenty five recently weaned pigs 22-36 Days of age, with a weight of 4.17 to 7.6 kg, from a vPRRS free farm were used. The animals were distributed into 5 groups; each group consisting of five pigs Group A: negative Control. Group B: Treated with FB1 12 ppm on day 0 (beginning of the experiment). Group C: inoculated with PRRSv on day 8. Group D: inoculated with vPRRS on day 0 and simultaneously intoxicated with FB1 12ppm. day 0 day 0. Group E: intoxicated with FB1 12ppm on day 0 and inoculated with vPRRS on day 8. Blood was collected in vacuum tubes containing EDTA on days 0, 8, 16 and 18, for processing by the nested RT-PCR technique to identify the PRRSv. For the histopathological study samples of kidney were collected and fixed in 10% buffered formalin for further processing (4) and finally stained with hematoxylin and eosin.

Results
The nested RT-PCR was negative for groups A and B. For groups C, D and E which were inoculated with PRRSv were positive. Histopathology in Group A was without evident pathological changes. The kidney damage was observed in groups B, D and E, and was characterized by basophilic cytoplasm in the cells of the tubules, suggestive of immature cells in the process of repair, on these tubules in presented polyploidy and in most of the observed lesions the tubules did not showed light (aberrant repair, non functional). These are located next to the glomerulus and areas of straight interlobullar tubules, so probably correspond to the proximal convoluted tubules. In most cases, it was observed mononuclear cell infiltration in association with these damaged nephrons. At the glomerular level very cellular and swollen glomeruli were observed, suggesting proliferative glomerulitis. We also observed in lesser quantities retracted, smaller atrophied glomeruli. In some sections the interstitial cortical area showed mononuclear infiltration, but rarely the medullary level.

Discussion
The kidney lesions observed are suggestive of toxic processes, apparently in proximal convoluted tubules, that can relate to the presence of FB1, of which there are no previous reports in pigs, only in rodents (5), so we suggest conducting trials to evaluate these effects. Glomerulonephritis and the PRRSv can lead to a hipoalbuminemia and to the development of edema. In Group C, where only PRRSv was applied, we also noted kidney injuries, it was noteworthy since the presence of these alterations in this pathology is not common. It has been reported kidney lesions associated with infection of the PRRSv, showing inflammatory infiltration observed in renal cortex and Medulla, as well as renal vascular changes (2).

Conclusions
It would be desirable to focus an investigation that concentrates in assessment of renal damage in pigs by FB1

We thank
Ing. Draucin Celis for his technical support.

1. Departamento de Anatomía y Anatomía Patológica Comparadas, Universidad de Córdoba, Córdoba, Spain; 2. Veterinary Laboratories Agency, New Haw, Addlestone, Surrey, UK; 3. Departamento de Anatomía y Anatomía Patológica Comparadas, Universidad de Murcia, Murcia, Spain

Introduction
Apoptosis is a strictly regulated mechanism of cell death that involves a complex network of biochemical pathways. Whether a cell undergoes apoptosis or not depends on a delicate balance of anti- and pro-apoptotic stimuli (1). This phenomenon can be induced by two different pathways: intrinsic and extrinsic pathways (2, 3). The main aim of this study was to determine the ideal fixative and antigen retrieval method in porcine paraffin embedded tissues for the immunohistochemical detection of apoptosis mediators, from both extrinsic and intrinsic pathways.

Materials and Methods
To carry out this study we used 5 week old pigs from a previous experiment (4) in which the animals were inoculated with a European PRRS virus strain. From this previous experiment we selected animals that were caspase 3-positive and TUNEL-positive. At the necropsy samples from the lung, tonsil and retropharyngeal lymph node were collected and fixed in different fixatives: 10% neutral buffered formalin, Bouin’s solution and Zinc salts solution. Four μm sections were performed and 6 primary antibodies were used for the immunohistochemical study: caspase 3, caspase 8, caspase 9, bcl-2, Fas, iNOS; and a kit for TUNEL technique. Different antigen retrieval methods were carried out: no pretreatment, Tween 20, Citrate microwave and Proteinase K. All the samples were evaluated determining the intensity of the positive reaction as well as the background. In addition, the number of cells per mm2 or structure (lymphoid follicle, paracortex, or medulla) and the main cells immunolabelled against each antibody were examined.

Results
The best fixative and antigen retrieval method for the antibodies against caspase 8 and Fas (extrinsic pathway of apoptosis) were Zinc salt fixative and Citrate microwave unmasking technique. To determine the intrinsic pathway the ideal fixative and antigen retrieval method for each antibody was as follows: for caspase 9, fixation in Zinc salt solution and antigen retrieval with Tween 20; for Bcl-2 and iNOS the optimal immunolabelling was observed in 10% neutral buffered formalin fixed samples and with Proteinase K and Citrate microwave as antigen retrieval methods, respectively.

The main cells immunolabelled against each antibody were macrophages and lymphocytes from paracortical areas (T-cell areas) of lymphoid organs and from the alveolar septa of the lung. Occasional immunolabelled cells were also observed in the lymphoid follicles (B-cell areas) of the retropharyngeal lymph node and tonsil and in the alveoli of the lung. Few neutrophils showed positive immunostaining against caspase 9 and iNOS antibodies.

Discussion
Our results show useful new tools which may be used to study apoptosis phenomena and to deepen in the knowledge of the pathogenesis of several porcine diseases.

References
Introduction
Respiratory diseases cause important economic losses in industrialized pig production. As respiratory diseases are mainly caused by multiple infections, these are referred to as porcine respiratory disease complex (PRDC). Viral pathogens, especially the Porcine Reproductive and Respiratory Syndrome Virus (PRRSV) and the Porcine Circovirus Type 2 (PCV2), are important players within the pathology of PRDC (1-3). Therefore an exact etiological diagnosis is of great importance for effective management of respiratory diseases.

Materials and Methods
A total of 677 pigs (494 weaned piglets, 151 fattening pigs, 11 gilts, 21 sows), which had been submitted to the clinic for swine of the University of Veterinary Medicine Vienna for diagnostic reasons due to respiratory distress in the course of three years, was sacrificed and post mortem analysed by means of standard bacteriological analyses and serological measurements using commercially available ELISA kits.

Results
Most frequently, PRRSV could be identified as etiological agent in weaned piglets (34.7%) as well as in fattening and breeding pigs (50.5%). A. pleuropneumoniae was isolated out of 21.3% of weaners and 31.1% of pigs over 30 kg BM. In weaners, α-hemolysing streptococci could be isolated out of 20.6% and P. multocida out of 16.6% of cases, whereas in fattening and breeding pigs the corresponding percentages were 17.4 and 26.6. The seroprevalence of SIV-antibodies was approximately the same in all age groups (14.4-14.7%). Also for H. parasuis no marked differences (weaners: 11.6%, fattening and breeding pigs: 12.6%) could be found. A. pyogenes, B. bronchiseptica, and mycoplasmae were isolated at even lower percentages.

Discussion
The results highlight the drawbacks of nowadays routine diagnosis as only in 43% of investigated pigs one or more specific pathogen(s) could be identified. This could be the consequence of an antibiotic treatment prior to submission to the clinic, or the missing of a more intense diagnostic search for viral pathogens, such as PCV2. The high incidence of viral diseases can also be delineated from the high incidence of interstitial pneumonias. Interestingly, the comparison of pathogen incidences in the two age groups (weaners on the one hand and fattening and breeding pigs on the other hand) clearly shows very similar distributions. Out of these reasons, increasing attention should be paid to (I) more sophisticated diagnostic procedures and (II) proper vaccination and management strategies against viral respiratory pathogens.

Targeted sampling for enhancing the detection of PRRS virus infection in suckling piglets

Jean P. Cano1 Scott Dee2 Albert Rovira2 Claudia M. Zanzi2 Sukumarannair Anil2 Robert Morrison2

1. Boehringer Ingelheim Vetmedica, Inc., St Joseph, MO, USA; 2. College of Veterinary Medicine, University of Minnesota, St Paul, MN, USA

Introduction

An important challenge for swine practitioners is to determine whether porcine reproductive and respiratory syndrome virus (PRRSv) transmission is occurring in the sow herd. A “traditional monitoring protocol” used in North America is to sample 20-30 piglets at weaning, pooling the samples in groups of 5, and testing them by PCR.1,2 However, if the prevalence is very low, the probability of detecting infected piglets with this protocol is also very low. “Targeted sampling” has been used to increase the likelihood of detecting low prevalence diseases in animal populations.3,4 This strategy focuses sampling on high-risk individuals in which specific risk factors exist. It was hypothesized that pigs with specific attributes were more likely to be infected. The objective of this study was to identify those factors and their distribution across infected and non-infected piglets and litters.

Materials and Methods

A 1500 sow farrow-to-wean farm originally populated as PRRSv-naïve became infected. The owners and the veterinarian decided to inject serum containing the herd specific PRRSv isolate to all the sows in an attempt to hasten the spread of the virus. This decision provided an opportunity to conduct the proposed study. To estimate the prevalence of PRRSv infected litters and piglets, blood was collected from a random sample of 38 litters at birth and again at weaning. All piglets in selected litters were sampled. Two farrowing groups were selected as being representative of epidemic (4 weeks post-inoculation / PI) and endemic infection (12 wks PI). Serum samples were randomly pooled in groups of 5 (1 mL of serum per piglet) and tested by RT-PCR. All samples in a positive pool were tested individually.

Results

During the study, 133 PCR-positive results were obtained from 1,507 piglets at birth and weaning. In the univariate logistic regression analysis, litter indicators including, light average litter weight and gilt litters were associated with the detection of PRRSv in at least one of the sampling times (P≤0.1). Significant piglet indicators included being a barrow, having a dome shape head and having a fuzzy hair coat (P≤0.1). The odds for a barrow sampled from light litters to be detected as PCR-positive was 6.86 (CI: 2.4 - 19.6) times higher than for the rest of the piglets sampled at weaning 12 wks PI (Table 1).

Discussion

Alternative sampling protocols should consider targeted sampling of piglets with attributes associated with infection. In our study, sampling barrows from light litters at weaning increased the probability of detecting PRRSv by PCR. However, further investigation is required to validate attribute associations and to improve monitoring programs.

Introduction
Porcine reproductive and respiratory syndrome virus (PRRSV) causes severe respiratory diseases in nursery and growing-finishing pigs and has a major role in porcine respiratory disease complex (PRDC). Outbreaks of PRRS in Taiwan swine herds between July 1991 and June 1993 incurred significant economic loss to the local pig industry (1). Following Vietnam, the Philippines was the second country experience a serious outbreak of the disease. Philippine pig herds were infected with highly pathogenic PRRSV in 2008, which has a 98% sequence similarity with the Chinese type and is characterized by high fever and pathogenic clinical syndrome (4). The growing commodity trade between Taiwan and Southeast Asian countries has increased the risk of importing PRRSV into Taiwan. This study collected serum samples from northern Taiwan pig farms to test for PRRSV antibody. Oral-nasal swabs were collected from sero-positive pig farms and PRRSV was detected by molecular diagnostic method. The data revealed the distribution of European, North American or China strain of PRRSV in Northern Taiwan.

Materials and Methods
The epidemiological survey of PRRSV was performed using nationwide stratified random sampling method. The sample size of 15 pigs per herd was tested that is intended to detect PRRSV at 95% confidence interval with a 20% infection rate. The serum samples were tested for PRRSV antibodies using a commercially available enzyme-linked immunosorbent assay (ELISA) kit (IDEXX PRRS Ab test kit), and a ratio higher than 0.4 was considered seropositive for PRRSV (2). Three farms were selected from each county that was seropositive for PRRSV, and 10-15 porcine oral-nasal swabs were collected from each farm for testing by reverse transcription and polymerase chain reaction (RT-PCR) to determine whether PRRSV was European type (EU) (3), North American type (NA) (3) or China type (CN)(4). All PCR products were sequenced and compared with PRRSV sequences obtained from Genbank.

Results
The epidemiological survey conducted in 2009 estimated the herd prevalence of PRRSV in northern Taiwan. Sixty-five randomly selected herds and 953 blood samples were examined in this study. The overall PRRSV herd prevalence was 80% (52/65) and sero-prevalence was 62% (595/953). The within-herd prevalence in the fifty-two sero-positive herds was 100% in twenty-four (37%) herds, between 50% and 100% in sixteen (25%) herds, and less than 50% in twelve herds. From each of twelve selected farms, 12-15 oral-nasal swabs were collected from nursing and growing-finishing pigs. Only one swab sample was positive for PRRSV NA type by RT-PCR. Sequence analysis of PCR products showed that the PRRSV was 91% homologous to VR-2332 (NA stain). No EU or CN type was detected in the study.

Discussion
Analysis of 953 blood samples taken from sixty-five northern Taiwan pig herds revealed a 62% sero-prevalence of PRRSV antibody, which was slightly lower than the 64-86% prevalence reported in a 1996 investigation (5). None of the sampled swine herds had received PRRSV vaccine within the previous year. The 80% herd prevalence of PRRSV could be considered the actual field PRRSV infection rate. Only one PRRS vaccine (Ingelvac® PRRS MLV) has been used in the field in Taiwan recently. Ingelvac® PRRS MLV is a modified live vaccine based on VR-2332 strain. However, sequence analysis demonstrated a substantial difference between VR-2332 strain and PRRSV detected from swab in swine herds, indicating that the status of PRRSV in swine herds had changed in Taiwan. Fortunately, no CN-type PRRSV was found. However, continuous tracking of PRRSV surveillance is essential.

Oral fluid diagnostic samples can be collected from individually-penned adult swine

Jeremy Johnson1 Mark Engle2 Apisit Kittawornrat1 John R. Prickett1 Trevor Schwartz1 Dan Whitney1 Chris Olsen1 Kent Schwartz1 Chong Wang1 Jeffrey J. Zimmerman1
1. Iowa State University, Ames, IA, USA; 2. PIC North America, Hendersonville, TN, USA

Introduction
Cumulatively, the literature supports the implementation of oral fluid-based diagnostics as a method to monitor infectious diseases in swine populations: (1) oral fluid samples are quickly and easily collected; (2) detectable levels of pathogen-specific IgA, IgM, and IgG antibodies are present in oral fluids; (3) a variety of infectious agents are shed in oral fluid, including highly significant pathogens of production animals, e.g., FMDV, CSFV, PRRSV (Prickett et al., 2008a), and PCV2 (Prickett et al., 2008b). Previous experiments used pen-based oral fluids to monitor PRRSV and/or PCV2 infections in wean-to-finish populations (Prickett et al., 2008a,b). The objective of this study was to determine if oral fluids could be collected from individually-housed boars.

Materials and Methods
The study was conducted using boars owned by PIC North America (Hendersonville, TN USA). Housing, procedures, and protocols were approved and supervised by the PIC USA Health Assurance and Welfare department. Three trials of 24 boars (6 months to 3.6 years of age) were conducted. Trial 1 used only select (young) boars; Trials 2 and 3 included both select and cull boars. Samples were collected for 8 days using 5/8", 3-strand, 100% cotton rope was cut into 22" lengths. One end was untwisted, soaked overnight in a flavoring solution (unsweetened apple juice with 50% (v/v) sucrose) and air-dried. Ropes were placed in brackets, threaded through the pipe, and knotted to prevent slipping. Boars had access to the ropes for 20 minutes. To recover the sample, a 6' segment of the "boar end" of the rope was cut, inserted, and sealed into a re-sealable plastic bag. Oral fluid was extracted by passing the plastic bag, with the rope inside, through a hand wringer, allowing the fluid to accumulate in a bottom corner of the bag. The bag was then cut and the contents decanted into a 50 ml tube.

Results
Among 576 attempted oral fluid samples (8 days x 24 boars x 3 trials), 524 (91%) samples were collected. Among a potential total of 192 potential samples in each trial, 188 (98%) samples were collected in Trial 1, 155 (81%) in Trial 2, and 181 (94%) in Trial 3. The rate of successful collection initially increased during the observation period and then stabilized. Analysis of these data showed that trial (p = 0.0339) and observation day (p < 0.001) were statistically significant sources of variation, but boar age (p = 0.9525) was not.

The average volume of oral fluid collected per boar across all trials was 17.9 ml (range: 1 to 39 ml). Analysis of the sample volume data showed that day (p < 0.0001), age (p = 0.0127) and in the interaction of trial x sampling day (p < 0.001) were statistically significant sources of variation.

Conclusions and Discussion
Oral fluid samples can be collected from individually-housed adult animals. Improvements in the success rate through the use of attractants or flavorings needs to be evaluated. As opposed to pen-based oral fluid testing, oral fluid samples from individual animals provide the opportunity to evaluate individual responses to infection under experimental and/or field conditions. This approach could offer significant improvement in the ease, timeliness, and cost of disease surveillance.

Seroprevalence of Porcine Reproductive and Respiratory Syndrome (PRRS) in wean to finish pig farms

Luminita Costinar1 Viorel Herman1 Corina Pascu2 Bogdan Faur1 Ioana Vaduva1 Anca Surpat1 Sorina Ieremie1

1. Faculty of Veterinary Medicine Timisoara, Timisoara, Romania; 2. USAMVB Timisoara, Timisoara, Romania

**Introduction**

PRRS is probably the most important swine disease of the last half-century. PRRS has been observed in the majority of European countries. In Romania, the disease has been continuously spreading in the pig population since it was first diagnosed by Stanuica and col. 1998. The PRRS virus is an enveloped RNA virus in the genus Arterivirus, classified in the virus family Arteriviridae and produce reproductive disorders in breedings farms and respiratory disorders in finishing farms.

An important feature of the PRRS virus is its ability to persist in long-term carrier pigs, greater than 200 days. The aim of the present study was to a cross-sectional study on 6 fattening farms to estimate the seroprevalence of antibodies directed against PRRSV in 4 week-old pigs, 12-13 week-old pigs and 20-27 week-old pigs.

**Materials and Methods**

There were tested 262 blood samples from 6 finishing farms at different times. Samples were analyzed for the presence of antibodies against PRRS by PRRS IDEXX ELISA (HerdChek® PRRS 2X, IDEXX, Switzerland). The presence or absence of antibody to PRRS in the sample is determined by relating the value of the unknown to the positive control mean by calculating the sample to positive (S/P). An S/P ≥ 0.4 was considered seropositive. Statistical analysis was performed using the xChek IDEXX (vers. 3.3 2003). Studied herds were unvaccinated for PRRS.

**Results**

Serology is an essential part of a PRRS diagnostic and control program. ELISA antibodies are not detectable until 9-10 days post infection and persist for longer periods, at least 5-6 months. The seroprevalence of PRRSV in studied farms was 51,5% (135 samples positive from 262 tested).

The seroprevalence of PRRSV in 4, 12-13 and 20-27 weeks-old pigs’ varied between all the three samplings for each farm. In the farm 1 and 2 seroprevalence of PRRSV in the younger pigs (4 week-old pigs) was significantly higher suggesting the presence of maternal antibodies, and high prevalence in the other category (12-13 and 20-27 weeks-old) show that PRRS infection or reinfection taken place in fattening units.

A high seroprevalence in 12-13 week-old pigs and 20-27 week-old pigs to indicate an active immune response to PRRSV, this fact it could be observed in farms 3, 4 and 6, showing a recent infection. Persistence of infection may be associated with large herds in pig-dense regions with repeated reintroduction.

</table>

In farm 5 the infection percent was lower than the other studied farms, that means the herd became free of infection or the animals was recently infected and is undergoing seroconversion.

**Discussion**

We conclude that most farms pigs wean to finish are seropositive for PRRSV, they indicate that the prevalence of PRRSV antibody in the swine populations tested was relatively high. Method ELISA may be helpful in confirming the seropositivity and to indicate high levels of antibody in recent infections. An accurate diagnosis is essential to confirm presence PRRSV and may serologic profile of pigs in the various stages of production. The lack of an antibody response in recently weaned pigs indicated the absence of PRRSV infection in the breeding and farrowing populations.

Monitoring of PRRS control protocol in two farrow-to-finish herds during three years in high risk area

Patrick Gambade1 Arlette Laval2 Luc Mieli4 Martial Rigaut3
1. Selas Univet Santé Elevage, Loudéac, France; 2. ONIRIS, Nantes, France; 3. Intervet / Schering-Plough AH, Beaucouzé, France; 4. LDA 22, Ploufragan, France

Introduction
In France, PRRS mass vaccination with a modified live Vaccine (MLV), Porcilis® PRRS, Intervet / Schering-Plough, have been already described (1, 2).

This study presents a three years monitoring PRRS control program used in two farrow-to-finish herds in PRRS high risk area.

Material and Methods
The trial was performed in two farrow-to-finish herds: Herd A (180 sows) known infected with PRRS virus since 1994; herd B (350 sows) since 2002.

From June 2005, a vaccination scheme was established as follows: Gilts: one injection at arrival in quarantine. Sows and boars: “mass vaccination” three times a year. Piglets: one injection between 5 and 6 weeks of age.

Serological monitoring data from February 2005 to December 2006 showed that PRRSv was under control since November 2005 (1). Monitoring was extended from 2007 to 2009 (3 years) in two ways:

- Serological monitoring: every 3 or 4 weeks, ELISA individual serology on sera sample (IDEXX Herdcheck PRRS 2XR) were done on a minimum of 10 non-vaccinated piglets. Each piglet, was identified by an ear tag. So a new cohort of ten piglets was chosen every six months and was followed from 70 to 140 days old.
- Virological monitoring: every 3 weeks, PCR tests (ADIAVET PRRS = RT-PCR EU and US strains qualitative test) done on 2 pools of three sera taken on 140 days old vaccinated piglets. All sera were analyzed by LDA 22 (laboratory, Ploufragan, France).

Results
In total, from January 2007 to December 2009, 630 non-vaccinated growing pigs were controlled by serology, and 585 vaccinated pigs by PCR. No positive results linked with PRRSv infection were observed (Table 1 and Table 2). The only serological positive results (farm B, first semester of 2007) were linked to indirect contacts of non-vaccinated piglets with vaccinated ones. In table 1: *2 positive sera, tested with other kit (AFSSA antigen): 1 negative, 1 inconclusive and negative by PCR; **13 positive sera, also positive by PCR, but 100% homology with the vaccine strain by PRRSv ORF7 sequencing.

Discussion and Conclusion
Regular controls showed no circulation of PRRSv “wild” or vaccine strain during 3 years. Since 2007, the sensibility of serological monitoring was increased: to avoid contact with vaccinated pigs, the non-vaccinated monitored piglets were split with other non-vaccinated piglets (80 piglets in total). In case of PRRSv infection, virus multiplication would probably be more important according to the high number of animals without vaccine protection. This field data confirm efficiency of Porcilis® PRRS in reducing significantly viral excretion after infection, and to control virus shedding within these two farms located in high risky area. Even if, we can’t claim eradication, results show that it might be a mean to start or even to achieve eradication, especially in geographic area where infection prevalence is low.

Feasibility of using FTA cards to transport samples for PRRSV testing

Daniel Linhares¹ Albert Rovira² Montserrat Torremorrell¹
¹. College of Veterinary Medicine, University of Minnesota, Saint Paul, MN, USA; 2. Veterinary Diag Lab, College of Veterinary Medicine, University of Minnesota, Saint Paul, MN, USA

Introduction
Porcine reproductive and respiratory syndrome (PRRS) is a devastating disease caused by PRRS virus (PRRSV). Farmers and veterinarians require having access to state of the art readily available diagnostics in order to respond rapidly to disease treats. FTA cards consist of a cellulose-based matrix paper containing chemicals that lyse the cells in the sample while preserving the nucleic acids and are available for the safe transfer of diagnostic samples. Because these chemicals render bacteria and viruses inactive, samples embedded in FTA cards are not infectious. Samples in FTA cards can be shipped and stored at room temperature because the nucleic acids are protected from degradation and clinical samples can be stored in a safe non-biohazard way suitable for molecular diagnostics. Data from a previous study has shown that PRRSV is detectable by RT-PCR from FTA cards (Inoue, 2000). However this study failed to validate the methods to properly assess the diagnostic sensitivity of RT-PCR in samples embedded in FTA cards.

The objective of this study was to evaluate the analytical sensitivity (limit of detection) and stability of FTA cards containing serum and oral fluid samples spiked with PRRSV under controlled laboratory conditions.

Materials and Methods
Porcine sera and oral fluid samples were spiked with a concentration of 10^5 TCID50 of PRRSV. Samples were diluted in 10-fold dilutions (from 10^5 to 10^-2 TCID50/ml) and used to inoculate FTA cards. Each sample from each dilution was inoculated in duplicate in 2 FTA cards and let dry at room temperature overnight. One FTA card embedded sample was tested directly at 24 h post inoculation. The other card was kept at room temperature and tested after 2 weeks. Oral fluids were evaluated directly and following a pre-processed protocol which consisted of treatment with a lysis solution before the extraction protocol (Prickett et al. 2008).

To elute the RNA from the FTA card, the RNA Rapid Extraction Solution (Ambion-Applied Biosystems) was used as recommended by the manufacturer. RNA was then purified and concentrated using high throughput magnetic bead-based technology (Ambion-Applied biosystems). The RT-PCR protocol used was a real time TaqMan-based multiplex protocol that detects both North American and European Strains of PRRSV (NAEU PRRSV) (Dee et al. 2009).

Results and Discussion

Results in table 1 indicate the minimum concentration of PRRSV detected by RT-PCR in samples embedded in FTA cards. Under the conditions of this study, the analytical sensitivity of PRRSV detection by RT-PCR from serum embedded-in FTA cards was reduced 10 times compared to detecting the virus directly from serum. However, the virus could still be detected at a very low concentration in FTA cards (10^1 TCID50). Moreover, there was no loss of sensitivity when comparing detection on FTA cards at 24h or 14 days of storage.

Table 1. PRRSV minimum concentration (in TCID50/ml) detected by RT-PCR.

Sensitivity of oral fluids in pre-processed samples was comparable to that of serum but was poor when testing was done directly.

In summary, this study provides preliminary data that indicate that the use of FTA cards is a sensitive tool to store and submit pig serum and saliva samples for PRRSV molecular diagnostics. Further validation is in process to evaluate the suitability to transport samples under field conditions.

Acknowledgments
This work has been partially funded by the National Pork Board. The authors would like to thank Michele Leiferman and Yin Jiang from the University of Minnesota Veterinary Diagnostic Laboratory for their excellent laboratory work. We also thank Dr. Enrique Mondaca from Boehringer Ingelheim for his ongoing support for this project.

**Modified live PRRS virus vaccination as a key component in nursery pig performance improvement**

*Gordon Spronk¹ Tom Wetzell² Reid Philips²*

¹. Boehringer Ingelheim Vetmedica, Inc., Pipestone, MN, USA; ². Boehringer Ingelheim Vetmedica, St Joseph, MO, USA

**Introduction**

Two sow farms had experienced continual PRRS instability (large periodic increases in abortion rates) due to multiple PRRS virus isolate introductions over the past several years. The highest mortality rates in grower pigs occurred in the first 8 weeks post-weaning with mean mortality rates in excess of 6% in nursery 1 flow for the previous 24 months and 12% during the previous 12 months in nursery 2 flow. The objective of this study was to determine if stabilization of the sow herd along with vaccinating pigs pre-weaning (5-10 days of age) with Ingelvac® PRRS ATP could reduce mortality in the first 8 weeks post-weaning.

**Materials and Methods**

The study was conducted in two 3,250 sow farrow to wean farms located in Iowa and Minnesota.

The breeding herd PRRS stabilization program followed a “Load/Close/Homogenize” approach. A 200 day supply of gilts was entered into the farms which were then closed to new animal entries for a minimum of 200 days. All breeding animals including developing gilts were mass vaccinated twice 30 days apart with Ingelvac® PRRS ATP (Boehringer Ingelheim Vetmedica, Inc., St Joseph, MO). Both herds practiced industry standard MCREB-EL methods with no piglet cross-fostering after 24 hours of age for at least 30 days.

Piglets were vaccinated at 5-10 days of age with the same vaccine. On most continuous flow sites, mass vaccination of all pigs occurred twice 30 days apart when the first PRRS vaccinated weaned pigs entered the site. PRRS PCR testing was conducted every 2-4 weeks on 20 poor quality pigs aged 5 days and younger pooled in groups of 5. “Sow herd stability” was defined as negative results on two consecutive PRRS PCR tests on these pooled piglet sera. PRRS PCR testing of 15 pigs (3 pools of 5 from sick pens) from each group at 4-8 weeks post weaning was done and PCR positives were sequenced. An in-process intervention analysis was done using statistical process control methods on mortality for the first 8 weeks post weaning.

**Results**

Pig mortality rates during the first 8 weeks post-weaning were significantly reduced from 6.4% to 2.84% and 12.6% to 3.0% from Farms 1 and 2 respectively.

**Discussion**

The sow herd stabilization program along with vaccination of pigs at 5-10 days of age has proven to be very effective in reducing mortality during the first 8 weeks post weaning. This occurred in spite of wild-type virus, including highly virulent isolates 1-18-2 and 1-8-4, persisting on or being laterally introduced to twelve of the nursery sites.
Efficacy of Ingelvac PRRS MLV on HP PRRS in a Chinese Pig Farm

Zhuogui Ao¹ Aiwu Huang² Nian Huang³
1. Shanwei Baoshan Pig Farm, Guangdong, China; 2. Guangdong Import & Export Trade Company, Guangdong, China; 3. Boehringer Ingelheim Int’l Trading (Shanghai) Co. Ltd., Beijing, China

Introduction

Highly Pathogenic Porcine Reproductive and Respiratory Disease (HP PRRS), which caused great economic losses in Chinese hog industry, induces reproductive failure in sows and high culling rate in fatteners(1). To prevent viral disease like PRRS, vaccination is the optimum choice (2). The present study evaluated the effect of Ingelvac® PRRS MLV in a pig farm in Guangdong Province, China.

Materials and Methods

The 700-sow farm in Guangdong was built years ago with poor ventilation. Killed PRRS vaccine had been used before March 2006 but performance kept low. PCR test results confirmed PRRS positive before PRRS MLV vaccination. From March 2006, mass vaccination program for breeders with Ingelvac® PRRS MLV started: 3 times per year in sows and twice per year in boars. 5 month later, in August 2006, piglets started to be inoculated with Ingelvac® PRRS MLV 1 dose/pig at 14 days of age. Replacement gilts were vaccinated twice before mating, with one month interval.

* In 2008, sow feed had been contaminated by mycotoxin for 2 months, causing poor reproductive performance.

Figure 1. Survival rate of commercial pigs after PRRS KV and MLV vaccination

Great increase is seen in average fattener survival rate by 9.23% since Aug. 2006(figure 1). The other parameters remained stable even despite a Mycotoxin problem in 2008.

Discussion

In this study, PRRS MLV vaccination improved sow reproductive performance in conception rate, abortion, pseudopregnancy, live and weak born, more than KV (table 1). Much more pigs were marketed after vaccination changed from KV to MLV (figure 1). Feed free of mycotoxin is an important contributor to stable reproductive performance (2).

In conclusion, Ingelvac® PRRS MLV vaccination program and good feed and health management are essential to achieve good performance in PRRS positive farms.

Successful control of Porcine High Fever Disease in a Chinese 1200 sow farm: a case report

GR Lin¹ Shuhe Fang² Nian Huang³

1. Swine Practitioner, Guangdong, China; 2. Boehringer Ingelheim Shanghai Pharmaceuticals, Co. Ltd, Beijing, China; 3. Boehringer Ingelheim Int’l Trading (Shanghai) Co. Ltd., Beijing, China

Introduction

Porcine High Fever Disease (PHFD), the primary pathogen of which is highly virulent porcine reproductive and respiratory syndrome virus (HP PRRSV), causes huge economic losses because of high morbidity and mortality in all infected Chinese pig farms(1). An outbreak of HP PRRS in a 1200 sow pig farm started in April of 2008 in Guangdong province, and it was controlled by Ingelvac® PRRS MLV mass vaccination one month later.

Materials and methods

This pig farm was built in 1990, with two units of 600 sows each, continuous flow management. Two-hundred newly purchased gilts were introduced into the breeding herd without acclimation in Jan.2007. PHFD broke out with evident clinical signs from Apr. 20th, whereby all animals seemed to be affected with following clinical signs: Anorexia, lethargy, dyspnea, hyperthermia and discolouration of the skin. On April 25th, abortion, preterm birth and stillbirth started. Until Apr. 30th, 80 sows aborted and 120 sows were culled.

On 26th, 40 blood samples and 5 tissue samples from the abortion embryo and stillbirth were sent to Guangdong swine disease diagnosis center for antibody and antigen test.

On May 1, all no-sign breeders, healthy suckling piglets were vaccinated with Ingelvac® PRRS MLV. Then breeders were given second shot 4 weeks later. Replacement gilts were vaccinated twice at a 4-week interval before mating. Piglets were given one shot at 2 weeks of age. Antibiotics were administered in water or feed against bacterial infection at same time.

Results

On May 10, sows started returning to normal appetite. Abortion reduced to 20 litters and no death was observed following start of vaccination. All pigs recovered in July. Reproductive performance of all sows in each quarter was getting better and better after vaccination, and even better than that before PHFD outbreak.

*PHFD broke out on Apr.20. Ingelvac® PRRS MLV intervention started from May 1.

Discussion

Analyzing the data recorded in 2008, we found that Ingelvac® PRRS MLV improved the reproductive performance by two times of vaccination in 4 weeks. One shot of Ingelvac® PRRS MLV to piglets obviously reduced the mortality and morbidity in nursery. Ingelvac® PRRS MLV provided cross-protection against HP PRRS in the farm. In conclusion, Ingelvac® PRRS MLV is a useful tool to control and prevent PHFD.

Effect of a modified live PRRS vaccine “AMERVAC®-PRRS” on pre-weaning and post-weaning mortality rates

Michael E. Quilitis² Sergi D. Bruguera¹ Redentor A. Manuel² Maria I. Torres² Dani G. Torrents³ David V. Llopart¹

Introduction
In previous studies in Asia, in spite of the increasing new PRRSV strain diversity³, vaccination programs with a live PRRS European (EU) strain vaccine could reduce the mortality in piglets¹ and in growing-fattening pigs². The objective of this study was to monitor the effect in pre-weaning and post-weaning mortality rates of a modified live virus PRRS EU strain vaccine (AMERVAC®-PRRS) program in sows and piglets.

Materials and methods
A 4000 sow level farm located north of Manila, Philippines, had a complaint of high pre-weaning (weaning at 4 weeks of age) and post-weaning (4-10 weeks of age) pig mortalities. PRRSV diagnosis was confirmed with the use of a commercial serology ELISA kit (CIVTEST™ suisPRRS E/S, HIPRA) an early serum conversion at 6-7 weeks of age. Gestating sows farrowed infected piglets which infected other litter mates before weaning time. So after veterinary advice, two mass vaccinations with a live PRRSV vaccine (AMERVAC®-PRRS) in breeders within 4 weeks interval were implemented in November 2007. At the same moment sows were administered with the second mass vaccination (December 2007), piglet vaccination started. Every piglet at 25 days of age was vaccinated intramuscularly with one shot of the same live PRRSV vaccine. Pre-weaning and post-weaning pig mortality rates were compared between batches of pigs 6 months before and 6 months after the implementation of the second mass vaccination in sows (December 2007).

Results
Mortality rates were significantly decreased (P<0.001; t test) after the vaccine program implementation (Table 1). Pre-weaning and post-weaning mortality rates decreased 75% and 80% respectively.

Table 1. Monthly mean (Mean±SD) pre-weaning (Pre) and post-weaning (Post) pig mortality 6 months before and 6 months after PRRSV vaccine implementation.

</tr>
</tbody>
</table>

*Results were significantly different, P<0.001.

Discussion
We can observe that as in previous field trials⁴,⁵, a mass vaccination in breeders with a live PRRSV vaccine resulted in a sow protected population, which farrowed healthier new born piglets and consequently induced a decrease of pre-weaning and post-weaning mortality rates. Vaccinated pigs at 3 weeks of age showed a lower post-weaning mortality rates that may be maintained during fattening period as in Guerzón, V. et al, 2008. In spite of the increasing diversity of PRRSV strains described worldwide³, in this field experience in Asia, a PRRSV vaccine, available in the field for more than 10 years (AMERVAC®-PRRS) was able to induce enough protection to reduce the negative impact of a PRRSV infection. Actual PRRSV strain classification according to genetic sequence of the ORF 5 RNA fragment of the PRRSV genome is not useful to forecast cross protection⁶. Previous studies confirmed that distant PRRSV strains according to this ORF 5 sequence classification, contrary to what was expected, can present clear cross protection⁷. Therefore, further studies are needed to disclose either viral structures or immune pathways or genetic markers that may determine cross protection between PRRSV strains.

Conclusion
Within these field conditions a vaccination program in sows and piglets with an EU MLV PRRSV vaccine (AMERVAC®-PRRS) reduced pre-weaning and post-weaning pig mortalities caused by a PRRSV infection.

Introduction
Porcine Reproductive and Respiratory Syndrome Virus (PRRSV) is one of the primary precursors of economic losses in pig production. Acute impact costs range from $236-502 per sow per year. Clinical signs include decreasing farrowing rates, abortions, stillborns and increase of respiratory clinic problems in pigs.

The objective of this field experience is to assess the effect of a live PRRSV European (EU) vaccine (AMERVAC®-PRRS) in the monthly farrowing rates in a farm endemically infected by PRRSV.

Materials and methods
A 2500 sow farm with a 2 site production system that is located in the southern Philippines had a complaint of unstable and variable farrowing rates. PRRSV diagnosis was based on Polymerase chain reaction technique (PCR) from lungs and lymph nodes from stillbirths and 1 day old weak born piglets. A PRRSV vaccination program was implemented in sows at October 2007, using a modified live PRRSV European (EU) vaccine (AMERVAC®PRRS). Every batch of sows was vaccinated with one dose at 60 days of pregnancy and another dose 7 days after each farrowing. Farrowing rates from April 2007 until December 2009 were monitored. Farrowing rates from April to October 2007 were compared with farrowing rates from November 2007 till December 2009 (unpaired t test).

Results
Variable and unstable farrowing rates were monitored from April to October 2007. The monthly farrowing rates after vaccine implementation became less variable and were significantly higher (Table 1) along the whole monitored period than in previous unvaccinated sows.

Discussion
The monthly farrowing rates seem to get stabilized around 3-4 months after the beginning of the vaccine program implementation. This slow recovery may be related with the necessary time to administer at least one vaccine dose to all the sows in the farm. Contrary to this experience, mass PRRSV vaccination programs in sows are more usually applied. Mass live PRRSV vaccination may build up faster vaccine immune response in the whole sow population just with the first dose. Nevertheless in the case of PRRSV infection the time needed to come back to normality after PRRSV infection depends also on some other factors, which are not directly related to vaccines or vaccination programs.

Conclusion
The PRRSV vaccination program implemented within these field conditions achieved to improve and stabilize sow monthly farrowing rates along the whole experiment.

Introduction
Sows infected by Porcine Reproductive and Respiratory Syndrome Virus (PRRSV) reduce farrowing rates and farrow infected piglets that will suffer higher pre-weaning and post-weaning mortality rates. The objective of this field experience was to assess the effect of a PRRSV vaccination protocol in multiparous (MS) and first pregnancy sows (FPS) in a PRRSV infected farm.

Materials and methods
The study is carried out in a 4000 sow farm located in South East Spain, endemically infected with a PRRSV. This is a farm that rears pigs only till 20Kg live weight (8-9 weeks of age). Gilts (G) and FPS are segregated and they remain separated from MS. From June 2008 return to oestrus % (RTO%) increased either in MS or FPS. Besides this, born alive piglets per litter (TAL) and weaned piglets per litter (TWL) decreased. From August to October 2008 post-weaning (from 3 to 8-9 weeks of age) mortality % (PM%) increased dramatically in pigs from both FPS and MS. PRRSV infection diagnosis was confirmed with the use of a commercial serology ELISA kit (CIVTEST ™suisPRRS E/S, HIPRA) in sows and PCR PRRSV detection from stillbirths and dead pigs. In September and again in October 2008, a mass vaccination was implemented in all MS, FPS and G with a live PRRSV vaccine (AMERVAC®-PRRS). Afterwards a mass vaccination with AMERVAC®-PRRS was implemented regularly every 4 months in MS and FPS. Every new batch of G was vaccinated twice with AMERVAC®-PRRS one month apart before the first mating. In this field experience we monitored monthly RTO%, TAL, TWL and PM%.

Results
TWL improved in MS and in FPS but the improvement was more remarkable in FPS (Graph.2). RTO% (Graph.1) decreased constantly from the first mass vaccination program in MS. RTO% from FPS decreased every month but in February 09 RTO% of FPS increased again till 28.2%. After this increase all the MS and FPS were vaccinated again (defined in material and methods) and the next month RTO% in FPS was reduced back to normality. Pigs in post-weaning period from non-yet vaccinated MS and FPS suffered a peak of mortality in September and October 08 (Graph.3). Weaned pigs from vaccinated sows may be healthier and PM% decreased markedly from November 2008 till the end of the study.

Discussion
The decreasing RTO% and the clear increasing trend of TWL in pigs from MS and FPS indicate, as in previous experiences1,2, that the immune response induced by the vaccine may build up a protection in sows that reduced the birth of infected piglets2. This effect probably reduced also the PM%, especially in batches of weaned piglets from FPS (Graph.3). According to these results FPS and their progeny seemed to suffer more severely during a PRRSV infection. This observation occurs frequently in the practice and recalls the need to submit new replacement gilts to proper acclimatisation procedures against PRRSV, previous to be introduced in an endemically PRRSV infected farm.

Conclusion
Within these field conditions, a vaccination program with AMERVAC®-PRRS in sows induced an immune response that reduced markedly the negative impact of a wild PRRSV infection in sows and their progeny.

Evaluation of a porcine reproductive respiratory syndrome virus (PRRSV) vaccination program with a modified live PRRSV Vaccine during 3 consecutive years in a Polish farm

Isaac R. Ballarà2 Sergi Bruguera2 Robert Panek1 David Llopart2
1. HIPRA Polska, Warsaw, Poland; 2. HIPRA, Technical Services, Amer, Spain

Introduction
Porcine reproductive and respiratory syndrome is an economically significant disease. Polish farms have suffered the two forms of this syndrome either from reproductive or respiratory clinical episodes 1. Modified live vaccines (MLV), in several field and experimental cases, have induced enough protection to control the negative clinical signs of PRRSV infection 1. The objective of this study is to evaluate the efficacy of a PRRSV vaccination program, in sows and pigs, with a modified live European (EU) PRRSV vaccine (AMERVAC®-PRRS Laboratorios HIPRA S.A.) along 3 consecutive years.

Materials and Methods
This study was performed in a one site farrow to finish farm with 2000 reproductive sows, located in Swidwin, Poland. We evaluated the PRRSV situation through several transversal serum profiles (CIVTEST™suisPRRS E/S ELISA). The first serum profile was performed in November 2005, in this moment the farm were suffering high pre-weaning and post-weaning mortality, and acute reproductive failure in sows. The second serum profile was performed in October 2006, and the last one in October 2007. The reproductive parameters in sows, pre-weaning and post-weaning pig performance parameters were monitored from November 2005 to October 2007. On December 2005 sows were vaccinated with a mass vaccination with a MLV vaccine (AMERVAC®-PRRS). One month after the mass vaccination sows were vaccinated with the following regular vaccination program: Gilts: One vaccine dose at 22 weeks of age and a second dose at 25 weeks of age in gilts. Sows: They were vaccinated in each gestation at 56 days of pregnancy, and once again in lactation period at 6 days after farrow. Piglet vaccination didn’t start till March 2006; piglets were vaccinated with one dose of AMERVAC®-PRRS at 26-28 days of age.

Results
After the implementation of the vaccination the farm became stabilized clinically and serologically, with a relevant reduction every year of % piglet mortality (Graphic 1 and Table 2), % mummified piglets, % stillbirth, % weak born piglets and the number of pigs in hospital pens.

Moreover a significant increase of average piglet weight at birth and at 10 weeks of age was recorded (Table 2). Sows also increase clearly the farrowing rates during the three year period (Table 1).

Discussion
MLV vaccine efficacy in pigs and in sows has been also described previously. In spite of these positive long lasting results, PRRSV control depends also on other important factors rather than vaccines or vaccination programs as proper gilt replacement policies or strict biosafety measures. Regardless the increasing diversity of PRRSV strains described recently in Poland 2, a PRRSV vaccine, available in different European and Asian countries for several years (AMERVAC®-PRRS) was able to induce enough cross protection to reduce the negative impact of a PRRSV infection.

Conclusion
We concluded that the use of a MLV vaccination program in sows and piglets during the whole studied period resulted in the control of the negative effects of a PRRSV infection and improved sows and piglets performance.

Introduction

In Asia, nowadays, pig producers need to protect their pigs and sows against several pathogens. Many vaccination programs have to be implemented in specific close periods during the pigs’ life either whether it is in sows during the gestating or lactating period or whether it is during the first weeks of life in pigs. Then the possibility of reducing or administering vaccines simultaneously can potentially improve either the pig welfare status or the labour efficiency. Therefore, the objective of this trial is to find out if the attenuated PRRS vaccine virus VP046-BIS (AMERVAC®-PRRS) can keep alive when it is reconstituted with an inactivated \textit{Haemophilus parasuis} vaccine (HIPRASUIS®-GLÄSSER) as a previous step to try in vivo the actual effect of these combined vaccines.

Material and methods

Material: 50 dose freeze-dried tablets of AMERVAC®-PRRS vaccine (attenuated PRRS virus), 50 dose of inactivated \textit{Haemophilus parasuis} vaccine HIPRASUIS®-GLÄSSER, 100 ml aqueous solvent vials and CLON8 cell line.

Methods: Two tablets of AMERVAC®-PRRS were reconstituted with HIPRASUIS®-GLÄSSER and with aqueous solvent respectively. After 0, 2, 4 and 6 hours post reconstitution the virus was titred in CLON8 cell line.

Results

Table 1. Results of titres per dose of PRRS vaccine virus VP046-BIS. Vaccine virus titres VP046-BIS per dose (2ml) (TCID\textsubscript{50}/dose). Regarding by CPE (Cytopathic Effect).

* PRRS vaccine virus VP046-BIS (AMERVAC®-PRRS) kept viable and with a dosage titre value equivalent or higher of $10^{3.5}$TCID\textsubscript{50} (minimum necessary effective concentration as product manufacturer recommendation) at 6 hours after reconstitution with the inactivated \textit{Haemophilus parasuis} vaccine HIPRASUIS®-GLÄSSER (100ml). The same results were obtained when mixed with the usual prescribed aqueous solvent (100ml).

Discussion

This in vitro trail experience may be also applicable in vivo as in Roof et al 2000. In Roof et al 2000, there was no interference between vaccine antigens either when a live PRRSV vaccine was reconstituted with a multi-antigen inactivated vaccine and administered in pigs.

Conclusion

HIPRASUIS®-GLÄSSER vaccine allows the viability of the attenuated PRRS vaccine virus VP046-BIS (AMERVAC®-PRRS) even 6 hours after the reconstitution. Further studies in vivo are required to discard any vaccine incompatibility.

In vitro evaluation of the impact of a needleless device on Ingelvac® PRRS ATP vaccine virus viability

Enrique Mondaca1 Albert Rovira2 Dale Polson

1. Boehringer Ingelheim Vetmedica, Inc., St Joseph, MO, USA; 2. College of Veterinary Medicine, University of Minnesota, St Paul, MN, USA

Introduction

Needle-free injection devices deliver product by pressure directly into subcutaneous or muscular tissue layers. This technology has been used in human and veterinary medicine since mid 1900’s, offering some advantages over conventional medicine delivery methods: elimination of broken needles, consistent vaccine delivery, elimination of accidental worker needle sticks, elimination of needle disposal, and less pain and stress1. It also has an significant potential as a tool when population-based injectable interventions are suitable for large livestock systems such as area/regional disease control programs. Some of their disadvantages include the relatively large initial financial investment in equipment and the need for technical training. Another potential disadvantage is the effect of the device’s high pressure on the integrity of viral particles when applying modified live vaccines.

The aim of this study was to determine if the needle-less injector AcuShot™ (AcuShot, Inc., Winnipeg, CA) affects the viability of Ingelvac® PRRS ATP (Boehringer Ingelheim Vetmedica, Inc., St. Joseph, MO) vaccine virus by comparing samples obtained directly from the bottle of vaccine to samples obtained through 10 of the AcuShot™ devices.

Materials and Methods

A TCID50 assay was run at the Virology Laboratory of the University of Minnesota on samples of Ingelvac® PRRS ATP vaccine virus obtained through: AcuShot™ devices, conventional needle-syringe, and pipetted directly from the vaccine bottle (controls). Thirty-five samples were taken from each of the 12 treatments in study: AcuShot™ devices (10), conventional needle-syringe (1), and pipetted directly from the vaccine bottle (control, 1). A sample size of 35 was determined applying Minitab® software version 15.1.0.0 (Minitab Inc., State College, PA), to detect a maximum difference between means of 0.3 log10 or about half a recommended dose of vaccine at P<0.05, and power >80%.

The statistical analysis was run with Minitab® applying ANOVA and Tukey’s test for comparison of means.

Results

TCID50 mean values (log10) did not differ significantly between any of the eleven treatments (ten Acushot devices and one needle/syringe) and the Control (samples pipetted directly from the bottle). The 95% confidence interval for all eleven treatments included zero, indicating no difference at P<0.05 from the Control (Figure 1).

Discussion

The results of this study indicate that the viability of Ingelvac® PRRS ATP vaccine is not affected when applied through AcuShot™ needleless devices. Further evaluation of needleless devices under field conditions is warranted to ensure their suitability for use in swine production.

Effect of a PRRS modified live vaccine (AMERVAC®-PRRS) on mortality rates in a pig farm in Venezuela

Carlos Rojo1 Gustavo Garcia3 Daniel Torrents2 Sergi Bruguera2
1. HIPRA China, Technical Services, Beijing, China; 2. HIPRA, Technical Services, Amer (Girona), Spain; 3. Orograinca, Turmero (Aragua), Venezuela; 4. Agrosuplidores, fl., Valencia, Venezuela

Introduction
Porcine Reproductive and Respiratory Syndrome (PRRS) is an economically important disease in pig production, mainly due to losses related to reproductive failure in sows and high mortality rates in commercial pigs from lactation to growing-finishing phase. In Venezuela, PRRS virus (PRRSV) was first identified in 19961 and nowadays is an endemic pathogen2 causing big impact on the productive parameters of swine farms in Venezuela3. The objective of this study was to monitor the effect of a live European (EU) PRRSV vaccine (AMERVAC®-PRRS) program on mortality rates in pigs at 3 different periods: pre-weaning, post-weaning and growing-finishing period.

Materials and methods
An 800 sows farm located in Venezuela, had a complaint of high pig mortalities. PRRSV diagnosis was confirmed with PRRSV antibody detection in serum samples with a serology ELISA kit (HerdChek® PRRS 2XR, IDEXX) in sows and pigs at early ages. After veterinary advice, in October and November 2008 within a 4 weeks interval, two mass vaccinations with a live PRRSV vaccine (AMERVAC®-PRRS) were implemented in breeders. From January 2009 onwards, every piglet at weaning was vaccinated intramuscularly with one shot of the same live PRRSV vaccine. Mortality rate was compared between batches of pigs 6 months before and 8 months after the implementation of the second mass vaccination in sows (November 2008).

Results
Mortality rates were significantly decreased (P<0.05 or P<0.001; unpaired t test) after the vaccine program implementation (Table 1). Pre-weaning, post-weaning and growing-finishing mortality rates decreased 45%, 46% and 34% respectively.

Table 1. Monthly (mean±SD) pre-weaning (Pre), post-weaning (Post) and growing-finishing (G-F) pig mortality rates (%) 6 months before and 8 months after PRRS vaccine implementation (November 2008).

* Results were significantly different, P<0.05
** Results were significantly different P<0.001

Discussion
Within these field conditions, we can observe that as in previous field trials4,5,6, a live PRRSV vaccine program resulted in a sow protected population, which farrowed healthier new born piglets that may respond properly to a intramuscularly live PRRSV vaccine dose and consequently induced a decrease of mortality rates during the whole growing period. In spite of the increasing diversity of PRRSV strains described worldwide7, in this field experience in Venezuela, (AMERVAC®-PRRS) was able to induce enough protection to reduce the negative impact of a PRRSV infection.

Conclusion
Within these field conditions a vaccination program in sows and piglets with an EU MLV PRRSV vaccine (AMERVAC®-PRRS) reduced pig mortalities caused by a wild PRRSV infection in a pig farm in South America.

Efficacy of AMERVAC®-PRRS vaccine on sow reproductive performance in a PRRSV (Porcine Reproductive and Respiratory Syndrome Virus) infected pig farm in Malaysia

Hang C. Lim² Ban K. Lim² Pow Y. Choo² Sergi D. Bruguera¹
1. HIPRA. Technical Services, Amer, Spain; 2. Vet Food Agro Diagnostic (M) Sdn Bhd, Selangor, Malaysia

Introduction
PRRSV is a common pathogen causing respiratory and reproductive clinical signs in Malaysian pig farms. PRRS vaccination in sows with AMERVAC®-PRRS has been used in pig farms in different countries and the benefits have shown to be encouraging (Quilitis² et al. 2009; Rodriguez³ et al. 2009). The objective of this trial is to monitor the effect of AMERVAC®-PRRS vaccination on sows’ reproductive performance in an infected PRRSV farm and to determine whether there is any adverse reaction observed in pregnant sows post vaccination.

Materials and methods
A 1800 sow commercial farrow-finish pig farm located in Selangor state, Malaysia, was diagnosed with a PRRSV infection by means of the PRRSV antibody detection from serum samples with an ELISA kit test (Herdcheck 2XR, Idexx) and by PRRSV detection with a PCR technique (data not shown). Serology results indicated the presence of active PRRSV infection in the sows’ population. On veterinary prescription, all breeders (sows and gilts) were vaccinated with a live European PRRS vaccine (AMERVAC®-PRRS) on September 2008 and boosted with the same vaccine 1 month later. Sows were then vaccinated regularly once every 4 months with AMERVAC®-PRRS. The farm is using Pig Champ® recording system to monitor production performance of the farm. Reproductive performance data for a period of 5 months before and after AMERVAC®-PRRS vaccination was collected and analyzed. The parameters and results observed are stated in Table 1.

Results and Discussion
There were no adverse reactions observed in sows after any of the vaccine inoculations. Reproductive parameters improved significantly after the vaccine program was implemented. A significantly improvement (P<0.05) in farrowing rate (+6%) and the average piglets born alive per litter (+0.54) was observed. The Return to estrus rate and average pigs weaned per sow per litter were improved but the results were not significantly different 5 months after vaccine implementation. These results confirmed previous positive field experiences in Asia after the use of a live European PRRSV (genotype-I) vaccine in sows¹,².

Protection efficacy of hyperimmune serum and vaccines from homologous and heterologous PRRS virus to challenge with highly pathogenic Chinese-type PRRSV

Sergey A. Kukushkin; Alexander E. Fomin; Taufik Z. Baybikov; Elena P. Baborenko
FGI Federal Centre for Animal Health, Vladimir, Russian Federation

Introduction
Epidemic of highly virulent PRRS caused by atypical virus of North American (NA) genotype was registered in China and Vietnam in 2006-2007 (Tian et al., 2007; To et al., 2007). In August 2007 the similar virus - “Irkutsky 2007” strain - was isolated in the Irkutskaya Oblast of Russia, where the first outbreak of new atypical PRRS outside South-East Asia was registered (Kukushkin et al., 2008). The purpose of our study was to compare resistance of pigs to challenge with highly pathogenic Chinese-type PRRS virus after seroimmunization and vaccination with commercial vaccines from European, North American PRRSV genotypes and a vaccine from a homologous strain.

Materials and Methods
Twenty-six 4-month-old PRRS-seronegative piglets were divided into five groups: Group 1 (6 piglets) was single immunized with a commercial live vaccine from North American PRRSV genotype; Group 2 (5 piglets) was twice immunized with an inactivated vaccine from a homologous PRRSV “Irkutsky 2007” strain; Group 3 (4 piglets) was twice immunized with a commercial inactivated vaccine from European PRRSV genotype; Group 4 (8 piglets) was immunized with hyperimmune (positive) serum to a homologous PRRSV “Irkutsky 2007” strain at a dose of 1 ml/kg before challenge; Group 5 (3 piglets) was a non-immunized control. After immunization all piglets were intranasally challenged with a highly pathogenic Chinese-type PRRS virus “Irkutsky 2007” strain. Blood sera collected before and 16 days after inoculation were tested for PRRSV antibodies using ELISA (IDEXX, Westbrook, ME, USA). All animals were slaughtered on day 16 after challenge for examination of lung lesions score according to Halbur et al. (1995).

Results
Hyperthermia was registered in all groups. The most lasting hyperthermia was observed in Groups 3 and 5 (12-15 days, maximum 41.7°C), hyperthermia of medium duration was recorded in Groups 2 and 4 (11-12 days, maximum 41.8-41.9°C), the shortest hyperthermia was in Group 1 (7 days, maximum 40.7-41.0°C). Disease clinical signs and their duration between groups were analogous to the manifestation of hyperthermia. Less pronounced clinical signs were present in the Group immunized with a commercial live vaccine.

The highest level of lung lesions was in Groups 5 and 3, the lowest level was in the Group immunized with a commercial live vaccine from N. American genotype (Table 1).

Discussion and Conclusion
Testing results showed that the best protection of piglets against challenge with highly virulent PRRS virus was provided by a commercial live vaccine from N. American genotype. Inactivated vaccine and hyperimmune serum from a homologous strain provided middle protection of lungs but did not prevent the appearance of clinical signs.

References
Introduction
Recently it has been demonstrated that significant differences can be observed among Type 1 PRRSV isolates (1). Previous studies demonstrated that genetic diversity within European genotype may affect the efficacy of currently available vaccines (2). The aim of the present study was to investigate the pathogenicity of a recently isolated virulent PRRSV Type I, subtype 1 field strain by evaluating the clinical outcome of the infection as well as the pathological lung lesions in vaccinated and non-vaccinated growing pigs.

Materials and Methods
Thirty-six 3-week-old PRRSV negative pigs were randomly assigned to three treatment groups with 12 pigs each. Group 3 was vaccinated with a commercial live PRRSV Type 1 vaccine (DV strain). Five weeks after vaccination pigs of groups 2 and 3 were challenged with $2.2 \times 10^5$ TCID$_{50}$ of a Type 1, subtype 1 virulent PRRSV field isolate. The challenge isolate and the vaccine strain shared 89 % nucleotide and 91 % amino acid identity on ORF5 (GP5) and 95 % nucleotide and 96 % amino acid identity on ORF7 (N). Group 1 served as a negative control. During the course of the study, viraemia, serology, clinical signs, rectal temperature and average daily weight gain were monitored. Animals were euthanized on 10 DPI (n=6 per group) and 21 DPI (n=6 per group). Severity of macroscopic and microscopic lung lesions was scored (0-3). The microscopical evaluation was performed as a blinded analysis.

Results
All group 3 animals became viremic following vaccination and all group 2 animals became viremic following challenge. Seroconversion was observed within one week after onset of PRRSV viraemia. Following challenge on SD 35, a significant ($p \leq 0.05$) increase in number of animals with fever ($\geq 40.5^\circ$C) occurred in the vaccinated group in comparison to the control group between SD 39-44, while a significant increase was observed in the challenged group between SD 42-44. Coughing was observed in more than 60% of animals in group 2 and 3 but in less than 10% of group 1 animals. Within the first 10 days following challenge, group 1 animals showed a significant higher body weight gain (6.8 kg) than group 2 (3.9 kg, $p<0.001$) and group 3 (5.0 kg, $p=0.004$) animals. Average daily weight gain of all 3 groups before and after challenge is presented in Figure 1.

Concerning lung lesions, significant differences (macroscopic lesions: $p \leq 0.0285$, microscopic lesions: $p \leq 0.0001$) were observed between challenged animals (group 2 and group 3) and the negative controls (group 1). In contrast to that, summarized lung score values of vaccinated (group 3) and non-vaccinated pigs (group 2) were not significantly different (macroscopic lesions $p \geq 0.0607$, microscopic lesions: $p = 0.7144$).

Discussion
The data demonstrate that a recent PRRS Type 1 field strain is able to induce clinical signs and macroscopic and microscopic lung lesions upon experimental challenge of growing pigs. The fact that no significant differences were observed between vaccinated and non-vaccinated challenged pigs is in line with other reports indicating that available live modified PRRS vaccines do not always provide complete protection against all types of currently circulating PRRS strains (2).

Comparaison of immune response between PRRS vaccination using PROGRESSIS® an inactivated vaccine or a combination of inactivated and a modified live vaccine

M. Gimeno2, 3 I. Diaz3 L. DARWICH2 Enrique Mateu2, 3 Antonio Callen4 Julie Venet1 François Joisel1
1. Merial S.A.S., Lyon, France; 2. Dept. Sanitat i Anatomia Animals, Bellaterra, Spain; 3. Centre de Recerca en Sanitat Animal (CRESA), Barcelona, Spain; 4. Merial Laboratorios S.A., Barcelona, Spain

Introduction
Successful control of PRRS often involves strategies for immunizing gilts and maintaining immunity in sows. The choice of a given strategy depends on the safety/efficacy balance. Objections about using a live PRRSV strain in gestating sows - except in the case of a severe PRRS outbreak- may coexist in the same farm with the use of live PRRSV. In Spain, another approach was tested in which gilts are firstly immunized by using live virus and then booster vaccination of sows is performed using PROGRESSIS®. This may avoid the use of live PRRSV in gestating sows. The present report examines the efficacy of such approach.

Material and Methods
Thirty-two high health pigs free from all major pig diseases were selected at weaning in a PRRSV-free farm. Animals were confirmed to be free of PRRSV by ELISA (HERDCHEK 2XR, IDEXX Laboratories) ear-tagged and let to acclimatize for two weeks. At six weeks of age, piglets were randomly allocated in four separated groups of eight animals: A, B, C and D and vaccinated with an adjuvanted modified-live PRRSV vaccine (MLV) or a placebo. Three months later, piglets were PROGRESSIS-revaccinated (once or twice) or with a MLV as shown in Table 1. At 6.5 months of age, all pigs were intranasally challenged with 1x10⁶ TCID₅₀ (2 ml) of a Lelystad-like PRRSV strain and were followed for 21 days. Humoral response was evaluated by ELISA and the frequency of PRRSV-specific IFN-γ cells in blood was measured by ELISPOT as reported before (1). After challenge viremia was examined by RT-PCR at days 0, +3, +7, +10, +14, +21. Statistical analysis was done using StatsDirect v2.7.5 by means of the Kruskal-Wallis test with multiple comparisons performed by the Conover-Inman test.

KV= PROGRESSIS; Pl.=Placebo; Ch. = Challenge

Results
No reaction after vaccination was observed, showing safety of these treatments. Initial vaccination with the MLV produced seroconversion and raised the PRRSV-specific cell-mediated response (Table 2 and Figure 1). No differences were seen in the humoral response but the use of PROGRESSIS as a booster antigen was equal or better than the use of a repeated MLV administration (group B) in terms of maintaining the PRRSV-specific IFN-γ response. Thus, at the time of challenge, the IFN-γ response of group C was higher (p<0.05) than the IFN-γ frequencies in groups B and D. After challenge, the higher booster in IFN-γ was seen in group C as well. By the end of the experiment, group A showed the higher IFN-γ frequencies compared to other groups (p<0.05). RT-PCR results showed that all unvaccinated became viremic after challenge while in groups A, B and C only one or two pigs became infected by day 3 PI (data not shown).

Clinical protection provided by AMERVAC®-PRRS against heterologous challenge with a highly virulent Asian (Genotype - II) strain

Merce Roca¹ Sergi Bruguera¹ Mariona Gimeno², ³ Ivan Díaz² Ivan Galindo², ³ Joaquim Segales², ³ Laila Darwich², ³ Enric Mateu², ³ Eva Martínez¹ David Llopart¹ Jaime Maldonado¹ Ricard March¹

1. HIPRA, Amer (Girona), Spain; 2. Centre de Recerca en Sanitat Animal (CReSA), Bellaterra (Barcelona), Spain; 3. Departament de Sanitat i Anatomia Animals (UAB), Bellaterra (Barcelona), Spain

Introduction

The emergence of highly virulent PRRS virus (PRRSV) strains in China in 2006<sup>1,2</sup> was a milestone in the epidemiology of PRRS in Asia. Nowadays, genotype II strains of different virulence coexist with genotype-I strains<sup>3,4</sup> in this continent. At present, AMERVAC®-PRRS (a genotype-I vaccine) is licensed and marketed in many countries of Asia and, therefore, contact of vaccinated herds with highly virulent genotype-II strains can be expected. The present study was aimed to explore the safety and potential efficacy of AMERVAC®-PRRS against highly virulent genotype-II strain.

Material and Methods

Twenty-one 4-week-old, PRRSV-naïve pigs were randomly divided into three groups (G1, n=8; G2, n=8; and G3, n=5) and housed separately in biosafety level 3 facilities at CReSA. Pigs in G1 were immunized intramuscularly with AMERVAC®-PRRS (2 ml of 10⁴.⁶ TCID₅₀/ml). G2 and G3 were kept as unvaccinated groups. At day 32 post-vaccination, G1 and G2 pigs were intranasally inoculated with 2 ml of (1x10⁵ TCID₅₀/ml) of the Asian highly virulent isolate PRRSV<sup>21</sup> (99% similar in ORF5 to other highly virulent isolates of Asia). Pigs in G3 remained as uninoculated controls. For the following 21 days, pigs were clinically examined (C) and rectal temperatures (T) were taken. Blood samples were taken on days, 0, 3, 7, 10, 14 and 21 post-challenge (PC). RT-PCR was used to assess the virological outcome of the challenge. Pigs were euthanized and necropsied on day 21 PC. Statistics were done using StatsDirect 2.7.5 software.

Results

Vaccination did not produce any adverse or side effect. All inoculated pigs became infected as determined by RT-PCR and developed fever but differences were noticed among groups (Figure 1). Thus, G1 pigs suffered less days of fever (p<0.05) than G2 ones did. Also, naïve (G2) pigs developed evident respiratory signs from day 5 PC that often persisted until day 18 PC. Two G2 pigs died (25 %). In G1 pigs, signs were milder, of shorter duration and affected less number of pigs. At necropsy, lesions were more frequent and more severe in G2 pigs compared to G1 (Table 1). Findings compatible with bacterial complications (i.e. polyserositis and bronchopneumonia) were more common in G2.

Discussion

Vaccinated animals had clinical protection against the virulent challenge in spite of the different genotypes of the vaccine and the challenge isolate. This observation also suggests the existence of conserved epitopes among PRRSV genotypes.

**Introduction**

Needle-free injection devices deliver product by pressure directly into subcutaneous or muscular tissue layers. This technology has been used in human and veterinary medicine since the mid 1900’s, offering some advantages over conventional vaccine or medicine delivery methods: elimination of broken needles, consistent product delivery, elimination of accidental worker needle sticks, elimination of needle disposal, and less pain and stress.1 It also has significant potential as a tool when population-based injectable interventions are suitable for large livestock systems such as area/regional disease control programs. Some of their disadvantages include the relatively large initial financial investment in equipment and the need for technical training. Another potential disadvantage is the effect of the device’s high pressure on the integrity of viral particles when applying modified live vaccines.

The aim of this study was to compare the post-vaccination seroresponse to Ingelvac® PRRS MLV (Boehringer Ingelheim Vetmedica, Inc., St. Joseph, MO) in pigs vaccinated with either the traditional syringe and needle technology, or AcuShot™ (Acushot, Inc., Winnipeg, CA) needleless approach.

**Materials and Methods**

Forty 4-week old PRRS virus and *M. hyopneumoniae* negative/naïve piglets were randomly allocated into two treatment groups: Treatment Group 1 (AcuShot) and Treatment Group 2 (Needle), both with a sample size of 20 pigs. Each pig in each treatment group was vaccinated I.M. with a 2 mL dose of Ingelvac® PRRS MLV per label recommendations. Blood samples were collected at days 0, 7, 14, 28, 42 and 56 for assessment by PRRS ELISA, PCR and quantitative PCR (qPCR).

The statistical analysis was run with Minitab® software version 15.1.0.0 (Minitab Inc., State College, PA), applying Mann-Whitney and Two Proportions tests.

**Results**

No significant difference was found at α=0.05 between treatments for viral load as determined by qPCR (Table 1).

<table>
<thead>

</tbody>
</table>

No significant differences at α=0.05 were detected between treatments for PRRS ELISA S/P ratios or percent PCR positive samples post-vaccination (Figure 1).

Post-vaccination viremia was detected by PCR at day 7, and was still present in serum in 20-26% of pigs at day 56 post-vaccination. Post-vaccination ELISA positive samples were detected from day 14 to the end of the study at day 56 (Figure 1).

**Discussion**

Under the conditions of this study, no significant differences were found between AcuShot and traditional syringe and needle in the Ingelvac® PRRS MLV post-vaccination seroresponses as measured by ELISA, PCR and qPCR.

Further evaluation of needleless devices under field conditions is warranted to ensure their suitability for use in swine production.

Evaluation of a needle-free injection system (AcuShot™) for reduction of hematogenous transmission of PRRS virus

Seth Baker¹ Enrique Mondaca² Dale Polson² Scott Dee³
1. University of Minnesota, St Paul, MN, USA; 2. Boehringer Ingelheim Vetmedica, Inc., St Joseph, MO, USA; 3. College of Veterinary Medicine, University of Minnesota, St Paul, MN, USA

Introduction

Needle-free injection devices deliver product by pressure directly into subcutaneous or muscular tissue layers. This technology offers some advantages over conventional vaccine or medicine delivery methods: elimination of broken needles, consistent vaccine delivery, elimination of accidental worker needle sticks, elimination of needle disposal, and less pain and stress⁴. Since it has been demonstrated that hematogenous transmission of porcine reproductive and respiratory syndrome virus (PRRSv) can occur from infected pigs to susceptible pigs via repeated use of the same needle⁵, another potential advantage of needle-free technology is the reduction of hematogenous transmission of PRRSv.

The aim of this study was to evaluate the ability of the AcuShot™ needle-less injection system (AcuShot, Inc., Winnipeg, CA) to reduce or eliminate the hematogenous transmission of PRRSv.

Materials and Methods

Four replicates of this study were conducted, each involving 22 four-week-old PRRSv naïve pigs. Each replicate consisted of 5 groups, and each group was housed in a separate room in an isolation facility at the University of Minnesota. Group #1 (PRRSv source population) consisted of 10 pigs which were intranasally inoculated on day 0 with 2 mL of the MN-184 PRRSv isolate at a concentration of 10⁴ TCID₅₀/ml. Group #2 AcuShot, Group #3 conventional needle or positive control, Group #4 sham-inoculated, and Group #5 negative control, each consisted of three pigs. All pigs in Group 4 (the sham-inoculated group) were intranasally inoculated with 2 mL of virus-free media. On days 5, 6 and 7 post-inoculation (PI) of Group #1, pigs from groups #1, #2 and #3 were vaccinated with a killed Mycoplasma hyopneumoniae (M. hyo) bacterin (Ingelvac MycoFLEX®, Boehringer Ingelheim Vetmedica, Inc., St. Joseph, MO). The same AcuShot device and needle/syringe used to initially M. hyo-vaccinate the PRRSv source pigs (group #1) on opposite sides of the neck were used to subsequently M. hyo-vaccinate pigs in groups #2 and #3, respectively. Serum samples were collected from all pigs on days 0, 2, 5, 7, 12, 19 and 22 PI for PRRS PCR, and PRRS ELISA at days 0 and 22. The statistical analysis was run with Minitab® software, applying Fisher’s exact test.

Results

At arrival (day 0), all pigs tested negative by PRRS ELISA and PCR. All Group 1 pigs tested PRRS PCR positive at days 2 and 5 PI. All 12 pigs (4 reps of 3 pigs) injected with the conventional needle/syringe became PRRS PCR-positive at days 12 and 19 PI, while 4 out of 12 pigs injected by AcuShot tested PRRS PCR-positive by day 19 PI. The proportion of PRRS PCR-positive animals was significantly lower in the AcuShot group compared with the needle/syringe group (P<0.05, Table 1). On day 22 PI, the final day of the study, all PRRSv source pigs tested PRRS ELISA-positive, as did the 12 animals injected with conventional needle/syringe. Three of 12 animals treated using AcuShot and none of the negative controls or sham-inoculated pigs tested ELISA positive on day 22 PI.

Table 1. Proportion of PRRS PCR-positive pigs per treatment by testing day.

Discussion

The results of this study indicate that hematogenous transmission of PRRSv occurs from infected pigs to susceptible pigs via repeated use of the same needle and that needle-free systems reduce, but do not eliminate, the hematogenous transmission of PRRSv. Further research is needed to identify the mechanisms of PRRSv transmission by needle-free devices. Further evaluation of needleless devices under field conditions is warranted to ensure their suitability for use in swine production.

Porcine Reproductive and Respiratory Syndrome (PRRS) – Vaccination

P.227

Effect in a Vietnamese farm of a live attenuated genotype-I PRRSV (Porcine Reproductive Reproductive Syndrome Virus) vaccine in sows that were previously vaccinated regularly with a live attenuated genotype-II PRRSV vaccine

Chung Kim1 Bui T. Dung2 Sergi D. Bruguera1

Introduction
In the last years pig Vietnamese farms have suffered the infection of very virulent PRRSV1 strains, which were responsible of important economic loses. The use of live PRRSV vaccines either of the genotype-I (European) or the genotype-II (American) family virus has been spread in Vietnam and other Asian countries in order to reduce PRRSV negative effects. Some Vietnamese pig farms, which were endemically infected by PRRSV, have been already for more than 4 years vaccinating their sows with different family type vaccines. The objective of this field study is to compare reproductive sow performance data of a pig farm in Vietnam, in which sows and gilts were vaccinated regularly during two different periods of time with live PRRSV vaccines of different genotype family.

Material and Methods
The study was carried out in a one site production pig farm with 3000 sows, which is located in Binh Duong province, Vietnam. In 2004 PRRSV was diagnosed and a vaccination program with a live genotype-II virus vaccine started. A vaccine dose was regularly inoculated in gilts at 80 days of age and sows were vaccinated once in each pregnancy on the 4th week of gestation. At the end of 2007 the live genotype-II PRRSV vaccine was replaced by a live genotype-I PRRSV vaccine. This new genotype-I vaccine is still used in the farm today (January 2010). The vaccination protocol implemented with the new vaccine was the same like it was with the genotype-II PRRSV vaccine. We have compared the average sow reproductive performance data between the last 2 years implementation period of both the live genotype-II PRRSV vaccine (from 2006 to 2007) and the live genotype-I PRRSV vaccine (from 2008 to 2009).

Results
In spite of the already long time stable reproductive results with the use of a live genotype-II PRRSV vaccine in sows we observed that reproductive parameters were improved during the next 2 years period, in which a live genotype-I PRRSV vaccine was used (Table 1). The only studied parameter that did not improve significantly was the total number of born piglets per litter.

Table 1. Monthly average reproductive performance results during 2 years periods, from year 2006 to 2007 (use of live genotype-II PRRSV vaccine) and from year 2008 to 2009 (use of live genotype-I PRRSV vaccine).

Discussion and conclusion
The use of a live genotype-I PRRSV vaccine improved results in a farm endemically infected with PRRSV, in which sows had been vaccinated with genotype-II PRRSV vaccine. Different degree of efficacy was also previously observed2 with the use of 2 different live PRRSV vaccines in experimental conditions against a pathogenic PRRSV challenge in sows at 90 days of pregnancy. In this experience, lower % of new born viraemic piglets resulted also in a lower % of pre-weaning piglet mortality. So the vaccine that could reduce better vertical transmission from sows to foetus was also the one giving as a result healthier born litters with lower mortality. This field experience is also indicating that other virus epitopes3 or other immune response factors, common in both genotype PRRSV families, could be related to vaccine protection features.

Conclusion
A genotype-I PRRSV vaccine within these field conditions seemed to induce better degree of efficacy against a PRRSV infection in sows, when used in an endemically PRRSV infected farm in Vietnam.

Construction of attenuated porcine reproductive and respiratory viruses with a marker of Nsp2-coding region deletion

Aihua Fang; Xin Guo; Xinna Ge; Hanchun Yang
China Agricultural University, Beijing, China

Introduction
Porcine reproductive and respiratory syndrome (PRRS) is one of the most economically important diseases for the pig industry worldwide. Non-structural protein 2 (Nsp2) of PRRSV is the most variable region that is able to tolerate natural and artificial amino acid deletion (1, 2, 3, 4). In the present study, we generated two candidates of PRRSV vaccine with a marker of Nsp2-coding region deletion using the reverse genetic operation method, based on the attenuated PRRSV strain HB-1/3.9M which can provide sufficient protection for pigs against the Chinese highly pathogenic PRRSV

Materials and Methods
Cells and viruses. MARC-145 cells were used for propagation of PRRSV and transfection of full-length cDNA clones. An attenuated PRRSV strain (HB-1/3.9M) was used for the study.

Construction of full-length cDNA clones HB-1/3.9M. The construction strategy of full-length cDNA clones for the virus was basically performed according to the methods previously described (1). The full-length cDNA clone plasmid was designated pWSK-HB1-WT.

Deletion mutagenesis of Nsp2-coding region of PRRSV HB-1/3.9M. A plasmid pEB-A possessing the first 3585 nucleotides of HB-1/3.9M was constructed, which contains partial Nsp2. To delete HB-1/3.9M Nsp2-coding region with 270 nt (Nsp2Δ1627-1896) and 528 nt (Nsp2Δ1627-2154) respectively, overlapping extension PCR was performed on pEB-A. The PCR product was gel-purified, digested with proper enzymes, and cloned into pEB-A, cut with the same enzymes. After confirmation by sequencing, mutated fragment A was inserted into the infectious clone backbone to construct the final full-length deletion clone designated as pWSK-HB1-D90 and pWSK-HB1-D176, respectively.

Recovery and identification of the viruses. The viruses were rescued from each full-length cDNA clone according to the method previously described (3). The cytopathic effect (CPE) was daily observed. The rescued viruses were identified by immunofluorescence assay (IFA) using monoclonal antibody for N protein of PRRSV. Meanwhile, the genetic markers were detected to differentiate the rescued viruses and parental viruses. Growth characterization of the rescued viruses was determined.

Results
Viable viruses could be rescued from the full-length cDNA clones. A typical PRRSV CPE could be observed at the first passage for all the full-length cDNA clones. The three rescued viruses designated as RVHB1-WT, RVHB1-D90 (90-aa deletion) and RVHB1-D176 (176-aa deletion) were identified by IFA, genetic markers check and partial Nsp2 sequencing (data not shown). Growth characteristics of the rescued viruses. The rescued viruses could be passaged stably on MARC-145 cells with higher viral titres. All the three rescued viruses displayed the similar replication rate like their parental virus (Fig. 1). After 20 passages, the deletions in Nsp2 of RVHB1-D90 and RVHB1-D176 were examined by RT-PCR and followed by sequencing, indicating that the deletions stably exist.

Discussion
In recent years, the highly pathogenic PRRSV was pandemic in China and brought huge losses for swine production. Therefore, developing an attenuated vaccine with a marker is important for prevention and control of the virus. We have attenuated a strain of Chinese PRRSV HB-1/3.9M that presented satisfactory immune efficacy against highly pathogenic PRRSV infection. In the present study, we obtained two viruses (RVHB1-D90 and RVHB1-D176) on the basis of HB-1/3.9M by using infectious cDNA clones, which could be propagated stably in vitro. These viruses contain a deletion within the Nsp2-encoding region, respectively, suggesting that they are potential to be used as the candidates of PRRSV vaccine with a marker. Their immunogenicities and methods for detection of antibody to the deleted region of Nsp2 for differentiating vaccinated pigs from infected pigs by field virus are still under investigation.

References
Introduction

Porcine Reproductive and Respiratory Syndrome (PRRS) is considered to be one of the most important causes of loss for the swine industry worldwide. Several techniques have been proposed not only to reduce the economic impact of this disease, but also to minimize PRRS virus circulation. Among them, vaccination with attenuated vaccines seems to be one of the most effective.

This paper describes field experience with a vaccine based on an attenuated strain (Porcilis® PRRS), used in a sow herd with active PRRS virus circulation.

Materials and Methods

This study was performed in a closed cycle herd of about 500 sows in the province of Toledo, in central Spain. Before the introduction of Porcilis® PRRS, replacement stock was vaccinated twice with an inactivated vaccine with a 3 week interval, during the quarantine period. This measure alone appeared unable to prevent new PRRSv circulation in the herd. This was evidenced by (between May and June 2009) more abortions, and weak born piglets and increasing mortality in lactating sows and weaned piglets associated with high levels of antibodies against PRRSv in the sows (Antibody test kit – IDEXX Laboratories Inc), and by the detection of PRRSv in piglets of 4 and 5 weeks of age (PCR and immunoperoxidase test).

The ORF-5 of the PRRSv strain involved in this disease was sequenced as 91.4% homologous with the Lelystad strain.

Porcilis® PRRS (Intervet International BV, Boxmeer, NL) is an attenuated live vaccine, based on a European strain of PRRS virus identified as DV strain.

In July 2009, the whole herd was vaccinated twice with Porcilis® PRRS with a three week interval between doses. After October 2009, sows were vaccinated according to a ‘5/50’ scheme (5 days into lactation and 50 days into pregnancy). To complement these measures, no replacement stock were introduced for 5 months, and the M. hyo and PCV2 vaccination of piglets ceased.

Statistical analysis was performed using the General Linear Model (GLM-SPSS 15.0 for Windows) and Pearson's chi-square test was used for comparisons of means.

Results

Table 1 and Graphs 1 and 2 summarize the development of the main parameters recorded.

Comparing the first and third periods with the second: NS: p>0.05; *: p<0.05; **: p<0.001).

Graph 1. Abortion rate over time

After vaccination, the number of abortions and stillbirths and the mortality rate were clearly reduced during the lactation and post-weaning periods. In September, piglets of 9 weeks of age were found to be seronegative for PRRS, indicating that the improvements were related to the changing pattern of PRRSv circulation.

Graph 2. Mortality rate in weaned piglets over time

Conclusion

Vaccination with Porcilis® PRRS is an effective means of controlling PRRS clinically, as well as from an epidemiological viewpoint.
Case control and management of virulent PRRS in a commercial farm in the Philippines

Angel Antonio C. Manabat
PIC Philippines, Ortigas, Pasig City, Philippines

Introduction
For years, active PRRS infections in local swine farms have resulted in large economic losses for farmers because of poor breeding performances, high morbidity and medication costs and mortalities. In 2008, there were reports that PRRS strains similar to China were found in selected Philippine farms 2, which could have further increased the magnitude of this disease problem.

There are many approaches in stabilising herds with PRRS, however for farms located in areas with high density pig population, a good vaccination program seems to be the main and possibly the only option to take1. We report here a case of a farm slowly getting back to profitability after months and possibly years of frustrating management of their PRRS problem.

Case description
An 800+ sow level farrow to finish operation located in a farm estate in Bulacan Province Philippines have been experiencing the effects of an active PRRS infection. Mortalities in the pre-weaning and post weaning have been in alarming levels for months, and there was a reported 15 abortions per month observed. Farrowing rates have stayed in the 50 to 65% rates for sometime. Other pig farms are located in the same farm estate, one even located just a few meters away, many reporting their own problems in dealing with a respiratory and reproductive problems in their herds. The farm has had many control and management measures implemented, strict adherence to all-in all-out loading, breeding audits, farm personnel trainings, strategic medication programs and was already on a breeder mass vaccination and piglet vaccination program for PRRS Modified Live Vaccine (MLV) using a European strain vaccine. However, performances stayed at unsatisfactory levels. On September 2008, the farm decided to implement a shift to another PRRS vaccine (Ingelvac PRRS MLV®, Boehringer Ingelheim). They mass vaccinated the breeding herd and placed the piglet vaccination on day 21, improvements in piglet mortalities would be their major evaluation factor.

Results
A few months after the shift of PRRS vaccine used, the farm has reported a significant decrease in mortalities of piglets in both the pre-weaning and post weaning stages (figure 1).

Conclusion
Despite dramatic improvements, the farm is still a case-control in progress, vaccinating with Ingelvac PRRS MLV just barely 6 months as of data availability. Inspite of a virulent PRRS that hit the herd, which wiped out the piglets before weaning, the use of a VR2332-strain MLV showed that it can bring back the performance particularly livability to more acceptable levels.

**Comparison of serological and virological analysis for infection patterns of porcine reproductive and respiratory syndrome virus to establish a farm level control strategy**

Choi-Kyu Park; Seong-Hee Kim; K-K Lee; Y-K Song; O-S Lee

*National Veterinary Research & Quarantine Service, Anyangcity, Korea*

**Introduction**

Porcine reproductive and respiratory syndrome virus (PRRSV) has plagued pig populations worldwide causing severe economical impacts. In order to establish effective strategies for prevention of PRRS, infection patterns on the herd level were primarily evaluated. In the present study, therefore, serological and virological analyses were conducted in 20 pig farms suffering from PRRS.

**Materials and Methods**

A total of 20 pig farms were selected that they were a 150-250-sow, three-site multiplier herd. The blood samples were taken from sow, piglet, 40, 70, 100, 130 days-old pig groups. A commercial kit for PRRS (HerdCheck; IDEXX Laboratories) was used for serological testing according to the manufacturer’s instruction. A reverse transcriptase-PCR (RT-PCR) was used to amplify open reading frame 7(ORF7) of PRRSV as previously described by Lyoo(1998).

**Results**

Seroprevalence levels in each farm were grouped into 3 patterns: SN (Stable sow groups/Not infected piglet groups), SI (Stable sow groups and Infected piglet groups), and UI (Unstable sow groups and Infected piglet groups). The rate of each viroprevalence were estimated at 50% (n=10), 30% (n=6), 10% (n=2), and 10%(n=2), respectively. PRRSV viroprevalence results of suckling pig groups revealed that 8 farms were considered the virus positive. In 2 farms among these farms, PRRSV appears to be transmitted vertically to sucking piglets from their sows. In contrast, piglet-to-piglet horizontal transmission of PRRSV seems to occur in sucking herds of the remaining farms. Thus, this virological analysis on sucking piglets will provide useful information to understand PRRSV transmission routes during the suckling period and to improve a PRRS control program.

**Discussion**

Our seroprevalence and viroprevalence data found that infection patterns between sow and piglet groups are not always coincident in the same farm. Remarkably, 15 farms belonging to the UI seroprevalence pattern showed four distinct viroprevalence patterns (SNI; 7, SII; 4, UNI; 2 and UII; 2). Among these farms, 11 farms with unstable seroprevalence sow groups were further identified as the stable viroprevalence pattern. These results indicated that despite the absence of typical seroconversion, PRRSV infection was detected in several farms, implying the limitation of serological analysis. Taken together, our data strongly suggested that both seroprevalence and viroprevalence should be determined in parallel so that a PRRS control strategy could be efficiently developed on a farm level.

Evaluation of the efficacy of PRRSV modified live vaccine in one-day old piglets

Sayoko Ishizeki1 Hiromichi Iswhikawa1 Hiroshi Iseki2 Michihiro Takagi2

Introduction
Porcine reproductive and respiratory syndrome virus (PRRSV) causes major economic losses in the pig industry. It has been proven that the modified-live vaccine (MLV) is one of the options to control PRRSV. The objective of this study was to evaluate the efficacy of using PRRSV-MLV in one day-old piglets to provide them with protective immunity in their nursery-growing stages.

Materials and Methods
The study was conducted in a conventional farm in Gunma, Japan (2 site system, 3,000 sows). A total of 25,000 pigs were born between February 2008 and June 2008, and the piglets received a half dose of PRRSV-MLV intramuscularly at 1-day of age. A total of 18 piglets were randomly bled prior to vaccination, at 28, 35 and 42 days of age. Sera were tested for PRRSV by ELISA and PCR. Samples that were PCR-positive were sequenced to determine the homogeneity of ORF-5 region of the viral nucleic acids. Additionally, tonsil, lymph nodes, lung, liver, spleen, intestines, kidney and brain were collected from one pig that died at 52 days of age. All the tissue samples were examined by histopathology. The same set of tissue samples was also collected from a 38-day old pig that was euthanized. All the tissue samples were tested for PRRSV by PCR. Production performance data including nursery mortality and average daily gain (ADG) were obtained, and compared with the data from the batches that were born prior to the vaccine implementation in a previous year (non-vaccinated controls). Statistical analysis using T-test was conducted to determine whether there was significant difference between vaccinated piglets and non-vaccinated piglets.

Results
Prior to vaccination, no piglets showed viremia or any other clinical signs. The vaccinated pigs showed typical PRRS clinical symptoms in suckling and nursery periods. The sera and tissue samples from the vaccinated pigs at 28, 35 and 42 days of age showed viremia for PRRSV(11/18). (Table 1) ORF-5 sequencing revealed that 10 out of 11 PCR-positive samples were 99.2-99.8% homologous to MLV PRRSV strain, while 1 out of 11 was found to be a wild strain of PRRSV (87.7% homologous to PRRSV-MLV strain). Typical PRRS-like histopathological lesions were found from the tissues collected from the dead pig at 52-day old. PRRSV nucleic acid was detected by PCR from the lymph nodes collected from the euthanized pig at 38-day old. Nursery mortality and ADG were significantly worse in vaccinated piglets compared to non vaccinated controls.

Discussion
Under the conditions of this study, it is concluded that vaccination of 1-day old piglets with PRRSV-MLV vaccine has negate effects on clinical signs, viremia, as well as production performance including nursery mortality and ADG.
**Effect of vaccination using AMERVAC®-PRRS on different production parameters in three Philippine commercial swine farms**

Renato T. Policarpio¹ Michael Felipe E. Quilitis² Sergi D. Bruguera² Ma. Immaculada T. Torres³ David V. Llopart²

1. Philippine College of Swine Practitioners, Quezon City, Philippines; 2. Hipra Swine Technical Department, Amer, Girona, Spain; 3. Swine Technical Services, Hipra Philippines, Muntinlupa, Philippines; 4. Laboratory and Technical Manager - DIAGNOS, Hipra Philippines, Muntinlupa City, Philippines

**Introduction**

Porcine Reproductive and Respiratory Syndrome Virus (PRRSV) has affected many farms in Asia including the Philippines. Clinical signs observed include abortions, pre-mature births, inconsistent farrowing rates and high mortality in sucklings, weanlings and growing-finishing pigs. As previously described, vaccination using a live PRRS vaccine (AMERVAC®-PRRS) has positive effects on different production parameters as farrowing rates¹,² and mortality in growing pigs⁴. In this study, the objective is to assess the effect of continuous vaccination using a Modified Live (MLV) PRRS vaccine (AMERVAC®-PRRS) in different production parameters in three Philippine swine farms.

**Materials and Methods**

Three Philippine commercial farms with sow level ranging from 1300 to 3000, one site production system are involved in this study. PRRSV diagnosis was carried out with PCR³ and an ELISA serology technique (CIVTEST™suis PRRS E/S) from necropsy findings and serum samples.

**Farm A:** 1800 sows, one site production system located in south of Manila. The farm had complaint of abortion in sows and high mortalities in growing pigs in June 2008. Two mass vaccinations in sows with 4 weeks interval were implemented in July 2008 with AMERVAC®-PRRS. Pigs from 18 to 70 days of age were also vaccinated once at the same time. Next batches of piglets were vaccinated once intramuscularly at 21-28 days of age.

**Farm B:** 3000 sows, one site production system located north of Manila had abortion storms in July 2008. High mortality in pre-weaning, weanling and growing-finishing pigs was also observed simultaneous with reproductive failure in sows. Two mass vaccinations with 4 weeks interval were implemented in August 2008. Pigs from 18 to 70 days of age were also vaccinated once at the same time. Next batches of piglets were vaccinated once intramuscularly at 21-28 days of age.

**Farm C:** 1300 sows, one site production system located south of Manila. It had complaint of abortions, erratic farrowing rate, and high mortality in growing pigs. Same vaccination program as in the farms A and B was implemented starting September 2008.

Average monthly Farrowing rate, Pre-weaning, Post-weaning and Growing-Finishing mortalities for the period of three years were obtained and summarized in the Table 1.

**Results**

All the parameters monitored within this study improved considerably in farms A, B and C during 2009. In 2009 all the sows and piglets had been already vaccinated. Reproductive performance stability was observed from the 3rd month after the beginning of the vaccination program until the end of 2009.

**Table 1.** Mean production data from three Philippine commercial swine farms. PRRSV vaccination program started in July 2008 in Farm A, in August 2008 in Farm B and in September 2008 in Farm C.

**Discussion**

Based on these specific results, the implementation of PRRS vaccination (AMERVAC PRRS®) in sows resulted in stabilization of breeding performance. It has subsequent positive effect in reducing pre-weaning mortality since vaccination lessens the negative effects of PRRS field virus. Vaccination in piglets reduced substantially the mortality in growing-finishing stages.

**Conclusion**

Based on the data presented, regular vaccination program with AMERVAC®-PRRS in sows and pigs improved production performances and prevented the negative impact of a field PRRSV infection.

**PRRS vaccine serological response of a live PRRSV vaccine (AMERVAC®-PRRS) in pigs when the diluents is a Haemophilus parasuis bacterin (HIPRASUIS®-GLASSER)**

Michael Felipe E. Quilitis¹ Ma. Immaculada T. Torres² Sergi D. Bruguera³ David V. Llopart³ Criselda T. Bautista² Zoilo M. Lapus⁴ Redentor A. Manuel¹

1. Swine Technical Services, Hipra Philippines, Muntinlupa, Philippines; 2. DIAGNOS, Hipra Philippines, Muntinlupa City, Philippines; 3. Hipra Swine Technical Department, Amer, Girona, Spain; 4. Fellow, Philippine College of Swine Practitioners, Quezon City, Philippines

**Introduction**

Combined administration of vaccines may be practical and convenient; however it may not be always possible. Haemophilus parasuis vaccine is most usually inoculated in pigs at 7 and 21-28 days of age. Vaccination at 21-28 days of age with a live PRRSV vaccine is common practice in PRRSV infected farms. A previous study¹ showed that PRRS vaccine virus of AMERVAC®-PRRS vaccine virus (VP046-BIS) could survive when the solvent used was a Haemophilus parasuis bacterin (HIPRASUIS®-GLASSER). In this study, the objective is to determine if PRRSV vaccine (AMERVAC®-PRRS) serological response in piglets when PRRSV vaccine is used in pigs after reconstitution with a Haemophilus parasuis bacterin in a commercial pig farm.

**Materials and Methods**

100 7 day-old piglets (Day 0) were randomly selected and allocated in two groups.

**Group A:** (Hps + Amervac PRRS) 50 apparently 7 day-old piglets were allocated separately and ear notched. This group was vaccinated with 2ml dose of a Haemophilus parasuis bacterin (HIPRASUIS®-GLASSER) at 7 days of age. The same group of animals was vaccinated intramuscularly in the same point of injection, in the long neck muscle, with the PRRSV vaccine (AMERVAC®-PRRS), using the Haemophilus parasuis bacterin vaccine (HIPRASUIS®-GLASSER) as diluents at 21 days of age. 15 piglets out of 50 were randomly selected for serial bleeding done every 2 weeks.

**Group B:** (Hps and Amervac PRRS) 50 apparently 7 day-old piglets were allocated separately and ear notched. This group was vaccinated with 2ml dose of a Haemophilus parasuis bacterin (HIPRASUIS®-GLASSER) at 7 days of age. The same group of animals was vaccinated intramuscularly at 21 days of age with a PRRSV vaccine (AMERVAC®-PRRS) and a Haemophilus parasuis bacterin (HIPRASUIS®-GLASSER) in separate long neck muscles. 15 piglets out of 50 would be randomly selected for serial bleeding done every 2 weeks. Serum samples were taken at day 0, 14, 28 and 42 and analyzed with a PRRSV Elisa kit (CIVTEST™suis PRRS E/S).

**Results**

Serological response to vaccination has no significant difference in the two groups during the course of the trial. Similarly, no significant difference was observed in terms of percentage of positive serum samples.

**Discussion**

Under field conditions, simultaneous vaccination of a live PRRSV vaccine (AMERVAC®-PRRS) and a Hemophilus parasuis can reduce stress to the animals and maximize the time for farm personnel in the implementation of vaccination. Previous study² also concluded that simultaneous vaccination with the live PRRSV vaccine and another vaccine did not influence PRRS serological response in pigs. In another in vivo³ experience there was no interference with live PRRSV vaccine when reconstituted with a multi-antigen inactivated vaccine and administered in pigs.

**Conclusion**

There were no differences observed on the serological PRRSV response in pigs when AMERVAC®-PRRS vaccine was inoculated separately or combined at the same inoculation point with HIPRASUIS®-GLASSER vaccine. This knowledge may have practical field implications. Further immune response studies should be done to discard any negative immune response interferences between vaccines.

DIAGNOS, Hipra Philippines, Muntinlupa City, Philippines; 4. Hipra Swine Technical Department, Amer, Girona, Spain; 5. Laboratory and Technical Manager - DIAGNOS, Hipra Philippines, Muntinlupa City, Philippines

Introduction
With the advent of combination vaccines, conveniences in the administration and the efficacy under field condition have been the primary concerns. Since the recommended vaccination program for Mycoplasma hyopneumoniae is at 7 and 21 days and for PRRSV is 21 days, then the second dose of Mycoplasma can be given simultaneous with PRRSV vaccine. Previous study has demonstrated that PRRSV vaccine can survive under laboratory condition using a Mycoplasma bacterin as the diluents1. In this study, the objective is to determine if PRRSV vaccine (AMERVAC®-PRRS) could elicit serological response using a mycoplasma bacterin (MYPRAVAC® SUIS) as the diluents under field conditions.

Materials and Methods
100 7 day-old piglets were randomly selected and allocated in two groups.

Group A. (Mypravac suis + Amervac PRRS) 50 apparently 7 day-old piglets allocated and ear notched. This group was vaccinated with 2ml dose of a Mycoplasma hyopneumoniae bacterin (MYPRAVAC® SUIS) at 7 days of age. The same group of animals was vaccinated with the combination of PRRSV vaccine (AMERVAC®-PRRS) and Mycoplasma hyopneumoniae bacterin (MYPRAVAC® SUIS) at 21 days of age. 15 piglets out 50 were randomly selected for serial bleeding done every 2 weeks.

Group B. (Mypravac suis and Amervac PRRS) 50 apparently 7 day-old piglets allocated and ear notched. This group was vaccinated with 2ml dose of a Mycoplasma hyopneumoniae bacterin (MYPRAVAC® SUIS) at 7 days of age. The same group of animals was vaccinated with a PRRSV vaccine (AMERVAC®-PRRS) and Mycoplasma hyopneumoniae bacterin (MYPRAVAC® SUIS) at 21 days of age. 15 piglets out 50 would be randomly selected for serial bleeding done every 2 weeks.

Blood samples were taken at day 0, 14, 28 and 42 of the experiment.

Results
Vaccination with the combination and separate injection has no significant difference in terms of serological response.

Discussion
Under field conditions, simultaneous vaccination of MLV PRRSV vaccine and Mypravac suis has been proven valid because it can reduce stress to the animals and can reduce cost. In this study, the combination of a MLV PRRSV vaccine (AMERVAC®-PRRS) and a Mycoplasma bacterin (MYPRAVAC® SUIS) can be useful tool to control the two diseases.

Conclusion
With the use of the two vaccination protocols, no difference was observed serologically in the two groups of animals. We can therefore recommend that the two vaccines (MYPRAVAC® SUIS and AMERVAC®-PRRS) can be used separately or in combination without reducing their efficacy.

Antibody titer against porcine reproductive and respiratory syndrome virus (PRRSV) after modified live PRRSV vaccination

Em-on Olanratmanee; Roongroje Thanawongnuwech; Annop Kunavongkrit; Padet Tummaruk
Chulalongkorn University, Bangkok, Thailand

Introduction
Porcine reproductive and respiratory syndrome virus (PRRSV) can be detected in the lymphoid tissue of pig up to 8-9 months post infection (1). During this period, the virus can be replicated continuously at a low level and transmitted to susceptible animals via direct contact. In the PRRSV endemic herds, the present of PRRSV subpopulations (susceptible pigs) may lead to reoccurrence of the disease in the herds. Herd closure, gilts acclimatization and mass exposure have been recommended to eliminate the subpopulations (2). The use of vaccination to immunize the pigs has been evaluated, in most cases, at individual level. However, only few studies on the immune response of PRRSV in the infected herd have been evaluated. Earlier study has demonstrated that vaccination of the entire herd (mass vaccination) could reduce persistence and duration of shedding even though the wild type of virus was not eliminated from the pigs (3). However, the successful results are varied among the herds and a limited information on the immune response of PRRS modified live virus (MLV) vaccine is available in pregnant gilts and sows. The present study aims to evaluate the humoral immune response of gilts/sows after mass vaccination of PRRS MLV vaccine in a PRRSV infected herd in Thailand.

Materials and Methods
The present study was conducted between May and September, 2009 in a 1,200-sow inventory swine herd in Thailand, which produced their own replacement gilts. The herd has never been vaccinated the gilts and sows with PRRSV vaccine. An occurrence of abortion in sows was observed in January 2009 and an American strain of PRRSV was detected in serum of aborted sows using reverse transcription polymerase chain reaction (RT-PCR). Gilts/sows were vaccinated against PRRS MLV vaccine (Ingelvac® PRRSTM MLV, Boehringer-Ingelheim, Vetmedica Inc., St. Joseph, Missouri, USA) 2 doses 3 weeks apart and booster at 14 week and 3 months. Blood samples were collected from replacement gilts and pregnant gilt/sow (36 samples) one day prior to first vaccination (week 0) and subsequently at 2, 5, 9, 12 and 18 weeks after vaccinations in the same animals. The sera were obtained for viral detection using RT-PCR technique (pooled serum) and analyzing antibodies against PRRSV using ELISA (HerdChek® PRRS virus antibody test kit 2XR, IDEXX Laboratories, Inc., USA). The percentage of sero-positive gilt/sow was compared using logistic regression. The differences of means of the serum sample/positive control (S/P) ratio were compared using pair t-test. P<0.05 was considered as statistically significant.

Results and Discussion
It was found that no viral shedding was detected during 2 to 18 weeks post vaccination (Table 1). Before vaccination, 11.1% (4/36) PRRSV susceptible pigs were observed. The percentage of PRRSV subpopulation was reduced to 6.1% within 18 week post vaccination (P=0.401). The S/P ratio was slightly increased two weeks post vaccination and significantly decreased at 5 weeks post vaccination (Table 1).

**Table 1.** The S/P ratio (mean±S.E.M.), the percentage of sero-positive gilts and sows and the viral detection by weeks post vaccination

a,b different letters differ significantly (P<0.05)

The present study demonstrated that mass vaccination of PRRSV MLV in pregnant gilts and sows did not cause viral shedding during 2-18 weeks post vaccination and might possibly minimize the number of PRRS subpopulations in the PRRSV infected herds. However, the shedding of PRRSV during 0-2 weeks post vaccination and reproductive performance of pregnant gilts/sows should be evaluated further.

Introduction
Porcine Reproductive and Respiratory Syndrome Virus (PRRSV) is one of the primary precursors of economic losses² in pig production. Only in Japan the annual cost of the disease in 2008 was close to 280 million USD<sup>4</sup>. Clinical signs include decreasing farrowing rates, abortions, stillborns and increase of respiratory clinic problems in pigs. The objective of this field experience is to assess the effect of continuous vaccination using a live PRRSV European (EU) vaccine (AMERVAC®-PRRS) in the monthly farrowing rates in a farm endemically infected by PRRSV.

Materials and Methods
A 2000 sow farm with a 2 site production system that is located in the southern Philippines had a complaint of unstable and variable farrowing rates. PRRSV diagnosis was based on Polymerase chain reaction technique³ (PCR) from lungs and lymph nodes from stillbirths and 1 day old weak born piglets. A PRRSV vaccination program was implemented in sows at October 2007, using a modified live PRRSV European (EU) vaccine (AMERVAC®-PRRS). Every batch of sows was vaccinated with one dose at 60 days of pregnancy and another dose 7 days after each farrowing. Farrowing rates from April to October 2007 were compared with farrowing rates from November 2007 until December 2009 (unpaired t test).

Results
Variable and unstable farrowing rates were monitored from April to October 2007. The monthly farrowing rates became less variable and were significantly higher during the 25 months period after the implementation of the PRRSV vaccination program.

Table 1. Monthly mean (Mean±SD) sow farrowing rates (December 2009) before and after PRRSV vaccine program implementation in sows.

*Results were significantly different, P<0.001

Discussion
These results match with previous field cases in Asia where PRRSV vaccination prevented against negative effects of a PRRSV infection in sows¹. PRRSV regular vaccination after two years seemed to keep a degree of protection in sows that protects them again new reproductive clinic signs outbreaks due to the field PRRSV in the farm and may reduce the economic losses provoked by unstable reproductive performance.

Conclusion
The continuous long term implementation of a PRRSV vaccination program in sows with AMERVAC®-PRRS was effective and improved the monthly farrowing rates in a PRRSV infected farm.

Efficacy of an experimental inactivated PRRSV vaccine based on a recently isolated field strain

Marc F. Geldhof¹ Merijn Vanhee¹ Jan Van Doorselaere² ¹ Hans J. Nauwynck¹
¹. Laboratory of Virology, Faculty of Veterinary Medicine, Ghent University, Merelbeke, Belgium; ². Department of Health Care and Biotechnology, KATHO Catholic University College of South-West Flanders, Roeselare, Belgium

Introduction
Porcine reproductive and respiratory syndrome virus (PRRSV) infection is characterized by reproductive failure in sows (1) and is associated with respiratory problems in pigs of all ages (2). The vaccines that are available give variable results regarding the efficacy against genetically diverse field strains. At present, it is generally accepted that there is a need for new safe and effective vaccines that easily can be adapted to prevalent PRRSV strains. Recently, it was demonstrated that by the use of a new procedure, an inactivated PRRSV vaccine can be developed that induces virus-neutralizing antibodies and offers partial protection upon homologous challenge (3). The aim of this study was to compare the efficacy of a homologous experimental inactivated PRRSV vaccine, with the efficacy of a heterologous (Lelystad virus) experimental inactivated PRRSV vaccine and commercially available, inactivated and attenuated vaccines upon challenge.

Materials and Methods
The following PRRSV vaccines were included in this study: a vaccine based on a circulating PRRSV strain 07V063 that was isolated from foetuses during reproductive failure in a vaccinated herd and inactivated using the procedure described in Delrue et al. (4); a heterologous experimental inactivated PRRSV vaccine based on Lelystad Virus (3); a commercial attenuated European virus vaccine; a commercial attenuated American virus vaccine and a commercial inactivated European virus vaccine. Piglets from a PRRSV-free farm were vaccinated twice at 5 and 9 weeks of age with the inactivated vaccines. The attenuated vaccines were given at 7 weeks of age. One group of pigs was kept unvaccinated and served as control group. All animals were challenged intranasally with 10⁶.0 TCID₅₀ of the virulent virus field strain 07V063 at the age of 13 weeks. Sera were collected by jugular venipuncture at 0, 1, 2, 3, 4, 5, 6 and 7 weeks after (primo) vaccination and at 0, 1, 3, 5, 7, 10, 14, 21, 28 and 35 days post challenge. Virus-specific and virus-neutralizing antibodies were determined by an IPMA- and SN-test, respectively. Virus titers in serum were determined by virus titration on pulmonary alveolar macrophages.

Results
It was shown that all vaccines, except the commercial inactivated vaccine, induced virus-specific antibodies after vaccination and only the two inactivated experimental vaccines induced 07V063-specific neutralizing antibodies after vaccination. Upon challenge, viremia was observed for 4 weeks in the control group and the groups that were vaccinated with the commercial inactivated and the experimental heterologous inactivated vaccine. Vaccination with the attenuated vaccines reduced the duration of viremia with one week. The virological protection upon challenge was the best in the group receiving the experimental homologous inactivated 07V063 vaccine (Fig. 1.).

Discussion
The genetic diversity of PRRSV can cause problems with the efficacy of the current available vaccines that are all based on one virus strain. In general, the advice is to use a vaccine strain that is homologous to the present PRRSV-isolate in the herd. A farm-specific vaccine, based on the circulating PRRSV field strain can be a solution on (vaccinated) farms with severe PRRSV-related problems. Future work will be done to investigate the efficacy of this kind of inactivated vaccine in the field.

Vaccination of pigs with replicon particles expressing various PRRSV open reading frames

Mark Mogler1,2 Ryan Vander Veen1,2 Brandon Russell1,2 DL Hank Harris1,2

1. Iowa State University, Ames, IA, USA; 2. Harrisvaccines Inc, Ames, IA, USA

Introduction

Porcine reproductive and respiratory syndrome (PRRS) virus causes abortion, anorexia and pneumonia. Due to the prevalence of the virus and the ineffectiveness of current countermeasures, it has become one of the most economically significant threats to the swine industry. Current immunization strategies rely on autogenous killed-virus vaccine, modified-live virus vaccine, or deliberate exposure to virulent virus. Each method has drawbacks, such as: ineffective cross-protection, shedding of virus to penmates and piglets, and lack of serological differentiation between infected and vaccinated animals (DIVA). New vaccination strategies are needed to achieve the goals of local and regional elimination of PRRS virus.

One such method involves the use of replication-incompetent, alphavirus-derived, single-cycle viral replicon particle (RP) vaccines. These vaccines consist of a viral particle derived from Venezuelan equine encephalitis (VEE) virus containing a modified RNA genome that does not include the VEE structural genes. The lack of vector-encoded structural genes renders the vector unable to form a new particle once it enters the host cell. This feature adds to the safety of the vaccine and helps the vector overcome host anti-vector immunity.

Our group has evaluated RP vaccine candidates expressing open reading frame (ORF) 3, 4, 5, and 6 in a young-pig heterologous challenge model.

Materials and Methods

Replicon plasmids containing the PRRS virus genes of interest were created and used to generate RP vaccines for the study as previously described1,2. Briefly, in vitro transcribed replicon RNA and helper RNAs were electroporated into Vero cells, which were then incubated for 18 hours. After incubation, packaged RP were harvested by affinity chromatography and formulated in phosphate buffered saline with 5% sucrose and 1% swine serum. Safety tests were performed to ensure that no replication-competent virus existed in the batch of RP. Aliquots of RP were frozen at -80°C until use in the study. On the day of each vaccination, RP were thawed and diluted to the desired dosage, then administered by intramuscular injection in the neck. Each formulated vaccine batch was titrated on Vero cells and quantified using an indirect fluorescent antibody assay.

Forty piglets were obtained at three weeks of age from a herd serologically and clinically negative for PRRS virus, swine influenza virus, and porcine circovirus 2. Pigs were randomized into four groups of ten pigs each. Blood samples were collected at intervals throughout the study. At four weeks of age, pigs were vaccinated with the appropriate RP vaccine, and booster immunization occurred at seven weeks of age. At ten weeks of age, pigs were challenged intranasally with 2x10^5 TCID50 PRRS virus. Study termination and necropsy occurred at twelve weeks of age. Serum samples from throughout the study were used to determine the magnitude of antibody and cell-mediated responses, as well as post-challenge viremia. Gross and microscopic pathology scores were determined by a pathologist blinded to the treatment groups.

Vaccine groups for the study were as follows: 1) RP expressing PRRS virus ORFs 3 and 4; 2) RP expressing PRRS virus ORFs 5 and 6; 3) RP expressing PRRS virus ORFs 3, 4, 5 and 6; 4) Placebo.

Results and Discussion

Prior to challenge, the majority of vaccinated pigs had a specific antibody response to the RP-expressed antigen in their vaccine, as determined by Western blot. Prior to challenge, no pigs had a positive anti-nucleocapsid antibody response, as determined by the IDEXX Herd-Chek ELISA at the ISU Diagnostic Laboratory.

An interferon-gamma ELISPOT assay was used to determine the magnitude of cell-mediated immunity on the day of challenge. These results indicated that vaccinates receiving RPs expressing ORFs 5 and 6 (with or without ORFs 3 and 4) had significantly higher antigen-specific cell stimulation than placebo. The lack of seroconversion to the nucleocapsid antigen among vaccinates illustrates the DIVA capabilities of the RP vaccines. The induction of specific cell-mediated and antibody-mediated immune responses following vaccination with RP vaccines demonstrates their potential to overcome the limitations of existing vaccine technology.

Additional results will be reported at the meeting.

Acknowledgments

The authors would like to thank AlphaVax Inc. (Research Triangle Park, NC) for assistance constructing the replicon plasmids.

Failure in protection conferred by recombinant Aujeszky’s disease viruses expressing non-apoptotic fragments of PRRSV GP5 protein in pigs

Francisco Díez-Fuertes; Cinta Prieto; Francisco Javier Martinez-Lobo; Isabel Simarro; Lidia Hornillos-Gumiel; José María Castro

Facultad de Veterinaria Universidad Complutense de Madrid, Madrid, Spain

Introduction

In the last years, porcine reproductive and respiratory syndrome virus (PRRSV) envelope glycoprotein GP5 has been a leading target for the design of new generation vaccines that solve safety problems of live attenuated vaccines and the limited efficacy of inactivated vaccines against PRRS. In a previous study, our research group identified and characterized different regions in the GP5 implicated in apoptotic processes (1). Taking advantage of this knowledge, EC1, a recombinant Aujeszky’s disease virus (rADV) which express a GP5 fragment deleting the first 127 amino acids of the N-terminus of the original GP5, and EA4, a rADV which express a chimera fusing 32-69 amino acids fragment to the last 74 amino acids fragment of the original GP5, were generated (2). Therefore, the aim of the present study was to test the immunoprotective properties of EC1 and EA4 by immunization of PRRS-negative pigs.

Materials and Methods

The experimental design included eighteen six-month old PRRS seronegative pigs. Five pigs of group A were immunized with 106,0 TCID50 of the Spanish virulent strain Sp-3 (positive controls). Groups B and C, both of five animals, were immunized intramuscularly with 106,5 TCID50 of EA4 or EC1, respectively. Three pigs of group D were not immunized but challenged (negative controls). The pigs were immunized on days 0, 21 and 42 of the experiment. On day 70, all animals were challenged intranasally with 5x106,0 TCID50 of the Spanish virulent fi eld strain of the experiment. The pigs were euthanized and necropsied. Blood samples and oral, rectal and nasal swabs were collected on immunization days, on challenge day and every three days after challenge. Different tissue samples were collected from all necropsied animals. All samples were tested for PRRSV detection by viral isolation. Specific antibodies production against PRRSV were assayed by ELISA (CIVTEST SUIS PRRS E/S), Western-blot and virus neutralization assay. T-lymphocyte proliferation measurement did not show any statistically significant difference between groups but a statistically significant difference between groups B and D (p<0.05) was found by ELISPOT on day 70.

Discussion

Enhanced expression levels obtained in vitro after GP5 apoptotic region deletion encouraged the study of the potential immunoprotective properties of EC1 and EA4 in pigs. However, both experimental vaccines failed to provide protection after challenge as demonstrate by virus isolation from experimental samples taken along the study. On the other hand, pigs immunized with a different PRRSV isolate were fully protected. As no significant differences in cell mediated immune response between rADVs vaccinated pigs and positive controls were found, protection failure elicited by rADVs could be related with the incapacity to observe neutralizing antibodies production. Although a neutralizing epitope has been described in the ectodomain of GP5, it is possible that conformational changes in the recombinant protein expressed by EA4 have prevented the recognition of this epitope by the immunized pigs. In the same way, EC1 has not this neutralizing epitope so the failure in protection conferred by rADV could be completely related with the absence or modification of this epitope.

Results

None of the vaccinated pigs showed any obvious clinical signs before challenge. After challenge, viremic animals were observed among rADV vaccinated pigs through all the experiment (Table 1). Moreover, PRRSV was found in at least one of the tissue samples collected at necropsy from each pig (except in one pig of group C) and in nasal, oral and rectal swabs collected during the first 15 days after challenge.

Immunization of pigs with PRRSV GP5 subunit vaccine produces a severe enhancement of clinical disease after challenge

Cinta Prieto; Francisco Javier Martínez-Lobo; Francisco Díez-Fuertes; Patricia Aguilar-Calvo; Isabel Simarro; José María Castro
Facultad de Veterinaria Universidad Complutense de Madrid, Madrid, Spain

Introduction
In the last years our research group has studied extensively the variability of PRRSV and obtained evidence of the existence of isolates with a greater ability to induce neutralizing antibodies capable to cross-react with different strains than others (Martínez-Lobo et al., 2008). These results have encouraged the development of a subunit vaccine expressing the GP5 of one of the pluripotent isolates described. On the other hand, no adverse effects have ever been observed after challenge of animals immunized with recombinant PRRSV vaccines and for this reason, the aim of the present communication is to report the exacerbation of disease observed after challenge with a virulent PRRSV isolate in a group of pigs that had been previously immunized with a PRRSV GP5 subunit vaccine produced in E. coli.

Materials and Methods
Eighteen six-month old PRRSV seronegative pigs were divided into three groups. Six pigs of group A were immunized twice with 600 μg of rGP5 on day -42 and with 300 μg of rGP5 on day -21. Six pigs of group B were challenged but not vaccinated and six pigs of group C were not vaccinated and not challenged. Three weeks after immunization, pigs of group A and B were inoculated intranasally with 105 TCID50 of PRRSV strain 5710. Clinical signs, rectal temperature and food intake were evaluated for each pig every day after vaccination and challenge. Blood samples and nasal culture swabs were collected in vaccination days and at various time points post-vaccination and post-challenge. All pigs were euthanized 18 days after challenge and different tissue samples were collected at necropsy. Every collected sample was assayed by virus isolation and titration. Specific antibodies production against PRRSV was evaluated by ELISA (CIVTEST SUIS PRRS E/S) and virus neutralization assay. Tissues samples were collected for routine histopathological examination.

Results
No adverse reactions to immunizations were noted in pigs but after challenge, moderate to severe clinical signs were observed in pigs of groups A and B. These clinical signs were more severe in pigs vaccinated with rGP5 than in pigs of group B. Furthermore, significant lower daily body weight gain and higher mean temperatures were found in pigs of group A. Pigs of both challenged groups exhibited high viremia titers through all the experiment and no statistically significant differences were encountered at any time. PRRSV was detected at least in one of the tissue samples collected from each pig of groups A and B. On the day of challenge, only two pigs on group A had seroconverted by ELISA and none of them had neutralizing antibodies. After challenge an increase in antibody titre was observed in pigs of group A but no statistically significant differences were observed between groups A and B in the neutralization assays. Pigs of groups A and B showed mild moderate to gross lesions, including areas of congestion in the lung and moderate enlargement and congestion of some lymph nodes. Microscopically, moderate subacute interstitial pneumonia was recorded in animals of group A.

Discussion
Results of the present study demonstrate that immunization of growing pigs with a recombinant fusion GP5 protein of PRRSV not only failed to provide protection, but appeared to result in an exacerbation of the acute disease produced by challenge with a virulent isolates of the virus. Exacerbation of disease can be mediated by different mechanisms, including an antibody-dependent enhancement (ADE) of infection (3) that facilitates viral uptaking and efficiency of replication in target cells. However, the exact mechanisms of in vivo vaccine-induced enhancement observed remain uncertain since no association could be established between clinical severity and non-neutralizing antibody titers or viral burden in serum samples or tissues collected at necropsy.

Elimination of PRRS with herd closure on small pig farm in Slovenia

Marina Stukelj; Zdravko Valencak
Institute for Health Care of Pigs, Ljubljana, Slovenia

Introduction
Porcine reproductive and respiratory syndrome (PRRS) has plagued the swine industry for the past two decades and is considered the most economically devastating disease of modern swine production (1). A variety of strategies has been described for PRRS eradication; total depopulation/repopulation, partial depopulation, segregated early weaning, test and removal, mass vaccination with unidirectional pig flow and herd closure (2).

PRRS elimination protocols by the herd closure method have been developed from the knowledge that infected animals will recover from the infection and will eliminate the PRRS virus from the body’s tissue when interruption of the introduction of susceptible animals takes place. With herd closure the introduction of gilts is temporally stopped to allow the older sow population to produce antibodies and to eliminate the virus from the herd. It is known and actually happens quite often in Europe that the PRRS infection can sporadically disappear from small swine population (2, 3). Herd closure is financially advantageous over depopulation because there is no required downtime, sows are not slaughtered, and there is no clean-up cost (1).

PRRS prevalence in Slovenia was according annual serological monitoring low before 2004. After joining to EU PRRS situation, worsen due to free trade of pigs. The aim of the study was to prove the effectiveness of herd closure in selected conditions on small pig farm on PRRS.

Materials and Methods

Farm
The study was conducted on one site pig farm with 50 sows and 3 boars, free of Classical swine fever and Aujeszky disease. Actual epizootiological data and increased mortality rate lead to suspicion of PRRS.

Sampling
• Nine blood samples (2 fatteners, 2 gilts, 2 sows, 3 boars) were taken after suspicion of PRRS.
• Three weeks later 15 blood samples (6 weaners, 5 fatteners, 4 gilts) were taken.
• After two months blood was taken from all sows (50) and boars (3).

All serum samples were tested with IDEXX PRRS ELISA (Herd-Chek, IDEXX Laboratories Westbrook, Maine, USA). Results were expressed in S/P (sample: positive) ratios.

Records of weaner succumbs and culls
Number of succumbed and culled weaners was recorded weekly.

Closure of the farm
After confirmation of PRRS, farm was closed (no introduction of gilts and boars on the farm) for at least 3 months.

Results
First sampling confirmed PRRS. S/P ratios were high (more than 2) in 8 samples. Second sampling showed high titers (14 samples). Third sampling showed uniformly low S/P (less than 1) in all samples. Number of succumbs and culls at the beginning was 77 (16%) and decreased to 18 (6, 25%) after last sampling.

Discussion
The effect of herd closure was evident by serological testing and with decreased number of succumbed and culled weaners. In future, we expect that farm will become PRRS negative if new PRRS virus will not be introduced on the farm. Strict biosecurity procedures and isolation area for all replacement pigs are imperative for farm to keep its health status.

Porcine Reproductive and Respiratory Syndrome (PRRS) – Control

Introduction
Porcine reproductive and respiratory syndrome (PRRS) has become one of the most important diseases in swine production around the world. PRRS was first diagnosed in the United States in 1987.1 The disease is manifested by reduced reproductive performance, poor growth, decreased feed efficiency and increased mortality. Recently, the cost of this disease in North America has been estimated to cost US$ 560 million per year in the United States.2 Veterinarians and producers have been able to eliminate the from farms, however, some herds become re-infected and aerosol3 transmission is often suspected. Therefore, a regional elimination approach may increase the odds of success of eliminating pathogens among swine herds.

Materials and Methods
In 2004, local producers in Stevens county a county located in west central Minnesota proposed to bring PRRS herd elimination to the next level and start a regional elimination project. This county has many breeding-stock herds with high biosecurity and health standards. The first step was to contact all producers in the county to obtain their farm location as well as a basic description of the type of pigs being raised. Locations were plotted on a map using ArcGIS 9.3 (ESRI, Redlands, CA). The second step was to obtain producer consent for testing and sharing of PRRS results. The third step was to have all herds tested through serology and PCR. The PRRS virus in infected herds would be further tested to characterize the strain present in the herd. Each location was classified as positive, negative or unknown based on expert opinion of the local veterinarian or by diagnostic tests such as serology and PCR. Infected breeding herds would start a control program called herd closure to stop transmission within the herd. Sites with growing pigs eliminated the virus through depop/repop and the remaining sites which were nursery/finishing sites have eliminated the virus through depop/repop. Quarterly meetings were held to share results, validate information and provide scientific information with regards to the latest PRRS findings.

Results and Discussion
A total of 89 farm locations, one truck cleaning facility, one truck service facility and one hog-buying station were plotted on the map. Of the 89 locations, there are 19 with sows, eight nursery sites, 40 finishing sites, two boar studs, two boar stud isolation units, two 4H finishing sites, 13 empty sites and 3 sites that have been abandoned. In 2004 there were 31 locations that were thought to have positive pigs. By 2006, the number of positive locations had decreased to 15 and in 2008 there were four positive locations. Presently, there is only one positive location that is under elimination planning (Table 1). A total of 18 PRRS isolates have been sequenced. Three sow sites eliminated the virus by serum inoculation and herd closure, two sow sites eliminated the virus through depop/repop and the remaining sites which were nursery/finishing sites have eliminated the virus through depop/repop. The project has been expanded to include six surrounding counties. To date, 85 additional locations have been identified, of which three are positive, 18 are in the process of status definition and the remaining sites are negative. Due to the low density of these additional six surrounding counties and the low prevalence of positive herds, the project has been expanded once again to northern Minnesota where farm location and testing has already started. To date, an additional 140 locations have been identified of which 15 are positive, 30 are negative and the remaining are in the process of status definition. These results indicate that PRRS can be eliminated from a region.

**Benefits of using Pulmotil Premix® in swine production infected by PRRSV**

Annick Saives¹ Nathalie Gautier²

¹. Elanco Europe, Brussels, Belgium; ². Selas Veterinaire de la Hunaudaye, Lamballe, France

**Introduction**

Respiratory disease is one of the most important diseases in swine production, with major economic consequences. Porcine Respiratory and Reproductive Syndrome Virus (PRRSV) is one of the main agents. Treatments are mostly used when an outbreak appears, especially during the fattening phase. The present study aimed to evaluate the effects of a treatment with Pulmotil Premix™ in a farm with history of PRRSV, before the outbreak in fattening pigs.

**Materials and Methods**

The swine facility is a farrow to finishing farm of 220 sows having a history of PRRSV symptoms at the end of post-weaning and at the beginning of fattening. PRRSV was diagnosed by laboratory analysis (Histology, March 2006).

Pulmotil Premix™ medication was implemented starting in March 2006 at a dosage of 5 kg/T (200 ppm) in feed from 12 to 20 kg of AW. The objective was to intervene before clinical symptoms appear, to improve the immunity of animals and to decrease the virus circulation, replication and virus expression. It was demonstrated before that tilmicosin has an effect in decreasing in vivo viral replication (1). Nothing else was changed during the follow-up period.

A monitoring technique was set up by comparing a time period before treatment (from 04/01/05 to 03/31/06), a transition period where all the pigs had not yet been treated (from 04/01/06 to 03/31/07) and a final period where all pigs received the treatment (from 04/01/07 to 03/31/08).

A 4th treatment period was evaluated (from 04/01/08 to 07/31/09), since the producer decided to continue the treatment to see if the improvement would continue.

To evaluate the economic interest of using Pulmotil™ we referred to the latest estimates published by the French Pig Institute (IFIP) (2).

**Results**

Table 1 presents the technical criteria per time period used and Table 2 shows the improvement in each criterion and its economic impact per pig.

**Discussion and Conclusion**

This study confirms the advantage of using Pulmotil Premix™ for the treatment of respiratory diseases even within a viral context. The cost of treatment, being estimated at 1.39 € per 25 kg of feed consumed per pig, shows the return on investment using Pulmotil is therefore at 12.28/1.39=8.8.

In vitro efficiency of a disinfectant (Virusnip™) on CSFV, PRV and PRRSV

Napawan Bunpapong¹ Sasiwimon Talummuk² Kai Sievert³ Penchan Chaiyanate² Roongroje Thanawongnuwech¹

Introduction
Classical swine fever virus (CSFV), pseudorabies virus (PRV) and porcine reproductive and respiratory syndrome virus (PRRSV) are economically significant pathogens in major swine raising countries including Thailand. Vaccination, quarantine regulation and management strategies have been practiced as prevention and control strategies to improve the animal herd health status (1). Biosecurity using disinfectants is able to break the disease cycle by reducing the pathogen load in the environment. Disinfectants can be classified into various groups such as phenol, chlorine-releasing, acid, alkalis etc (2). The objective of this study is to evaluate the in vitro efficacy of Virusnip (Novartis Animal Health) against the major swine pathogens (CSFV, PRV and PRRSV) in Thailand.

Materials and Methods
Disinfectant: Virusnip, a commercial oxidizing disinfectant composed of Potassium monopersulfate. Viruses and cells: CSFV (ALD) and PRV (Tongsong) were prepared in SK6 cell line (2,3). PRRSV (01NP1) was prepared in MARC-145 with 5% fetal bovine serum (FBS) in growth medium incubated in 5%CO2 at 37ºC for 48 hours (5).

Virucidal activity: Virusnip was prepared in a 2X concentration and mixed with the equal volume of the virus stock to yield a final concentration of 1:100, 1:200 and 1:400. The mixtures were incubated at room temperature for 30 seconds and 5 minutes then were filtrated through Sephadex™ column and titrated in a 10-fold dilution manner. The mixtures were inoculated into a 96 well microtiter plates then incubated in 5%CO2 at 37ºC for 1 hour. Maintenance medium with 2% FCS was added and incubated in 5% CO2 at 37ºC for 48 hours. Indirect immunoperoxidase monolayer assay (IPMA) was performed for CSFV and PRRSV antigen demonstration to confirm the infections. An evidence of cytopathic effect (CPE) was observed to determine the PRV-infected cell compared with the control. Virus titer was calculated by Reed and Muench method (4). The titers were expressed as TCID50/ml.

Results and Discussion
The efficacy of Virusnip against CSFV, PRV and PRRSV is shown in Table 1. CSFV was completely killed at all dilutions tested within 30 seconds. However, PRV remained alive at all dilutions within 30 seconds but was completely killed at all dilutions by 5 minutes. PRRSV was completely killed at all dilutions within 30 seconds. CSFV, PRV and PRRSV are enveloped swine viruses. These swine viruses may be highly resistant in the suitable environment but are easily destroyed by lipophilic agent and very sensitive to acid or alkalis. Virusnip is able to kill CSFV, PRV and PRRSV at different concentrations depending on the viral susceptibility. CSFV and PRRSV appeared to be more susceptible to Virusnip than PRV. Virusnip can be considered as an alternative disinfectant in the swine farms.

Antiviral activity of Tilmicosin vs. European and North American genotypes of Porcine Reproductive and Respiratory Syndrome Virus (PRRSV)

Yijun Du1 Dongwan Yoo1 Gail Scherba1 Marie Anne Paradis2 Tom Shryock 3
1. University of Illinois at Urbana-Champaign, Urbana, IL, USA; 2. Elanco Canada, Montreal, QC, Canada; 3. Elanco Animal Health, Greenfield, USA

Introduction
Porcine reproductive and respiratory syndrome (PRRS) has spread to most pig-producing countries and has continued to evolve. Thus, vaccination for PRRS has been less effective than anticipated and the PRRS-associated economic losses continue. Since a satisfactory vaccine is currently absent, antiviral chemotherapy is a worthwhile consideration for PRRS. Tilmicosin is a macrolide antibiotic, which has been developed and marketed under the brand name Pulmotil® as a premix and Pulmotil AC® as an aqueous concentrate for swine respiratory disease. Tilmicosin has previously been shown to have antiviral effects on PRRSV in pigs, with improved clinical scores, feed consumption and gain, and a reduction in mortality and abortion rate in treated vs. untreated sows (1, 2, 3). Tilmicosin accumulates in macrophages at high concentrations (4), and since PRRSV preferably infects alveolar macrophages as the primary target cells, the inhibitory effect of tilmicosin in macrophages may explain the reduced clinical severity in vivo as observed in the tilmicosin-fed pigs. In the present study, the antiviral effects of tilmicosin were examined for both North American and European genotypes of PRRSV in porcine alveolar macrophages (PAMs), and the mechanism of action has been studied.

Materials and Methods
Cells and viruses: PAMs were grown in RPMI1640 with 10% FBS. PA8 strain (5) was used as a representative virus for North American genotype PRRSV, and Lelystad virus (LV, 6) was used as the European genotype PRRSV.

Determination for antiviral activity: PAMs were seeded in 96-well plates in a volume of 100 μl per well. Cells were treated with tilmicosin, and 24 h later, infected with 100 TCID50 of PA8 or LV in the presence of tilmicosin. Supernatants were collected and titrated by micro-titration infectivity assays 18 h post-infection. For real-time RT-PCR, viral RNA was extracted from cell culture supernatants and subjected to quantitative reverse transcription (RT)-PCR.

Discussion
The results show that tilmicosin inhibited replication of both genotypes of PRRSV, but was more potent vs. the European genotype.

Conclusion
The data suggests that tilmicosin may be used as a preventative measure for pigs infected with either the European or North American PRRSV genotype.

Introduction

PRRS has a high economic impact on swine production worldwide (4). Eradication of the disease on a herd basis is described by different groups (1,3,5). Every breeding organisation has its own strategy to clarify the being unsuspected status for PRRS of their farms, esp. AI-stations. The schemes, diagnostic tests and sample numbers can not be compared at this moment.

Materials and Methods

A PRRS working group of the swine health services of Germany, Austria, Switzerland, Luxembourg, Belgium and the Netherlands has developed a standard procedure of certification for a PRRS-unsuspicous status of AI-stations.

Auditing process:

1. Requirements:
   • Agreement with the local Swine Health Service
   • Compliance with the biosecurity standards
   • Clinical unsuspected for PRRS
   • Unsuspected for PRRS by Serology and PCR
   • Purchase livestock from unsuspected farms
   • Quarantine
   • No vaccination

2. Biosecurity check
   • Biosecurity check according to a specially developed checklist by a Swine Health Service Veterinarian

3. Status survey
   • AI-stations: serological survey of all boars on PRRS alternative 12x / year 1/12 of the herd, or 4x /year 1/4 of the herd or 2x /year 1/2 of the herd.
   • All acquired boars 3x negative (PCR and serological)
   • Minimum time between two surveys 4 weeks maximum 6 months.

4. Ongoing investigations
   • Minimum 30 samples / epidemiological unit per 1/2 year (serological) (2)
   • 2 visits per year by a Swine Health Service Veterinarian or/ and official government veterinarian (guideline EU 90/429)

5. Clarification of “false” positive Results
   • Resampling of the positive animal within two weeks along with at least 10 contact animals (PCR and serological investigation)
   • Again positive animals gets removed from the station

6. Certification:
   • Biosecurity-check positive
   • Status survey all samples negative
   • Ongoing investigations all negative or clarified
   • The certificate is valid for the last 1/2 year

Results

So far 15 AI-stations have joined the program.

Discussion

The above procedure makes comparison between AI stations possible by using same standards for biosecurity, numbers of samples, test procedures and frequencies of farm visits. Hence, this contributes towards a non-governmental approach to control PRRS.

Phylogenetic analysis of Dutch PRRSV strains

Gerard J. Wellenberg¹ Toine Cruijisen²
1. Animal Health Service, Deventer, Netherlands; 2. Intervet/Shering-Plough Animal Health, Boxmeer, Netherlands

Introduction
Since the introduction of porcine reproductive and respiratory syndrome virus (PRRSV) in Europe at the beginning of the 90ths, the characterisation of different virus strains demonstrated significant genetic differences between isolated virus strains. It became clear that genetic differences were no longer observed between American and European strains (1), but also within European PRRSV strains. The aim of this study was to characterise the ORF5 sequence of Dutch PRRSV strains and compare them with other EU and US strains.

Materials and Methods
Dutch PRRSV strains (n=284) were selected from PRRSV-positive samples during 2004-2009. Tissue samples or serum samples were originated from aborted fetuses or weak born piglets, and sera were also obtained from diseased and healthy (vaccinated) pigs. ORF5 sequence alignments and construction of parsimony trees were performed using the BioNumerics package (Applied Maths NV, Sint-Martens-Latem, Belgium).

Results
Two separate parsimony trees (Figure 1) were constructed based on the EU- of US-type PRRSV ORF5 sequences. The EU-type tree was constructed based on 262 field strains, using the EU-type vaccine strain (DV), Lelystad virus (LV; M96262), Italian strains (AY035930 and AY739971), Belarus strains (DQ324677 and DQ324687), Lithuanian (DQ324667) and the Spanish strain (ESP; DQ345755) as reference strains.

For the US-type PRRSV, 22 field strains (7.7%) were compared with the US reference strain VR-2332 (VR). Thirty strains (10.6%) were very likely EU modified live vaccine strains (>99% homology (NT) with DV) and all these 30 strains were isolated from DV vaccinated pigs (within 4 weeks post-vaccination).

Clear genetic differences were detected in the remaining PRRSV strains (81.7%) with homologies ranging from 83 to 100% compared to the DV vaccine strain (DV) (Figure 2). The average in homology was 90% in 2005, and it decreased to 88% in 2007 and 86% in 2009.

Discussion
The investigated ORF5 from Dutch EU-type PRRSV field strains, detected in the period 2004 – 2009, are on average 88% homologous to DV, and LV was not found. Compared to the DV vaccine strain, the homology of ORF5 sequences of EU-type PRRSV field strains might be decreased since 2005.

The spread of the DV strain appears to be very limited as it was found in DV-vaccinated animals (1-4 weeks pv).

Whether new branches, e.g. ESP-branches, appear in the PRRSV parsimony tree in the Netherlands, or whether this is a European phenomenon, has to be investigated.

Outbreak and fade out of Porcine Reproductive and Respiratory Syndrome virus in a Dutch SPF-herd: role of vaccination and strict hygienic procedures

Manon Houben1 John van der Wielen2 Toine Cruijsen3 Leo van Leengoed4
1. PorQ BV, Breugel, Netherlands; 2. Veterinary Centre The Overlaet, OSS, Netherlands; 3. Intervet/shering Plough, Boxmeer, Netherlands; 4. Veterinary Faculty, Utrecht, Netherlands

Abstract
This paper describes a newly started SPF-herd getting infected by an EU-strain of Porcine Reproductive and Respiratory Syndrome virus (PRRSv). The consecutive eradication strategy was based upon both vaccination and hygienic measurements to prevent the infection from becoming endemic and to produce PRRSv negative pigs again. Fade out of infection was extensively monitored by stratified cohort sampling. A cohort consists of all piglets born in 1 farrowing compartment. Nine months after the initial outbreak no PRRS infected pigs were traced anymore.

Introduction
PRRSv is widely spread among Dutch sow herds. There is an increased demand for PRRS negative breeding gilts and grower pigs. PRRSv-free herds risk introduction of virulent field virus strains. Strategies to cope with PRRS may vary between herds and depend on estimated introduction risk and the ability to control endemic infections. Preferably, this strategy should lead to eradication of the field infection from the herd. This study demonstrates how vaccination and well-defined internal biosecurity are successfully combined.

Material and Methods
Herd: A 350 SPF-sow herd was started with caesarian derived piglets from various breeding-herds and combined with gilts form existing SPF-herds. Selected sows with a high genetic index produced the piglets for this new herd (1).

Monitoring: The herd was repeatedly (3 times/year) tested for PRRSv-antibodies (30 randomly selected pigs). In addition, all produced pigs that were sold for reproduction were tested. At August 2006, 10 months after the herd was started, 3 boars out a group of 16 were tested positive for PRRSv (Idexx Elisa). The oldest pigs at the farm then aged 9-10 months. All pigs from the herd were bled and tested for presence of PRRSv antibodies. Thirty-one out of 421 pigs were tested positive and culled. Three weeks later 380 pigs were retested and 28 animals tested positive. Positive tests, reconfirmed by IFA, indicated the herd being infected by an eu-type PRRS-v. Approximately 8 weeks after PRRSv was diagnosed all pigs of the herd were vaccinated with Porcillis PRRS®(EU-live vaccine, Intervet/Shering-Plough) by IDAL (intradermal applicator of liquids) in an attempt to prevent further spread of the infection. Needle-free injection was used to avoid pig-to-pig transmission by needle.

Farm management and hygiene protocol: Stringent hygienic procedures were implemented: -the farrowing departments were strictly isolated by blocked corridors. -clothes were changed between farrowing compartments (max.10 sows per compartment), as well as surgical gowns, masks and hairnets. From each litter pooled blood samples of 4 piglets were tested by PCR to ensure absence of viremia. When negative by PCR, all piglets were tested serologically at 6 weeks and 10 weeks of age to ensure absence of PRRS. Only those cohorts of piglets that were tested negative for PRRS were allowed to be moved to the grower compartments.

Results
Initial introduction of PRRSv in this SPF-herd, did not coincide with clinical signs. The infection was detected by serology in August 2006 (3 out of 16 boars). 3 weeks later 7% of the pigs in the herd tested serologically positive. After culling the positive pigs again 7% of the remaining pigs tested positive by Idexx 3 weeks later. Two months later (October 2006), when the first piglets were born, characteristic reproductive signs of PRRS were seen, like high numbers of still born piglets, mummies, weakly born piglets and high preweaning mortality. Thereafter these signs gradually declined. The course of infection was extensively monitored by blood sampling of the newborn piglets by PCR. From February 2007 on most of the cohorts were PCR negative. From May on, sera from 6 and 10 weeks old pigs, tested negative for PRRS.

Conclusion and Discussion
The vaccination and well-defined internal biosecurity were successfully combined. In our strategy we assume that vaccination reduces vertical transmission of PRRSv and shortens the infectious period of infected pigs. Together with compartmenting of the herd hygienic procedures will lower the risk for susceptible pigs of becoming infected (3). By combining vaccination and hygienic procedures the infection faded out, resulting in the production of PRRSv-negative pigs.

Although introduction of PRRSv in a naive population may not induce clinical signs, the infection may continue to spread within the herd. Especially when no pregnant sows are present, a PRRSv infection may stay unapparent. Only during end-term pregnancy the virus will infect the placenta that leads to mummification, fetal death and weakly born piglets. Viremic born piglets will further spread the infection through the herd. As a consequence the infection may become endemic in weaned piglet groups (2).

In our study we prevented further spread of the infection by vaccination, internal biosecurity procedures, and the removal of viremic born piglets. The relative effect of these contributing factors cannot be calculated, and will need further research.

Our data proved that this approach was successful in eradicating PRRSv from the offspring of a breeding-herd.

Antiviral effect of dietary alminosilicate supplement against porcine reproductive and respiratory syndrome virus in experimentally infected pigs

Bock-Gie Jung¹ Jae-Hyung Ko¹ Il-Yung Yang¹ Yeon-Kwon Jung² Bong-Joo Lee¹

1. College of Veterinary Medicine, Chonnam National University, Gwanju, Korea; 2. Seobong Biobestech Co., Ltd, Seoul, Korea

Introduction
Porcine reproductive and respiratory syndrome (PRRS), caused by PRRSV, is characterized by respiratory problems in growing and finishing pigs and reproductive failure in sows, with late term abortion, stillbirth and increased preweaning mortality.¹ Our previous study has demonstrated that dietary aluminosilicate (Al₂SiO₅) supplement (DAS) enhances immune activity in mice and reinforces clearance of porcine circovirus type 2 in experimentally infected pigs.² The aim of the present study was to demonstrate the antiviral effects of the DAS against PRRSV in experimentally infected pigs.

Materials and Methods
Animals and diets
Conventional 6-week-old pigs were used to demonstrate antiviral effect of DAS against experimental PRRSV infection. All animals were confirmed to be free of PRRSV, as determined by a commercial ELISA kit (IDEXX Laboratories, Westbrook, ME, USA). They were randomized into two groups of three pigs each. The control group received a commercial, nutritionally complete, swine feed. The experiment group received the same swine feed supplemented with 0.3% (w/w) DAS.

Virus titration and histological analysis
All pigs were acclimatized to the particular diet for 2 weeks before experimental virus infection. Five milliliters of the viral culture (1×10⁷ pfu/ml) was inoculated intranasally in each nostril of each pig. All pigs were sacrificed at 12 day post-infection (DPI). Lymphoid tissues and lung were collected from each animal. Titration of PRRSV in each sample was performed by plaque assay. Histological analysis was performed as previously described.²

Results
Virus quantity in various tissues
Virus titer in bronchial lymph node, tonsil, thymus and lung of the 0.3% DAS feeding group was significantly decreased compared with those of the control group at 12 DPI (P<0.05) (Fig. 1).

Discussion
In the present study, titer of PRRSV in almost tested lymphoid tissues and lung of 0.3% DAS feeding group was significantly decreased compared with those of the control group at 12 DPI. These results are similar to those of previous our study that 0.3% DAS reinforces clearance of porcine circovirus type 2 in experimentally infected pigs.² Previous studies have reported that Al₂SiO₅ act as nonspecific immunostimulators similar to superantigens.³ In addition, our previous study has also demonstrated that DAS enhances immune activity in mice.² Therefore, antiviral effect of DAS may relate to nonspecific immunostimulatory effects of Al₂SiO₅. Taken together, these findings suggest that DAS have an antiviral effect against PRRSV in experimentally infected pigs.

Control of PRRS outbreak in a naïve herd using killed local US-strain PRRSv vaccine: A case report

Pariwat Poolperm; Kitcha Urairong; Preeyaphan Udomprasert; Worawidh Wajjwalku
Kasetsart University, Nakornpathom, Thailand

Introduction
Porcine reproductive and respiratory syndrome (PRRS), caused by PRRS virus (PRRSv), is the most costly disease currently affecting pig industry worldwide. PRRS outbreak seriously caused high losses in reproductive system, including highly increase in abortion, mummified fetuses, stillbirth, weak piglets born and sow death. For a naïve herd, these losses are drastically high and need more intensive action to control and stop losses. Vaccine is one effective tool in controlling the disease. Commercial vaccines are available worldwide. Killed PRRSv vaccine was chosen due to the regulation of the company. However, killed PRRSv US-strain vaccine is not commercialized in Thailand. Therefore, a homemade killed vaccine using local US strain (KU-killed-PRRS) was developed at the faculty of veterinary medicine, Kasetsart University, Thailand.

The objective of this study was to assess the efficacy of the KU-killed-PRRS vaccine in controlling PRRS outbreak in a naïve nucleus herd.

Materials and Methods
A 2,100 sows nucleus herd, had been free from PRRS for 6 years, was serologically positive for PRRS antibody using ELISA (HerdChek 2XR Ab, IDEXX Lab., Westbrook, MA, USA) in March 2009. The virus was determined as US strain using RT-PCR. Area veterinary consultants decided to use a vaccine, developed in a research project funded in part by National Research Council of Thailand, using local PRRSv US-strain (KU-killed-PRRS). The vaccine contains at least 106.5 TCID50/dose in oil-in-water adjuvant.

Mass vaccination was applied to all sows twice using KU-killed-PRRS vaccine, 4 weeks apart. Then vaccine was programmed at week 11 and 14 of gestation. In piglets, vaccine was programmed at 2 and 6 weeks of age to enhance antibody level for protecting early infection during suckling period.

Serological profiles and RT-PCR were monitored on monthly basis. Sow reproductive performance, percentage of preweaning and nursery losses were recorded.

Results
Sow reproductive and lactational performance parameters were shown in table 1. Serological profiles and RT-PCR results were positive in sows, suckling and nursery pigs. However, serological and RT-PCR results for suckling and nursery pigs turned to be negative in August, 6 months after vaccine was applied. During the outbreak, there was no increasing of losses in nursery pigs, however, the ADG was dropped about 26% during Apr-Jun 2009 (ADG 460g/d to 340 g/d).

Table 1. Represents sow reproductive and lactational performance during Feb-Aug 2009. (sb=%stillbirth, mm=%mummies, pwm=%preweaning mortality, lwg=average daily litter weight gain (kg/d), ab=number of aborted sows, day=average gestation length at abortion)

Discussion
The first PRRS outbreak in a naïve nucleus herd caused severe abortion in all parity sows, as high as 10%. The most detrimental effects are during lactation period, including, high percentage of stillbirth, mummies and weak piglets consequently increase preweaning mortality. Application of homemade killed local PRRSv US-strain vaccine could stop losses in an outbreak herd within two months and could produce PRRS free-infection for weaned and nursery pigs within 6 months. Off-site nursery is a recommended strategy to achieve PRRS free herd in the future.
Elimination of PRRS virus infection in a boar stud by vaccination and replacement

Michael Alt; Friedrich Delbeck
Chambre of Agriculture, Oldenburg, Germany

Introduction
As PRRS imposes high costs on pig production elimination of PRRSV is the best response to the disease (1). Transmission of the virus also by airosol and insects is possible and re-infections are frequent so that eradication must be conducted on a regional basis. Although the risk of virus transmission by semen from infected boars is low compared to other factors (2), negative herds should only be supplied from negative boar studs. If re-infection occurs, PRRSV should be eliminated immediately to prevent transmission to other farms. Successful eradications by vaccination with live vaccines have been reported from breeding herds (3), whereas for boars killed vaccines should be preferred because no adverse effects on semen quality nor shedding of vaccine virus were reported (4). A combined testing of blood samples by PCR and serological methods has been shown to be the safest method for monitoring boar studs (5).

Material and Methods
A boar stud consisting of two parts was re-infected after a period of several years being negative. The infection was limited to one part consisting of 200 boars. In order to prevent the transmission to the other part that is situated only 150 m apart housing 100 boars, strict bio-security measures were implemented including elimination of arthropods and rodents as well as separation of personal and feeding supply. For monitoring samples were taken every month and tested using a RT-PCR (blood and semen) and the IDEXX® Herd check ELISA 2X and X3. All young boars (60 % replacement/a) absolved a triple testing within 6 weeks in separate isolation farms situated at least 5 km apart. Two months after infection all boars of the infected stud 2 were vaccinated applying a killed vaccine (PROGRESSIS®, Merial). The vaccination of this herd is repeated three times at an interval of three months. Young boars are vaccinated before introduction as well. semen quality is controlled permanently.

Results
Vaccinated boars of stud 2 revealed no adverse effects concerning general behaviour or semen quality. All boars in stud 1 remained free of infection until now. Whereas virus material could be detected by the PCR in blood samples only at the onset of infection, no PRRSV in semen occurred at any time. Initially high levels of PRRSV antibodies declined on a relatively low and stable level. All of the tested animals with the exception of two developed antibodies after vaccination.

Discussion
No adverse effects of semen quality have been found following the vaccination. The spreading of the virus in stud 2 and transmission of virus to stud 1 could be prevented. The vaccination antibodies declined. Newly introduced boars remained free of detectable virus material. The antibody level is expected to decline after the end of the vaccination period. These preliminary results promise that elimination of the PRRSV can be achieved without depopulation.

Eradication of PRRSV: an approach using mass vaccination and high standard internal biosecurity without herd closure and partial depopulation

Geertjan van Groenland¹ Tom F. Duinhof² Paul J.M. Franssen²
1. TOPIGS S&D, Helvoirt, Netherlands; 2. GD Deventer, Deventer, Netherlands

Introduction
For the eradication of PRRS from infected farms methods as herd-closure, partial or total depopulation including strict biosecurity (1), and the use of vaccination (2) have proved to be effective. However, the costs of these methods, caused by loss of production and genetic material, question if other methods can be effective. Aim of this paper is to describe an attempt to eradicate PRRSV using all herd-vaccination combined with high standard internal hygiene and biosecurity procedures, without the use of (partial) depopulation. This approach was used on a breeding farm holding all sows, weaners, rearing and testing of breeding stock under one roof.

Materials en Methods
A breeding farm with 500 sows and 2000 young breeding stock, that started in August 2006 on a new location with SPF PRRSV-free gilts, was infected early 2007. March 2007 the diagnoses of an infection with an EU-type PRRS-virus strain was confirmed by PCR and serology. Sows were vaccinated 4 times, all other pigs (piglets included) were vaccinated twice, starting from an age of 14 days, with an interval of 2 weeks. The used vaccine was Porcilis PRRS (Intervet/Schering Plough) administered using Intra-dermal application (IDAL-technique), to avoid the use of needles. After the initial mass vaccination, the sows were vaccinated by 60 (gest.) – 6 (lact.) scheme, the piglets at 3 and 5 weeks of age. Vaccination of piglets was ended 6 months after the outbreak. For biosecurity four separate internal units were created with hygiene-barriers between them: a. sows and replacement gilts; b. farrowing rooms; c. weaned piglets; d. rearing testing stock. The hygiene-barriers included: changing of coveralls and boots, disinfection of hands and separated materials, including those for individual treatments. Unilateral flow and strict all in all out were standard procedures. The used sampling scheme was: a. monthly sampling of 20 non vaccinated weaners of 9 weeks of age (tested with Idexx ELISA Herdcheck PRRS 2XR), b. weekly sampling of 4 piglets per each newborn litter, samples pooled for rt-PCR-testing, c. all sold breeding pigs at individual level.

Results
In table 1 the results of testing are provided. In total 4 litters, 4 weaners and three 6 months old breeding pigs were found positive (Table 1).

Discussion
Although more than 99% of the tested animals became seronegative (weaners at 6 months and rearing stock at 12 months after the outbreak) the occurrence of a few infected pigs indicates that eradication of PRRSV was not fully successful. Reasons for finding positive test-results could not be determined. Unfortunately sequencing of the EU-virus strain found in a breeding pig in September 2008 was not possible due to technical reasons. Thus it could not be determined if a new strain had entered the farm, and virus spread from persistently infected sows could not be ruled out. Possible reasons for new virus circulation could be: internal influx of gilts into the sowherd started again after 3 in stead of 6 months, and the fact that not all sows were culled which could account for a low level of virus circulation. In spite of these facts the used vaccination-protocol and the high level of internal biosecurity have contributed to a rapid decline in percentage of infected animals.

Unfortunately the effect of the used approach could not be evaluated totally, because the farm got infected with a new PRRS-virus strain in December 2008, 96% homologous to the US-MLV-vaccine strain VR2332. Possible routes of this new virus introduction were considered to be: a) introduction of virus in incoming air either from neighbouring farms (500 m distance), b) from a slurry-container, c) non compliance to biosecurity protocols for humans d) open doors when loading pigs for transport. Next to reconsidering biosecurity protocols, the farmer now considers the use of air filtration to prevent virus introductions in future.

Dept. Anatomía y Patología Comparada , Córdoba, Spain; 4. APC Europe, Granollers, Spain

Introduction
Spray-dried porcine plasma (SDPP) is used as a feed ingredient in diets of weanling pigs to provide beneficial effects on productive parameters. Some epidemiological studies have described a significant association of dietary SDPP with lower post weaning mortality1 and improved productive records in sows from a PRRS unstable farm2. According to these studies the positive effect of SDPP could be related to a modulation of the inflammatory immune responses. The aim of the present study was to determine the effect of SDPP as a supplement in the diet on the outcome of experimental PRRS virus (PRRSV) infection.

Material and Methods
Experimental design. 55 three-weeks-old piglets obtained from a PRRSV-free farm were randomly distributed in three groups: pigs in I and II were intranasally inoculated with PRRSV (10^6 TCID_50/ml) and group III was kept as a control. Group I received a supplemented diet (8% SDPP, AP-820P from APC Europe, SA) from four days before challenge to 28 days post-inoculation (PI) and drinking water supplemented with 2% spray-dried porcine serum until 7 days PI.

Clinical follow-up and sample taking. Individual body temperatures were measured daily (from 0 to 14 PI). Sera samples were taken from 0 to 28 days PI and analyzed for PRRSV viremia by nested RT-PCR (nPCR)3. The presence of antibodies to PRRS was checked by a commercial ELISA kit (HerdChek® PRRS 2XR, Idexx).

Histopathology. Serial examination of tissues was performed after humane killing of pigs at days 0, 3, 7, 14 and 28 PI. Severity of microscopic interstitial pneumonic lesions was semi-quantified following a previously reported scoring system4.

Immunohistochemistry (IHC). IFN-γ, IL-1 and IL-10 were measured from apical and intermediate lobes of lungs by IHC as described before5.

Statistics. Statistical analysis was performed with StatsDirect 2.7.5

Results
Clinical follow-up. Temperatures of both infected groups showed a biphasic pattern of two peaks (day 4 PI and day 8-12 PI) of fever (≥40°C). All infected groups seroconverted at day 14 PI and were positive by nPCR until 21 PI. Five of six pigs in group II and only two of five in group I were viroaemic at day 28 PI (p=0.07).

Histopathology. Sum of interstitial pneumonia scores from day 3 to 28 PI showed significant differences among groups (II = 129 > I= 94 > III= 25; p<0.05).

IHC. Interestingly, higher frequency of cells expressing IFN-γ and IL-1 (day 3 PI and days 3, 7 and 14 PI, respectively) were detected in apical and intermediate lobes for group I (p<0.05) (Figure 1). No significant differences were observed for IL-10.

Discussion
After the PRRSV inoculation, a significant lower interstitial pneumonia was found in the group receiving SDPP (I) (p<0.05). Besides, this group also showed less nPCR positive pigs at day 28PI (p=0.07). Both facts suggest that pigs fed SDPP may have an earlier virus clearance compared to non-SDPP challenged group (II).

The increase of cytokine expression (IFN-γ and IL-1) in lungs of group I points to a Th1 enhancement that might be related with the data discussed above.

Results of the present report indicate that SDPP used in the diet may have a potential positive effect during a PRRS challenge.

**Comparative analysis of different strategies for PRRS control**

I. De Blas¹ Antonio Callén² J. Q. Cabanes³ J. A. Munoz¹ François Joisel⁴

¹. Veterinary Faculty, Universidad de Zaragoza, Zaragoza, Spain; ². Merial Laboratorios S.A., Barcelona, Spain; ³. Agrocesa, Valladolid, Spain; ⁴. Merial S.A.S., Lyon, France

**Introduction**

PRRS is a devastating disease for intensive pig production. Seroprevalence studies show that it is an endemic disease in most farms. Several control measures are currently used at farm level with variable results (1).

The objective of this study was to assess, under field conditions, the effectiveness of different health management strategies for PRRS control.

**Material and Methods**

Forty-three Spanish farms belonging to the same company and with a census between 100 and 5,250 sows and gilts (mean±SD: 643±1,012), were surveyed during a minimum period of 3 years (maximum of 10 years) (total of 397 farm-years) in a prospective observational study.

Four different strategies for PRRS control were used in these farms: S1: PRRS-Positive Gilts, Live Vaccine and No Infection with Piglets; S2: PRRS-Positive Gilts, Live Vaccine and back passage (infection) with viremic piglets; S3: PRRS-Positive Gilts, Killed Vaccine and Infection with Piglets; and S4: PRRS-Negative Gilts, Killed Vaccine and Infection with Piglets.

Live vaccine (AMERVAC®-PRRS (Hipra, Spain)) and killed vaccine (PROGRESSIS® (Merial)) were applied according to producer specifications in gilts in quarantine, except in some farms where adult sows were also vaccinated with PROGRESSIS.

In this study, a PRRS outbreak was defined as the sudden occurrence of reproductive problems associated to an abrupt increase of seroprevalence to this disease.

A commercial indirect-ELISA test was used for PRRS diagnosis (Ingezim PRRS K1, Ingenasa). Seroprevalences were calculated every year from min. 20 samples (max. 370) depending on farm size (48.3 ± 35.1).

Comparison of average year seroprevalences was performed with ANOVA or Student t-test (normality was previously checked with Kolmorogov-Smirnov test). Error α was established at 0.05. Statistical analyses were performed with SPSS® 15.0 (WIN-DOWS®).

Comparison between outbreak prevalence was tested with classical percentage comparison.

**Results**

Using live vaccine and introducing PRRS-positive gilts (S1, starting point) gave us an average seroprevalence of 52% (minimum 11%). Further infection of gilts with positive piglets (S2) produced a significant increment of seroprevalence (71.9%, minimum 28.6%). A change from live to killed vaccine (S3) led to a significant decrease of seroprevalence (63.4%, minimum 2%). Finally, introducing PRRS-negative gilts (S4) led to a further reduction of seroprevalence (47.4%, with some farms becoming totally seronegative) in spite of the infection of gilts with piglets (Table 1).

However, some farms under S4 strategy still showed high seroprevalence as a probable result of PRRS virus circulation. Only a very low number of outbreaks occurred whatever the strategy (Table 2).

**Discussion and Conclusion**

It is well known that ELISA antibodies are more of a proof that pigs have been in contact with the virus than related to protection (2) and that ELISA antibody response to PROGRESSIS vaccination are variable (3). The use of killed vaccine in seronegative gilts with infected piglets did lead to a significant reduction of PRRS-seroprevalence in most farms due to no new virus brought through the incoming gilts and through the control of existing infection. This was confirmed by the low overall number of outbreaks occurring during the study. The PRRS status reached in most of the farms could eventually let us consider an eradication program.

Isolation of a swine influenza type A virus from pigs during a reproductive outbreak in Mexico

Pedro J. Pradal-Roa1 Ivan Sánchez-Betancourt1 Mario Velasco-J2 Antonio Morilla-González3
1. Universidad Nacional Autónoma de México (UNAM), Facultad de Medicina Veterinaria y Zootecnia, Departamento de Producción Animal: Cerdos, Ciudad, CHIH, Mexico; 2. National University of Mexico, Mexico, DF, Mexico; 3. CENID-Microbiología, INIFAP, Mexico, DF, Mexico

Introduction
Swine influenza virus (SIV) causes outbreaks of pneumonia and respiratory disease of short course with high fever and morbidity and mortality of less than 1%. Clinical signs generally are of respiratory type however it has also been reported as a cause of reproductive disease (1, 2, 3) and it is a public health concern. In this paper the isolation in Mexico of an influenza type A virus from pigs during a reproductive outbreak is described.

Materials and Methods
The outbreak took place in a 250 sow herd which produces only weaners, located in the State of Mexico and considered free of PRRSv and Porcine Rubulavirus. Antibodies against PRRSv, influenza virus (H1N1, H3N2) were measured by ELISA (IDEXX), for Parvovirus and Porcine Rubulavirus haemagglutination inhibition test (HI) was used. Tissues from dead newborns and semen from males were inoculated in PK15 and Vero cell line and in chicken embryos for virus isolation. Primers against the M gen (Matrix) were used for RT-PCR. From the isolated virus an inactivated vaccine was prepared with 1x10^5 50 IDCE and Freud adjuvant.

Results
Herd fertility decreased at the end of 2007 (figure 1), and born death and mummies increased. Mortality during the suckling period increased from 3% to 8% and piglets showed nervous and respiratory signs. An increment of repeating sows with irregular cycles, abortions and sudden death were recorded. None of the males had apparent testicular abnormalities but some had azoospermia and others agglutination, low viability or death spermatozoa. Serology of sows and piglets was negative for Porcine Rubulavirus and PRRSv, and few sows had antibodies to parvovirus at low titer. Therefore these viruses were not circulating in the herd. Antibodies against H1N1 and H3N2 SIV were detected only in 4th to 5th parity sows indicating that these types of influenza virus infected the herd in 2006. A haemagglutinating virus was isolated from lung tissue and semen. The isolated virus was positive to type A influenza virus by RT-PCR and was inhibited weakly with an specific anti H1N1 sera, but not with H3N2. By means of an HI test using the isolated virus, all parity sows (1 to 5) had antibodies indicating that the new virus was infecting them. The inactivated vaccine was applied to gestating sows and males at the end of 2008 and fertility returned to normal values by mid 2009.

Discussion
The clinical presentation described has not been reported globally and it is very important to mention that it can only be diagnosed through molecular biology tests such as RT-PCR or Real-Time PCR, once the complete viral genome has been fully sequenced. The typification and characterization of the virus is on its way, however, the search for new viral subtypes is needed because at the moment the reproductive clinical impact associated with the influenza virus still unknown; since, generally reproductive disorders are associated with other viruses such as Aujeszky, Parvovirus, Circovirus or PRRS, that means that we are identifying the influenza virus as directly responsible for the reproductive failure. It was concluded that a type A influenza virus, different to H1 or H3 subtypes, was involved in the reproductive outbreak described.

References

Percentage of fertility (2007-2009)
Introduction

In South America, reports about swine influenza virus (SIV) are scarce. Serological surveys have revealed that SIV subtypes H3N2 and H1N1 are currently in circulation in Venezuela, Colombia, Brazil and Argentina (1). However, as neither isolation nor sequence has been performed, subtype, genotype and source of virus remains unknown. In this work we describe the epidemiology, clinical outcome, pathology and the techniques applied for isolation, subtype and sequence of influenza A virus outbreak in Argentina.

Materials and Methods

The disease appeared at the nursery barns of 3 site farrow-to-finish farm with its own replacement gilts, located in Buenos Aires province. Each barn had an average of 3,000 pigs with a total pig population at risk of more than 21,000. The clinical signs such as cough, dysnea, off of feed and fever affected 1.2% of 40 days-old pigs and rapidly elevated up to 40% in pigs of 48-55 days-old and almost disappeared at 83 days. The cycle of infection persisted for 8 weeks. Average weight of pigs was recorded by barns. Ten pigs were submitted for post-mortem studies. Lung samples were processed for histopathology and immuno-histochemistry (IHC) against NP of influenza A viruses (2). Nine bronchial swabs and lungs samples from 45 to 50 days-old pigs with pneumonic lesions were processed by real time RT-PCR directed to the matrix (M) gene (3). Positive samples by rRT-PCR were processed for virus isolation in MDCK cells. The genome segments were amplified by RT-PCR and directly sequenced with the BigDye terminator kit (Applied Biosystems™, Foster City, CA, USA). Partial sequences of HA, NP, NA, M1, NS, and PB2, PB1 and PA were obtained. Genomic information was derived from overlapping sequences covered by forward and reverse primers. At least two independent RT-PCR reactions were produced for each gene and used for sequencing. Nucleotide BLAST analysis was initially used to identify the most closely related influenza A virus gene for each respective segment.

Results

Overall average daily gain, feed intake and mortality records were not affected during the outbreak. However, in 9 post-mortem examined pigs, body condition was under the target weight. All pigs had cranioventral plum colored consolidate areas. In 2 pigs, distinctive lobular consolidation like “chess-board” distribution was observed. In 6/10 severe necrotizing bronchiolitis was a characteristic microscopic finding. Small and medium sized bronchioles were plugged with neutrophils, cellular debris and proteinaceous exudates. IHC showed distinctive positive reaction only in the bronchial or bronchiolar epithelia that showed minimal changes. Seven samples were rRT-PCR positive to influenza A. Further, rRT-PCR procedure demonstrated H3N2 subtype. The partial sequence of the eight genome segments revealed a high nucleotide identity with wholly human origin influenza A H3N2.

Discussion

Since 1970, infection of pigs with H3N2 viruses of human origin have been reported in Asia and Europe, but only after 1984 it was associated with clinical outbreaks (4). Currently, double and triple reassortant H3N2 viruses are the predominant in Europe and in North America respectively (5). However, wholly human influenza viruses are some times isolated from pigs without sustained circulation. The origin of this isolate and its prevalence in Argentinean farms are yet unknown. From an epidemiological, clinical and pathological point of view the reported outbreak was in agreement with those described for endemic SIV. However cycle of infection and clinical signs persisted longer than those reported (5). The age-dependent susceptibility of pigs may reflect a higher innate immune response to the virus in older pigs (6) or the decline of maternally acquired immunity. This is the first report of SIV H3N2 isolated and genotyped from a clinical case in Argentina and South America.

**Introduction**

Swine influenza virus (SIV) subtypes H1N1, H1N2 and H3N2 are well-estabished in the pig population worldwide. Since 1999, the H1N2 subtype has emerged and caused abortion storms in pregnant sows in the U.S. swine farms (1). In Thailand, H1N2 SIV was first isolated in the non-clinical swine farms in Saraburi province located in the central part in 2005 (2). It was not until 2009 that we found the H1N2 SIV associated with severe respiratory distress in two pig farms in the eastern part of Thailand. The objective of this study was to characterize the major envelope glycoprotein genes, HA and NA of the re-emerging Thai H1N2 SIV.

**Materials and Methods**

Two separate pig farms in Chacheongsoa province located in the eastern part of Thailand, faced with respiratory problems in the nursery to early grower pigs (4-12 wk). The morbidity rate was over 50% and mortality rate was approximately 10-20%. Fresh 6 lung tissues were submitted to the Chulalongkorn University-Veterinary Diagnostic Laboratory. Lungs were diagnosed of PRRSV, PCV2 and SIV by PCR. SIV subtyping and characterization of HA and NA gene were performed (1).

Both SIV isolates designated as A/Swine/Thailand/CU-K4/09 (H1N2) and A/Swine/Thailand/CU-CHL2/09 (H1N2) were characterized.

**Results**

The nucleotide homology of the HA and NA genes of the two current H1N2 virus compared to the first Thai swine H1N2 isolated in 2005 (H1N2/2005) are 87.5-88.2% and 82.3-82.6%, respectively. HA genes of both 2009 isolates belonged to classic swine lineage similar to the H1N2/2005 but located in different clusters. The NA gene of both 2009 H1N2 belonged to the human-like SIV similar to the H1N2/2005 but also located in different clusters.

**Discussion**

Previous data indicated that the Thai H1N1 and H3N2 subtypes were separated into 2 clusters (a and b) (2). The Thai H1N2 SIV reported in 2005 contained a combination of H1N1 (H1-classical swine (Cl) b) and H3N2 (N2-human (H) b). The origin of the N2 of both 2009 H1N2 viruses in this study appeared to be similar to the human-like in cluster a (Ha) closely related to the Thai human influenza viruses. Characterization of the internal genes is pending. No pathogenesis or epidemiological data was done with the 2005 H1N2 SIV.

Introduction
Swine influenza viruses (SIVs) represented by three different subtypes, H1N1, H3N2 and H1N2 are now co-circulating in European countries (1). In France, according to recent virological and serological surveillance studies, H1N1 and H1N2 are the major subtypes and no or very few H3N2 viruses have been evidenced (2,3).

The objective of this survey was to evaluate the seroprevalence of SIVs in farms affected with acute respiratory clinical signs in France.

Material and Methods
Experimental design: 29 farms (2 farrowing units, 17 farrow-to-finish and 10 finishing herds) located mostly in Brittany and western part of France were investigated. These farms had been affected with acute respiratory clinical signs at least 3 weeks before sampling. Four farms used to vaccinate the sows against H1N1 and H3N2 strains; in these specific cases, only H1N2 serological results were considered on sow sera. Farms were sampled from January to June 2009 as follow: 10 sows of different parity in farrowing units, 10 sows and 10 fattening pigs before slaughter in farrow-to-finish farms and 10 pigs before slaughter in fattening farms. In one farm, where fattening pigs showed fever, nasal swabs were collected for virus isolation. All sera and swabs were sent to IZLER laboratory at Parma, Italy, to be submitted to haemagglutination inhibition tests (HI) (4) and to virus isolation. The strains used for the HI test were H1N1 sw/Belgium/1/98, H1N2 sw/Scotland/41440/94, H1N2 sw/France/134240/09 (strain isolated on nasal swabs from one farm in Brittany during the study) and H3N2 sw/Gent/84. The results were analyzed according to the following rules: samples were considered positive for one specific subtype if the titre is ≥1/20; one farm was classified as positive against one given subtype if at least 2 sera showed an HI titre ≥1/20 against this subtype. Risks of misinterpretation due to cross-reactivity between H1N2 and H1N1 strains were decreased by considering negative for H1N2 a serum that showed higher (3 log2) HI titre against H1N1.

Results and discussion
The serological results are presented in table 1. Globally, 96.6% of farms tested were positive for at least one SIV subtype. The use in the HI test of the strain H1N2 sw/France/13240/09, isolated in Brittany, increased the sensitivity of the HI test, as showed in the table 2. This observation confirms the importance to use local strains in HI tests in SIV surveillance programme. Some farms were infected with both strains H1N1 and H1N2: this represents 38% of tested farms. One farm not vaccinated against flu was found to show positive sera against H3N2, and another one was doubtful. H3N2 subtype infection has not been shown since many years in pigs in Brittany, the possibility that cross reactions could have been occurred must be considered.

Conclusion
This serological survey confirms the major role of SIVs in swine respiratory disorders in French farms. SIV of H1N1 and H1N2 subtype are enzootic in swine producing region of Brittany, particularly about 50% of tested farms were found to be infected by H1N2 subtype when tested with a strain representative of the strains circulating in the region.

Introduction
Swine influenza (SI) remains one of the most important and worldwide prevalent viral respiratory diseases in pig population, causing economic losses in swine industry. It is also considered an important factor in public health concern. Therefore the regular monitoring of the epidemiological situation as well as rapid and sensitive detection of IV in clinical specimens is of great necessity.

The surveillance program for swine influenza was initiated in Poland at the end of 90s. The aim of this paper is to present both, the current epidemiological situation concerning SI in Poland and its retrospective analysis over 10 years period.

Materials and Methods
Serological survey. In total 33001 sera were tested, including 30829 pig sera taken in slaughter houses located in all 16 districts of Poland; 1477 blood samples taken from heart or pleural cavity of wild boars, hunted in 11 districts; and 695 human sera taken from volunteers (554 from producers or animal caretakers and 141 from veterinarians). The samples were tested according to the standard procedure in HI test against the reference viruses representing 3 subtypes (H1N1 - A/sw/Belgium /1/98, H3N2 - A/sw/Flanders/1/98, H1N2 - A/sw/Gent/ 7625/99). All necessary reference sera, virus and RBC controls were included in each test. The sample was considered positive when the antibody titer was \( \geq 1:20 \).

Virological survey. In total 421 samples were tested, including: 312 nasal swabs, 49 lung tissue samples and 60 blood samples. The biological material was taken from pigs demonstrating influenza-like symptoms, raised in 41 farms located in 12 districts. Additionally 4 aborted foetuses were taken from the sows demonstrating influenza symptoms. Virological investigations include: virus isolation in 10 days old embryonated SPF chicken eggs and tissue culture, detection of viral RNA by RT-PCR, molecular subtyping in mPCRs, and phylogenetic analysis.

Results
In serological investigation of the pig sera it was clearly demonstrated that H1N1 subtype is dominated in Poland. In 2009 the seroconversion reached 14% of tested sera. The percentage of animals possessing antibodies against the mentioned subtype varied over the time, with the range from 5 to 14.4%. Within last five years we observed about 2 fold increase of seroconversion against H1N1. We also evidenced that the H1N1 subtype circulate at the higher frequency in the West part of Poland, in pig densely area where the pig production is better developed. The survey for H1N2 subtype performed in 2009 demonstrated 9.4% of seropositive samples. It also varied over the time, ranging from 2.4 to 9.4%, with about 2-fold increase within last 5 years. The seroconversion to H3N2 antigen in 2009 was detected in 10.9% of tested sera. The significant increase (about 5 fold) of antibodies against H3N2 subtype was evidenced within last 5 years. In contrast to H1N1, H3N2 subtype circulate at the higher frequency in the East part of the country, where the small private farms are mainly located and pig production is less developed. The situation among wild boars was similar to that observed among pigs but the prevalence of antibodies was significantly smaller. Interestingly the highest occurrence of antibodies against the tested SIV strains was evidenced in human. In 2009 seroprevalence for H1N1, H1N2 and H3N2 antigens reached 45.4%, 34% and 62.4%, respectively. Over the time it ranged from 9.4 to 45.4% in case of H1N1; from 14.3 to 37.5% for H1N2 and from 62.4 to 88.5% for H3N2 subtype.

Using conventional virology method 45 SIV isolates were obtained. RNA of SIV was detected in 127 (30%) samples (49% of tested lung and 33% of tested nasal swabs), originated from 68.3% farms. In molecular subtyping 93% of isolates were determined as H1N1 subtype, 4.4% as H3N2 subtype and 2% as H1N2. HA gene of Polish isolates have been derived from contemporay strains of “avian-like” SIV. M1 gene may have originated from avian influenza viruses. H3N2 strain was located in swine cluster, in the main prevalent European group of H3N2 isolates (A/PortChalmers/1/73-like lineage).

Discussion
Due to the fact that infections of pigs with H1N1 virus were described in most European countries intensively producing pig we can state that epidemiological situation of Polish pig herds concerning SI is similar to that observed in European countries but the prevalence of virus specific antibodies is smaller and is entirely different from that observed in USA (66.3%-100%) and Asia (45%).

Introduction and objective
Swine influenza virus (SIV) causes an acute respiratory disease in pigs that occasionally can be transmitted to human. It is one of the major viral pathogen that contributes to porcine respiratory disease complex (PRDC) (1). In Thailand H1N1, H3N2 and H1N2 SIV has been reported in the pig population. SIV-infected pigs shed virus for a short period. Therefore serological tests have been used as an indirect method to study SIV epidemiology in the Thai swine population. However the most updated SIV seroprevalence data was reported since 2005 (2). Previous genetic data characterized Thai SIV H1 subtype into classical swine lineage which is subgrouped into two clusters; classical swine cluster a (Cla) and b (Clb). Thai H1 Cla and Clb were thought to have derived from a hypothetical Classical swine H1N1 common ancestor in 1981 and 1990, respectively. The Thai SIV H3 subtype belonged to human lineage and can be subgrouped into two clusters; human cluster a (Ha) and b (Hb). Thai H3 Ha SIVs were closely related to Thai human H3N2 virus isolated in 1997 while Thai H3 Hb SIVs were closely related to human-like H3N2 virus circulating in the early 1970s (3). This study, we provide an update data of the SIV seroprevalence based on both clusters of H1 and H3 SIV in pigs from the high pig population provinces in Thailand during June 2008 to May 2009.

Materials and method
During June 2008 to 2009, 850 pig sera were collected from pigs of various age in the four provinces that have the highest density of pigs in Thailand. Those provinces include, Ratchaburi, Nakhon-Pathom, Chonburi and Chachoengsao. A standard hemagglutination-inhibition (HI) assay was used to evaluate the antibody titer against Thai H1 and H3 SIV. HI test was performed, according to WHO (4). All sera subjected to test with H3 virus were treated with receptor-destroying enzyme (RDE) and adsorbed with 50% chicken red blood (RBC) cells to remove non-specific inhibitors of agglutination and natural serum agglutinins. Sera subjected to test with H1 SIV were absorbed with 50% RBC without RDE treatment. Positive SI was considered when HI titer was ≥ 40. Virus antigen used for HI tests were H1N1 Cla and Clb and H3N2 Ha and Hb (3).

Results and discussion
Table 1 shows the percentage of pigs with positive antibody to H1 and H3 SIV in each province. It was demonstrated that pigs in all provinces were antibody positive to both H1 and H3 SIV. However, overall the percentage of positive pigs to H3 Ha was significantly higher than H3 Hb (p<0.01). There were geographical differences of seropositive pigs to different clusters of H3. Pigs that were seropositive to H3 Ha in Nakorn-Pathom was significantly higher than Chonburi and Chachoengsao (p<0.01). The percentage of seropositive pigs to H1N1 SIV was indifferent between each province. However, percentage of seropositive pigs to H1 Clb was significantly higher than Cla (p<0.01). The findings indicated that Thai SIV currently circulating in Thai pig populations are diverse antigenically. The data highlights the importance of updating SIV test antigen used in serological test for diagnostic purposes.

Swine Influenza Virus (SIV) is a (-) ssRNA, enveloped, Influenza A virus in the family Orthomyxoviridae. It is a continuously evolving virus that causes swine respiratory disease with fever, reduced activity and food intake, conjunctivitis, sneezing and coughing and nasal discharge. Respiratory disease can be caused by multiple SIV genotypes continuously undergoing changes by genetic drift and shift. SIV genotype is determined by the antigenic characteristics of two surface glycoproteins (hemagglutinin and neuraminidase). The three main genotypes currently present in the swine population are H1N1, H1N2, and H3N2. Monitoring/surveillance and genetic characterization of SIV in swine herds are critical for successful control of the disease and are essential for selection of vaccine treatment and novel vaccine development.

The following data were filed to support a Product License Application filed with the USDA, Center for Veterinary Biologics. Applied Biosystems developed an integrated workflow consisting of high throughput nucleic acid purification, and TaqMan® RT-PCR for amplification and genotyping of Swine Influenza. Nucleic acid is purified using the MagMAX™ Nucleic Acid Isolation Kit and purified viral RNA is detected using the VetMAX™ –Gold SIV Detection Kit. The SIV-A TaqMan assay targets multiple genetic regions of the Influenza A genome decreasing the likelihood of false negatives due to viral mutation. The assay is multiplexed with an internal control RNA, Xeno™RNA, to monitor nucleic acid purification efficiency, detect the presence of reaction inhibitors, and determine assay reagents functionality. The analytical amplification limit is 50 copies of SIV-A transcript RNA per 25ul TaqMan PCR.

The performance of the SIV-A TaqMan reagents was compared to a published SIV screening protocol (Richt, et. al. 2004). Nucleic acid from an SIV vaccine (Novartis PneumoSTARTM vaccine) was purified using the MagMAX™-96 Viral RNA Isolation Kit. The purified nucleic acid was then serially diluted to extinction and tested using both the VetMAX™ SIV screening reagents and the published assay protocol. SIV Cts using the VetMAX™ - Gold SIV Detection Kit were 4-5Cts earlier than the published protocol and detection sensitivity was approximately 64-fold better. To ensure the specificity of the SIV screening reagents, RNA from field samples containing other common porcine pathogens (PCV2, M.Hyopneumoniae, PRRSV) were purified using MagMAX™-96 Viral RNA Isolation Kit and tested with the VetMAX™ SIV Detection Kit (n=3). No false positives were detected using the VetMAX-Gold SIV Detection Kit.

The performance of the workflow was evaluated using field samples (n=60) of known SIV status and diverse reference SIV genotypes. RNA was isolated from swine nasal swabs, tonsil and lung tissue homogenates, virus, and cell lysate supernatant using MagMAX™-96 Viral RNA Isolation Kit. The purified RNA was utilized for TaqMan RT-PCR employing the SIV screening reagents on the Applied Biosystems 7500 Fast Real-Time PCR System. The SIV screening results showed 100% concordance with secondary laboratory PCR results. These results as well as the superior analytical sensitivity demonstrate that this method provides an economical and rapid solution for SIV identification.

**Introduction**

Swine influenza is an acute respiratory disease caused by influenza A viruses. Influenza A viruses cause respiratory disease in humans. There are many sorts of assays to detect SIV. Specially, the M gene is used commonly as PCR target for screening, as well as the NP whose sequences are highly conserved. The aim of this study was to report the prevalence of swine influenza virus by targeting matrix gene which is highly conserved among Influenza A.

**Materials and Methods**

**Virus isolation**

A total of samples, all tissues including lung were submitted from the swine farms in South Korea from July 2009 to January 2010. About 20% suspension of lung tissue homogenate was prepared in PBS. Then, they were centrifuged at 3000rpm for 10min., the supernatants were used for virus isolation and RNA extraction.

**Viral RNA extraction**

Viral RNA was extracted from virus suspension using Trizol LS. 750ul of Trizol LS was mixed with 250ul of homogenized samples. 200ul of Chloroform was added and the suspension was centrifuged at 12000rpm for 15min. The RNA-containing aqueous phase was precipitated with an equal volume (350ul) of isopropanol, maintained for 10min at room temperature, centrifuged at 12000rpm for 15min. The RNA pellet was washed by 75% ethanol, centrifuged at 12000rpm for 10min. Dried over 15min, resuspended by 30ul of DEPC-DW.

Of the 328 samples, 46 samples proved positive for matrix gene of influenza A virus.

**Discussion**

From July 2009 to January 2010, we collected tissue samples and placed them in PBS. In field specimens selected at random from Korean farms, the influenza virus was detected in 46 of 328 samples. As shown (table 2), we could know the prevalence of Influenza A viruses. Influenza A was peaked from September to November which would be the change of seasons. The percentage of positive samples for Influenza A declined sharply for winter from November. The winter season would not be a multiplication period of Influenza A viruses. Universidad Nacional Autónoma de México (UNAM), Facultad de Medicina Veterinaria y Zootecnia, Departamento de Producción Animal: Cerdos, Ciudad, CHIH, Mexico

Introduction

Swine influenza virus (SIV) is an RNA virus that belongs to the Orthomixoviridae family. There are different subtypes characterized for their surface glycoproteins: a hemagglutinin and a neuraminidase. The main viral subtypes affecting pigs are H1N1 and H3N2. The SIV is associated as a primary agent of the porcine respiratory complex and currently pigs have been identified as intermediaries because in their respiratory tract they have epithelial cells of human and avian viruses. For this reason the diagnosis is important to understand the dynamics of infection by a serological profile and by molecular diagnostic tools, identify specific viral RNA to implement prevention, control and treatment strategies.

Materials and Methods

A longitudinal study was carried out for the diagnosis of H1N1 and H3N2 SIV subtypes. A total of 111 serum samples and nasal swabs were collected from pigs of 4, 8, 12, 16, 20, 24 weeks of age. Serologic diagnosis was made by Hemoagglutination inhibition (HI) test with a 1:80 cutting point, multiple RT-PCR technique (1) was applied for the molecular diagnosis from sera and nasal swabs. Titters from IH were transformed to a logarithmic base to apply statistical analysis using variance test between treatments (P<0.05). The mean difference was determined by Tukey test and Ji-square was used to evaluate the differences in the percentage of positive and negative animals per treatment.

Results

Serology showed 100% prevalence for the H1N1 subtype in 4 week old pigs. In week 8 decreased to 73% for week 12 increased to 94% and for weeks 16, 20 and 24 a 100% of samples were positive (Figures 1-2). For subtype H3N2 75% of seropositives were recorded in week 4, 36% for week 8 and 83% for week 12 (Fig. 2). Significant statistical differences (P<0.05) for the H1N1 subtype were found between samples from week 8 and weeks 4, 16 and 24; for subtype H3N2 significant differences were found in week 8 when compared to 4, 16, 20 and 24 weeks, however, samples from week 8 did not showed differences with the 12 weeks samples. RT-PCR identification of viral nucleic acid for the H1N1 subtype was 1.8% from serum and 6.3% in nasal swabs, for the H3N2 subtype 5.4% was identified in nasal swabs where statistical differences were significant (P<0.05). All serum samples were negative for subtype H3N2.

Discussion

The co-existence of diagnostic techniques allows us identifying with a high sensitivity and a very timely manner any subtype of SIV present in a sample. Through the integration of diagnosis we are able to establish the dynamics of viral infection within the farm and allows us to identify the group of animals that carry the virus (PCR), as well as those animals that have already been affected by the virus and that are negative to PCR, but have antibodies (HI); both panoramas show us the dynamics of infection associated with the clinical signs, allowing us to understand the process of the disease in the herd. With this information you can intervene promptly to control and prevent the infection process.

Polygen™ induced the highest H1N1-specific and H3N2-specific influenza of adjuvant on relative ratios of IgG2 to IgG1 in pigs: Results and Discussion

Introduction
Since no single adjuvant is universally applicable for all antigens, it is critical to include different types of adjuvant systems in an experimental vaccine for evaluation. In this study, an inactivated commercial swine influenza A (SIV) vaccine was used to evaluate the influence of five adjuvant systems on antibody avidity and the relative ratios of IgG2 to IgG1 (Th1 to Th2) in young pigs after booster immunizations.

Materials and Methods
Thirty-six 21 day old pigs were assigned to six groups. Experimental vaccines were prepared by mixing the manufacturer’s recommended amount of SIV antigens with one of five adjuvants supplied by MVP Laboratories, Inc. Pigs of group 1 through group 5 were given vaccines containing 20% Emulsigen®-D, 12% Emulsigen®/4% Rehydragel, 20% Emulsigen®-BCL, 20% Polygen™, and an adjuvant supplied by the manufacturer of the commercial SIV vaccine respectively. Pigs of group 6 were given PBS only. On day 0, all of the vaccinated pigs were given a 2 ml dose intramuscularly. On day 21, all pigs were given a second dose. All pigs were bled on day 0, day 21, and day 42. The hemagglutination inhibition (HI) test was conducted by the Veterinary Diagnostic Laboratory at Iowa State University. The antibody avidity of each pig serum was measured using a thiocyanate elution ELISA as described (1). IgG1 and IgG2 were determined.

Results and Discussion
Influence of adjuvant on relative ratios of IgG2 to IgG1 in pigs: Polygen™ induced the highest H1N1-specific and H3N2-specific IgG2 response (Table 1). This signals a Th1 response that leads to cellular immunity. Furesz, et al, demonstrated that a high anti-hemolysin IgG2:IgG1 ratio correlated with hemolysin neutralization antibody titers and reduced lung lesion scores in A. pleuropneumoniae infected pigs (3). Emulsigen®-D and Emulsigen®/Rehydragel induced the highest levels of H1N1-specific and H3N2-specific IgG1. This indicates a Th2 response that leads to humoral immunity which is of importance in SIV infections.

Influence of adjuvant on antibody avidity: There is a significant difference between the SIV-specific antibody avidity indices (GMAI) of the five adjuvant groups with Emulsigen®-D producing the highest results (Table 2). It has been reported that higher serum avidity indices indicate more effective bactericidal activity of the microphages (2). This study indicates that the measurement of ratios of IgG2 to IgG1 and GMAI are useful as supplementary methods for predicting the properties of each test adjuvant in terms of their tendency to direct cellular (Th1) or humoral (Th2) immune response and antibody functional activity. These findings suggest that Th1 or Th2 responses in pigs are determined by both the adjuvant and its co-injected antigen.

Respiratory diseases – Swine influenz
Efficient protection against heterologous H1N2 infection using a trivalent swine flu vaccine

Michael Schlegel¹ Andi Krumbholz² Roland Zell² Hans-Joachim Selbitz¹ Ralf Dürrwald¹
1. IDT Biologika GmbH, Dessau-Roßlau, Germany; 2. Universitätsklinikum Jena, Institut für Virologie und Antivirale Therapie, Jena, Germany

Introduction
In the course of several reassortment events the novel swine influenza A virus subtype H1N2 emerged in Europe in the 1990s (1). Its lacking cross-reactivity to H1N1+H3N2 vaccines required the development of a new trivalent swine flu vaccine (2).

Materials and Methods
Three strains of subtypes H1N1, H3N2, and H1N2 were selected as vaccine strains. Viruses were grown in cell culture and inactivated. A substance from the carboxyvinylpolymers group was used as an adjuvant. Experimental batches were blended and investigated in laboratory and clinical trials. A major focus of investigation was the proof of efficacy against heterologous H1N2 field strains in experimental infection trials. Five challenge experiments were conducted on a total of 158 pigs. Three recently isolated field isolates of subtype H1N2 were used for the experiments. The strains were sequenced and analysed phylogenetically. Pigs were vaccinated twice. For proof of efficacy an aerosol method was used in which high doses of field viruses are sprayed by a generator. For comparison an additional intratracheal infection was done in one trial.

Results
Vaccinated pigs displayed neutralizing and hemagglutination inhibiting antibodies as early as 7 days after the second vaccination.

Vaccinated animals had almost no clinical symptoms after infection, whereas unvaccinated animals exhibited fever, dyspnoea and sleepiness. The viral load in the lungs was significantly lower in vaccinated pigs compared to unvaccinated animals. Lung lesions typical for influenza were observed in the apical parts of medial and cranial lung lobes of the control animals, whereas vaccinated pigs showed no lesions. Moreover, histological investigations revealed a higher degree of inflammation in the unvaccinated pigs. Fig. 1: Viral lung load in egg infectious dose 50 (EID50), clinical score and rectal temperatures of vaccinated and unvaccinated pigs after experimental infection with H1N2 virus; Statistics: Mann-Whitney U test (p = statistical probability, ≤ 0.05 significant, ≤ 0.01 highly significant, ≤ 0.001 very highly significant); Clinical score: 1, enhanced abdominal breathing, 2, strong abdominal breathing, 3, severe breathing covering the whole body; Vaccinated, vaccinated pigs (2x 2.0 ml i.m.); Control, unvaccinated pigs (n=15 pigs in each group)

Discussion
Vaccinated pigs were protected against all three H1N2 field strains used in a number of experimental infection trials. The very high efficacy of the vaccine against different strains of European H1N2 viruses has been demonstrated.

Field safety of the administration of a new swine influenza virus vaccine 
Respiporc® Flu3/Gripovac® 3 in pregnant sows and gilts

1. Merial S.A.S., Lyon, France; 2. IDT Biologika GmbH, Dessau-Rossau, Germany; 
3. Tierärztliche Hochschule Hannover, Hannover, Germany

Introduction
The objective of these studies was to confirm the safety of a new swine influenza vaccine including the 3 swine influenza A virus subtypes, H1N1, H3N2 and H1N2: RESPIPORC® FLU3/GRIPOVAC®3 administered during gestation to sows and gilts in the field.

Material and Methods
A total of 107 sows and gilts from several farrow-to-finish conventional farms were used at different stages of pregnancy. 

Experimental design

Safety criteria were rectal body temperature, local reactions i.e. skin colour, swelling, abscess, and systemic reactions i.e. behaviour, respiration, digestion, skin, coughing, others. Clinical status was monitored every day throughout the study. Clinical observation: T1, T2 and T3 sow temperature was measured on D0, D0+4h, D1, D2, D21, D21+4h, D22 and D23. In gilts it was measured on D0, D0+4h, D1, D2, D21, D21 +4h, D22, D23, D133, D133+4h, D134 and D135.

The local reactions have been monitored at the same time points and on D106 in T1 sows, on D100 in T2 sows, on D64 in T3 sows and on D177 in gilts, i.e. the last day of the study in each case. Statistical analyses: A Student T test was used to compare the absence of difference between temperatures. The level of significance was 5%.

Results
Neither relevant local nor systemic reactions were noticed. The temperature was significantly non-different both in vaccinated and control groups.

Conclusion
The use of RESPIPORC FLU3/GRIPOVAC 3 is perfectly safe in pregnant sows and gilts, any time during gestation.

Duration of clinical protection after vaccination with Respiporc® Flu3/Gripovac® 3

Michael Schlegel1 Hans-Joachim Selbitz1 Thaïs Vila2 Ralf Dürrwald1
1. IDT Biologika GmbH, Dessau-Rosslau, Germany; 2. Merial S.A.S., Lyon, France

Introduction
This paper summarizes several studies aiming at showing the duration of clinical protection after vaccination of piglets with a new swine influenza vaccine (RESPIPORC FLU3/GRIPOVAC 3) including the FLUAVsw subtypes H1N1, H3N2 and H1N2.

Material and Methods
Before vaccination, piglets were free of antibodies against H1N1, H1N2 and H3N2. The studies were blinded, placebo controlled and randomised. Challenge at more than 4 months after basic immunisation was done by aerosol nebulisation with heterologous strains from Central Europe isolated from pigs affected with severe respiratory illness as described in table 1.

Vaccination schedule: vaccination after 56 days of age 2 ml, twice 3 weeks apart. Control piglets were injected with NaCl 0.9%. Criteria of data collection: Temperature was measured twice a day. Dyspnoea was scored from 1 to 3: 1= enhanced abdominal breathing; 2= severe abdominal breathing; 3= strong breathing covering the whole body.

Results
After challenge 4 months after vaccination, flu-associated clinical signs as high temperature or dyspnoea were significantly lower in vaccinated piglets than in control piglets (Figure 1 and table 2).

Effect of ibuprofen, aspirin or saline water medications on pigs challenged with swine influenza virus (SIV)

Peggy Anne Hawkins1 Nathan Winkelman2 Michael Strobel1 Enrique Mondaca1

Introduction
Swine influenza virus (SIV) commonly infects growing pigs. Antibiotics are of no use against viral infections. However, anti-inflammatory products such as ibuprofen and aspirin are often proportioned to pigs through the water. The objective of this study was to evaluate the anti-inflammatory action of ibuprofen (IB) or aspirin (SS) (sodium salicylate) or saline (SA) in pigs challenged with SIV. The ibuprofen significantly reduced fever as compared to aspirin or saline. Additionally, the use of ibuprofen during a field SIV outbreak that reduced death loss and signs of disease is covered in the discussion.

Materials and Methods
Sixty-three SIV-negative, M. hyopneumoniae- negative and PRRSV negative crossbred pigs were randomly assigned to 3 treatments blocked by gender and weight and placed in 9 pens at 7 pigs per pen. Pens were randomized into treatments. Pigs were acclimated for 1 week and then challenged with SIV (H1N1 sub-type, Asw Iowa 239:2004) provided by U of Minnesota. Treatments were dosed according to label directions. IB 16oz (473ml) per gallon stock solution (~6mg/lb). SS 8oz (236ml) per gallon stock solution (4mg/lb). SA 12oz (354ml) per gallon stock solution. Stock solution should then be metered at 1:128. Twenty-four (24) hours after inoculation, treatments were added to the water and remained in the water for 5 complete days. Individual measures of clinical observations, weight, rectal temperature, nasal swabs, blood samples and lung lesions scores were recorded. Water and feed intakes were measure by pen (1).

Results
The SIV challenge was successful. On day three, 61 of 63 pigs had virus by nasal swab PCR or virus isolation. Virus was not detected in 2 SA pigs. For this study, 103.5°F or less was considered normal rectal temperature. Across treatments, pigs started with a low- normal rectal temperature at inoculation (103.1°F). 24-hours later all treatments spiked a fever (104.9°F). One day after treatment began the pigs in the IB group had a significantly lower rectal temperature averaging 103.2°F compared to the SS (103.6°F) or SA (103.7°F) groups. On the 5th day of the study, the SS group spiked a fever. The cause was unknown (Fig. 1). **im-age1** There were no differences between treatments in clinical observations, feed intake, water intake or weight gain. The IB group did have higher lung lesion scores on treatment day 10 as compared to SA or SS. Wilcoxon rank sum test was used for analysis.

Discussion
Sodium salicylate (SS) was chosen over acetylsalicylic acid (ASA) as a result of work done by Patterson et al. showing that measureable plasma concentrations of SS and not ASA were found when administered at 4.5mg/lb body weight (2). In this study treatments were added 24 hours after inoculation to simulate a field outbreak in which a producer would notice that pigs are sick and then would start treatment the next day. As a result of having the IB in the water, rectal temperatures were reduced to normal levels. Saline control and aspirin did not affect the rectal temperature. The number of pigs in this study limited the ability to see other significant differences. In a related field case, a 1000 head barn lost 17 pigs in an outbreak of SIV. The herd veterinarian put IB in the water for 5 days in 3 subsequent 1000 head barns and lost only 2 pigs to SIV. The cost of treatment with IB was about $0.75 per pig. Diagnosing SIV quickly is key to getting IB in the water fast enough to stop/reduce death loss and morbidity.

Development of a trivalent swine flu vaccine based on a safe adjuvant

Ralf Dürrwald1 Michael Schlegel1 Hans-Joachim Selbitz1 Andi Krumbholz2 Roland Zell2

1. IDT Biologika GmbH, Dessau-Roßlau, Germany; 2. Universitätsklinikum Jena, Institut für Virologie und Antivirale Therapie, Jena, Germany

Introduction

The introduction via reassortment of a human H1 hemagglutinin into the European swine influenza A virus population that lacks cross-reactivity to avian and classical porcine H1N1 viruses has remarkably changed the otherwise epidemiologically very stable situation of swine flu (1, 2). This stimulated the development of a new trivalent swine flu vaccine that provides protection against all three subtypes, including the new subtype H1N2, and improves safety through the use of a non-pyrogenic and non-virucidal adjuvant.

Materials and Methods

A surveillance program for swine influenza in Germany was initiated which gave an overview on the epidemiological situation and led to the isolation of numerous viruses of all three subtypes. Three virus strains of subtypes H1N1, H3N2, and H1N2 originally isolated in regions with dense swine populations were chosen as vaccine strains. A very efficient cell culture production procedure was developed. Viruses were produced and inactivated by ethylenimine. Experimental and production batches were blended. A substance from the carboxyvinylpolymers group was used as an adjuvant. Dose titration studies and safety and efficacy investigations were performed. The vaccination scheme comprises a twofold administration of 2.0 ml of the vaccine 21 days apart intramuscularly. An aerosol-mediated challenge procedure was applied to investigate efficacy of the vaccine. A batch potency test was established which measures the geometric mean of neutralizing antibodies in guinea pigs. Clinical trials were carried out.

Results

It was shown by phylogenetic analysis of the hemagglutinin and neuraminidase genes of the vaccine strains that all three strains fit well with currently circulating swine flu viruses throughout Europe. The production in cell culture provides virus harvests with titers up to 10^8.5 TCID50/ml within a short time. The viruses are inactivated rapidly by ethylenimine without influencing the content of antigen. The range of the immunostimulating activity of the adjuvant was shown to be very broad and the final adjuvant blending was chosen midway through. The optimal antigen content was determined in dose titration experiments. None of the vaccinated animals had elevated body temperatures after administration of the vaccine, not even in the critical phase of the first 24 hours after vaccination in which mineral-oil adjuvanted vaccines cause severe fever reactions up to 42°C. Vaccinated pigs display neutralizing and hemagglutination inhibiting antibodies as soon as 7 days after the second vaccination which is the onset of immunity. For proof of efficacy an aerosol method was developed in which field viruses are sprayed by a generator. Vaccinated animals had no clinical symptoms or only slight ones after infection, whereas unvaccinated animals exhibited fever, dyspnoea and sleepiness, accompanied by varying degrees of loss of appetite. The viral load in the lungs was significantly lower in vaccinated pigs compared to unvaccinated animals. The duration of immunity is age-dependent and lasts up to 6 months in older pigs after two vaccination shots. A third vaccination stabilizes the immune response and prolongs immunity. The batch potency was determined. The vaccine induces at least 10.22, 10.53 and 12.34 GMNU (Geometric Mean of Neutralizing Units log2) in guinea pigs against the H1N1, H3N2, and H1N2 strains respectively.

Discussion

A new trivalent swine flu vaccine has been developed in response to recent epidemiological events in the European swine influenza A virus population and an increased sensitivity of pigs to vaccinations. The high safety of the vaccine and its very high efficacy against each of the three subtypes currently circulating in swine has been demonstrated in a number of safety and infection trials. The vaccine went through a central registration procedure and was approved in 2010.

Serological response to Respiporc® Flu3/Gripovac® 3 in pregnant sows against H1N1, H1N2 and H3N2 influenza viruses

Ralf Dürrwald1 Michael Schlegel1 Lothar Kreienbrock2 Thaïs Vila3 Hans-Joachim Selbitz1
1. IDT Biologika GmbH, Dessau-Rosslau, Germany; 2. Tierärztliche Hochschule Hannover, Hannover, Germany; 3. Merial S.A.S., Lyon, France

Introduction
The prevalence of swine influenza viruses may be high with 60% of farms affected (1). Previous studies showed an increase in the prevalence of the H1N2 subtype (2).

The objective of these studies was to show the serological responses in pregnant sows after vaccination of sows with a new swine flu vaccine, RESPIPORC FLU3/GRIPOVAC 3 including the 3 subtypes, H1N1, H3N2 and H1N2.

Material and Methods
For this blinded controlled trial, 77 swine flu-antibody-free or with very low antibody titres sows from several farrow-to-finish conventional farms were used at different stages of pregnancy (Table 1).

Sows were kept in the farm of origin.

T1: D0=from day 1 to day 38 of pregnancy
T2: D0=from day 39 to day 78 of pregnancy
T3: D0=from day 76 to day 114 of pregnancy

Statistical analyses: Fisher’s exact test was used to compare the titres. Significance: p<0.01.

Results
Mean antibody titres after vaccination versus control are shown in Figure 1: in the 1st third, only H1N2 titres are significantly different. They are all significantly different in the 2nd third. And both H1N2 and H3N2 titres are significantly different in the 3rd third.

Figure 1 a,b,c: Mean HI antibody titres against the different subtypes at different pregnancy stages in sows

No difference was noticed between vaccinated and control sows in all groups for performance parameters such as:
- Live born piglets
- Still born piglets
- Weaned pigs
- Suckling piglets loss

Conclusion
These studies show this vaccine ability to induce a significant seroconversion in pregnant sows against the subtypes H1N1, H3N2 and H1N2 of swine influenza A virus.

Safety of the administration of a new swine influenza vaccine: Respiporc® Flu3/Gripovac® 3 in sows during lactation

Olaf Lüder¹ Guntram Hagemann¹ Michael Schlegel¹ Hans-Joachim Selbitz¹ Lothar Kreienbrock² Thaïs Vila³ Ralf Dürrwald¹
1. IDT Biologika GmbH, Dessau-Roßlau, Germany; 2. Tierärztliche Hochschule Hannover, Hannover, Germany; 3. Merial S.A.S., Lyon, France

Introduction

The objective of this study was to evidence the safety of the vaccination with a new swine influenza vaccine RESPIPORC® FLU3/GRIPOVAC® 3 including H1N1, H3N2 and H1N2 in sows during the lactation.

Material and Methods

Sows: a total of 13 conventional lactating sows, 7 vaccinated and 6 control, were used in this trial.

Vaccination schedule: the 7 vaccinated sows were injected with a double dose of RESPIPORC FLU3/GRIPOVAC 3 just after farrowing (D0) and a single dose of vaccine 3 weeks after. The 6 control sows were injected with NaCl 0.9% at the same time of the vaccinated sows.

Temperature monitoring: in vaccinated and control sows the temperature was measured on D0, D2, D4, D14, D18, D20, D21, D22 and D23. In gilts it was measured on D0, D0+4h, D1, D2, D21+2h, D21+8h, D22, D24 and D28.

Clinical observation: adverse clinical signs were monitored every day throughout the study until Day 35. Safety criteria were lactation performance (the day of farrowing (D0) and the day of weaning (D35): number and weight of weaned piglets) rectal body temperature, food consumption, local reactions, i.e. skin colour, swelling, abscess, and systemic reactions i.e. behaviour, respiration, digestion, skin, coughing, and other possible signs.

Statistical analyses: permutation tests (for non-parametric Behrens Fisher problem) for equality were used in the study.

Results

Temperatures in vaccinated sows were not significantly different from temperature in control groups (Figure 1). No statistical difference was found between the 2 groups compared regarding neither reproductive parameters (Table 1) nor in the performance of their litter (Figure 2).

Neither local reactions nor systemic reactions were noticed at any time during the observation period.

Conclusion

The administration of RESPIPORC FLU3/GRIPOVAC 3 in sows is safe during lactation.® RESPITPORC is a registered trademark of IDT.

Cross-protection of Respiorc® Flu3/Gripovac® 3 against swine flu: challenge trials with two recent European H1N1 strains

Ralf Dürrwald¹ Michael Schlegel¹ Hans-Joachim Selbitz¹ Thaïs Vila²
1. IDT Biologika GmbH, Dessau-Rosslau, Germany; 2. Merial S.A.S., Lyon, France

Introduction
Swine influenza viruses of three different subtypes, H1N1, H3N2 and H1N2 are now co-circulating in European countries (1). The commercial vaccine based on H1N1 and H3N2 strains doesn’t protect against H1N2 infection (2). A new swine influenza vaccine RESPIPORC® FLU3/ GRIPOVAC 3 adapted to European epidemiology contains H1N1, H3N2 and H1N2 recently isolated strains. The objective of this study was to evidence the cross-protection of this vaccine against recent H1N1 strains isolated in France.

Material and Methods
H1N1 strains from two different genotypes of swine influenza viruses isolated in Brittany (France) were used in this study: A/sw/Cotes d’Armor/0190/06 (reassortant H1N1=RA) and A/sw/ Morbihan/0070/05 (avian-like H1N1=AL) (3). The antigenic character of these strains was investigated by cross-neutralisation with specific hyper immune sera of pigs (Kuntz-Simon et al., in preparation). They were kindly provided by G. Kuntz-Simon, AFSSA-LERAPP, F-Ploufragan. Pig vaccination: All 49 experimental pigs were seronegative against H1N1, H1N2 and H3N2 prior to vaccination. Half of the pigs (N=24) were vaccinated with 2ml RESPIPORC FLU3/GRIPOVAC 3, IM twice, 3 weeks apart. The other half was injected with a placebo. Challenge: One week after 2nd administration of 2.0 ml of the vaccine, an aerosol challenge validated in previous studies was conducted. Viral load in lung tissue homogenates was quantified by egg culture and expressed in number of egg infection dose 50% (EID50).

Results and Discussion
The challenge strain RA did not induce clinical signs of the disease (neither dyspnoea nor fever). Vaccinated pigs had significantly lower viral lung load than not vaccinated pigs both 1 and 3 days after challenge.

Day 1: p=0.026; Day 3: p=0.021

The challenge strain AL did induce only mild clinical signs of disease (mild dyspnoea but no fever), consequently no difference was observed between treatment groups. Vaccinated pigs had a highly significantly lower viral lung load than not vaccinated pigs (no virus in the lungs of the vaccinated pigs) both 1 and 3 days after challenge.

Figure 2: Mean viral load (EID50 in 10 mg lung tissue) after aerosol challenge with strain AL

Day 1 and Day 3: p=0.008

Conclusion
These experiments with heterologous swine influenza viruses challenge clearly show the cross-protection of the vaccine strains of RESPIPORC FLU3/ GRIPOVAC 3 with recent H1N1 Swine Influenza A field strains from Europe.

Introduction
Swine influenza viruses of three different subtypes, H1N1, H3N2 and H1N2 are now co-circulating in European countries (1). The commercial vaccine based on H1N1 and H3N2 strains doesn’t protect against H1N2 infection (2). A new swine influenza vaccine RESPIPORC® FLU3/ GRIPOVAC® 3 adapted to European epidemiology contains H1N1, H3N2 and H1N2 recently isolated strains.

The objective of this study was to evidence the cross-protection of the vaccine against two H1N2 French strains.

Material and Methods
Two strains of the H1N2 subtype isolated in Brittany were used in this study: A/sw/Cotes d’Armor/0214/06 (genotype 1 H1N2=G1) & A/sw/Cotes d’Armor/0113/06 (genotype 2 H1N2=G2) (3). These strains are heterologous from the vaccine strain and belong antigenetically to the human-like H1N2 subtype as confirmed by cross-neutralisation (Kuntz-Simon et al., in preparation). They were kindly provided by G. Kuntz-Simon, AFSSA-LERAPP, F-Ploufragan. Vaccination and challenge G1: All pigs (N=28) were seronegative against H1N1, H1N2 and H3N2 prior to vaccination. Half of the pigs were vaccinated twice 3 weeks apart with 2ml of RESPIPORC FLU3/GRIPOVAC 3. One week after 2nd administration of the vaccine, an aerosol challenge was performed. Vaccination and challenge G2: All pigs (N=20) were seronegative against H1N1, H1N2 and H3N2 prior to vaccination. Half of the pigs were vaccinated with 2ml of RESPIPORC FLU3/GRIPOVAC 3. One week after 2nd administration of the vaccine, an aerosol challenge was performed. Viral load in lung tissue homogenates was quantified 1 and 3 days (d1 and d3) after challenge by egg culture and expressed in number of egg infection dose 50% (EID50).

Results
The challenge with strains G1 and G2 induced typical clinical signs of influenza, i.e. dyspnoea and fever in control pigs. Vaccinated pigs were protected against fever and other clinical signs (data not shown). Vaccinated pigs had very significantly lower viral lung load than non-vaccinated pigs (Figures 1 and 2).

Conclusion
Clinical and viral cross-protection of pigs vaccinated with RESPIPORC FLU3/ GRIPOVAC 3 with recent Swine Influenza A Virus H1N2 strains in Europe has been confirmed in these challenge studies.

Over the last two decades, DNA vaccines have become a potent means of providing immune responses or protective immunity against viruses, bacteria and parasites. DNA vaccines comprised of plasmid DNA encoding proteins from pathogens, allergens, and tumors, are being evaluated as prophylactic vaccines and therapeutic treatments for infectious diseases, allergies and cancer. The use of DNA as a means of vaccination offers advantage in protective efficacy, cross-strain applicability, development speed with lower manufacturing cost over conventional vaccines. DNA vaccines are known to be particularly effective in inducing antibody responses which are critical to fighting infections.

Recently, the USDA reported there was limited cross-reactivity against the new 2009 A/H1N1 virus in pig herds vaccinated with existing swine influenza vaccines.

This presentation describes a study in which pigs were immunized with consensus H1N1 influenza DNA vaccine candidate on day 0, day 14, and day 28. Sera collected on day 28 and day 42, after two or three doses of vaccine, respectively, showed hemagglutination inhibition (HI) titers above the protection threshold in 100% of the vaccinated animals against a swine H1N1 virus previously isolated from pigs (Swine 1999). In addition the immune sera were tested for responses against a virus isolated from the current circulating strain of swine origin influenza A/ H1N1 (Swine A/Mexico/InDRE4487/2009). Four of the six pigs immunized with the H1N1 vaccine developed HI titers exceeding the 1:40 level commonly associated with protective immunity (see Table 1).

These findings have been verified in other animal species. In a previous study, we demonstrated that mice immunized with SynCon™ H1N1 DNA vaccine provided 100% protection in a lethal challenge study against an unmatched H1N1 virus that caused the 1918 Spanish flu, which killed over 40 million people worldwide. In addition, ferrets immunized with similar SynCon™ universal flu vaccine combinations were 100% protected against death and sickness in a challenge with the A/H1N1 Mexico/ InDRE/4487/2009 pandemic swine-origin influenza.

VGX Animal Health's novel SynCon™ technology enables the design of DNA-based vaccines with the potential to protect against unmatched sub-types and strains of pathogens. Using a designer approach, VGX Animal Health can formulate these DNA plasmids together to rapidly develop a universal influenza vaccine potentially targeting all important strains. The resulting vaccine could target seasonal as well as pandemic-potential influenza strains such as avian influenza and swine flu, which has already been designated pandemic status. Significantly, being based on a common set of antigens derived from a broad range of flu strains, such a universal vaccine would have the potential to provide greater protection against evolving, unmatched flu strains in multiple species.

Pandemic (H1N1) 2009 influenza a infection in pigs in Northern Ireland

Jesus Borobia Belsué
MOSSVET, Portadown, UK

Introduction
In October 2009 a 120 sow unit experienced an increase in abdominal breathing, coughing and inappetance in the breeding herd and sucking piglets. The breeding herd and weaners are 0.5 miles away from the growing/finishing accommodation. Clinical signs started 4 days before vet visit.

A week earlier, 6 year old farmer’s daughter had a "cold". All family members –except the farmer- contracted this illness. Changeable weather conditions in the area two weeks earlier.

Materials and Methods
Clinical investigation consisted in a farm visit (27 Oct 2009). Rectal temperature was taken from affected animals. Two dead 4 week old piglets from the same litter were post-mortemmed and their lungs submitted to the laboratory (AFBI, Belfast, Northern Ireland) with 5 clotted blood samples of affected sows.

Two more farm visits were carried out (3 & 10 Nov 2009). More clotted blood samples were collected.

Results
During the first farm visit, 5 lactating sows, 7 dry sows, 2 sows in service room and one boar had abdominal breathing, barking cough, inappetance and prostration. Piglets of affected lactating sows had abdominal breathing but good appetite. Five 4 week old piglets of a litter of 11 died. No fertility problems detected. Rectal temperature ranged from 40 to 41.5°C.

Growing/finishing accommodation did not have clinical signs.

Post-mortem examination of the lungs detected 30 – 40% lung consolidation of cranioventral lobes with interstitial pneumonia. Bronchiomediastinal lymph nodes were congested.

Histological changes of the bronchiolo showed desquamation and necrosis of the respiratory epithelium, along with marked lymphocytic infiltration of the lamina propia and submucosa. Furthermore, there was perivascular lymphocyte infiltration in the lung.

Virology came back positive to FluMatrix RTPCR.

Serology came back negative to Aujeszky, PRRS and H1N1 Belg/79. However, one sow was positive to PRCV and all were positive to H1N1 Eng/92. Serological progression is shown in Table 1.

Table 1. Serological results for H1N1 Eng/92 from clotted bloods

Discussion
SIV (Swine Influenza Virus) is an acute, infectious, respiratory disease caused by influenza A viruses. It causes a sudden onset, coughing, dyspnea, fever, prostration, followed by a rapid recovery.

Northern Ireland has a high intensity of Pandemic (H1N1) 2009 in human population (ECDPC, 2009).

Weather conditions were favorable for the spread of the virus during that period of time.

Likely humans infected pigs and/or airborne in this case. Mortality was low. Taylor (1995) & Easterday et al. (1999) reported <1% mortality unless intercurrent infections and/or pigs very young.

PRCV did not appear to exacerbate infection experimentally (Lanza et al., 1992; Taylor, 1995).

SIV morbidity is reported near 100% (Taylor, 1995; Easterday et al., 1999). It was, however, 60% in this case. This could be related to the pathogenicity of the virus and/or prompt treatment by nursing care of warm environment, minimising stress and medicating the sow’s diet.

No reproductive, farrowing and neonatal problems were reported in this case, contrary to Taylor, 1995; Muirhead et al., 1997; Easterday et al., 1999 and Jackson et al. 2007).

Viral isolation and/or specific antibodies detection is necessary for diagnosis (Easterday et al., 1999).

Serum samples were positive to SI/A/Swine/England/92(H1N1) with rising titres the following weeks. Viruses with the same H (haemagglutinin) cross react with antibodies to related strains (Brown, 2002).

PCR in lung confirmed Pandemic (H1N1) 2009.

Bacteriology was not performed because the laboratory had issues about hazards to staff.

SIV is not a Notifiable Disease (WHO, GB and rest of EU). However, Influenza A viruses are Notifiable Disease in Northern Ireland (The Disease of Animals (Northern Ireland) Order 1981).

Some authorities can over-react in this situation and there is some concern of the possible consequences on pig trade and consumption since first signs in humans appeared in Mexico (April 2009).
Outbreak of 2009 pandemic influenza A H1N1 in Korean pigs

Seonghee Kim; C-I Yeo; C-W Bae; Y-K Song; K-K Lee; O-S Lee; Choi-Kyu Park
National Veterinary Research & Quarantine Service, Anyangcity, Korea

Introduction
Pigs could play the role of intermediate host as a “mixing vessel” which could give rise to an outbreak of new variants through the process of genetic reassortment event because their tracheal cells contain both human and avian influenza virus receptors. That is why continuous monitoring of influenza virus in pigs is significant in terms of public health. To this end, National Veterinary Research & Quarantine Service (NVRQS) in South Korea, starting the 2nd quarter of 2009, launched a nationwide disease prevention program and embarked on monitoring of pH1N1 in pig farms throughout the nation. In the case of commercial pig farms, 708 farms, 1,057 farms and 1,060 farms were monitored in the 2nd, 3rd and 4th quarter of 2009, respectively. Meanwhile, with respect to pig breeding farms, 198 farms were monitored in the 4th quarter of the year, since influenza viruses typically have high prevalence during winter season.

Materials and Methods
For test sample, seventeen nasal swab samples per one pig farm were collected from the pigs showing respiratory symptom among weaners, growers and finishers. The samples were inoculated into each embryonated chicken egg and Madin-Darby canine kidney (MDCK) cells. Total RNA was extracted, using RNeasy® Mini Kit (Qiagen), from the samples whose hemagglutination titers were higher than 2 times. Identification of influenza virus among the extracted total RNA was run on a Roche LightCycler 2.0 using artus® Infl./H1 LC/RG RT-PCR kit (Qiagen). Final confirmation of the pH1N1 virus were done through sequence analysis of hemagglutine (HA), neuraminidase (NA) and matrix (M) region using the universal primers.

Results
As a result, while the pH1N1 virus was not found at the tests conducted during the 2nd and 3rd quarters of 2009, it was detected from 17 farms during the period from the 4th week of November to December of the year. While most of pH1N1-positive farms were tested negative at the tests conducted a week after notification of the virus infection to them, one pig-breeding farm still remained positive to the virus. After a week of suspension, additional antigen test was conducted for the pig-breeding farm. As the test did not detect any antigen, the farm was freed from the movement restriction. This fact indicates that, in the case of large-scale pig-breeding farms where biosecurity is relatively well managed at each breeding stage, the transmission speed of influenza virus is relatively slow, causing a continuous circulating virus infection to antibody-negative pigs.

Discussion
Movement restrictions had been imposed on pH1N1-confirmed pig farms for three weeks, during which antigen tests were conducted at the interval of one week and the restrictions were lifted for the farms that had been tested negative. For the pigs that were to be shipped out to market, the shipment, even during the restriction period, was allowed to each individual pig, if tested negative for the pH1N1 virus.

All things taken together, it is highly likely that the outbreak of pH1N1 in South Korea was caused by the transmission from infected humans to pigs as with other countries, given following factors: first, the outbreak of pH1N1 in pigs was reported after the first week of November 2009 when the rate of Influenza-like Illness of Koreans was at its peak of 50%. Second, any epidemical relevance indicating that the pH1N1 was transmitted by the movement of pigs of infected pig farms was not found. Even though an analysis on the full genome sequencing data of the pH1N1 isolated in Korea assures that so far there has not been any outbreak of new variant through genetic reassortment (data not shown), we can not rule out the possibility of emergence of those variants in the near future. Thus, continuous surveillance on the pig farms has been conducted to detect the emergence of any variants in South Korea, and the use of vaccine for pig against the pH1N1 which is at its final stage of development is being carefully considered.

Pandemic influenza virus (A/H1N1) outbreak in pig farm in north of Italy

Loris G. Alborali; Matteo Gradassi; Mariagrazia Zanoni; Anna Moreno Martin; Anna Catelli; Cristian Salogni; Enrica Sozzi; Emanuela Foni; Paolo Cordioli
IZSLER, Brescia, Italy

Introduction and Objectives

The swine influenza virus (SIV) frequently causes acute respiratory disease in pigs worldwide and is an important pathogen in the porcine respiratory disease complex (PRDC). SIV is one of the “door opener” and frequently is associated with viral (PRRSV, PCV2), bacterial respiratory pathogens and M. hyopneumoniae. (1). H1N1, H3N2 and H1N2 are the most common influenza subtypes isolated in Italian pig farms (2) In 2009 a novel (H1N1)v influenza A virus caused annual worldwide epidemics. In Italy, in order to examine the emergence of the new pandemic virus and confirm the recent reports about human to animal transmission (3, 4), all swine type A influenza positive samples were tested for (H1N1)v. The first H1N1 pandemic outbreak in sow farm in Italy is described in this paper.

Material and methods

On November 2009, in a Northern Italy farm clinical signs in sows and piglets were observed in farrowing units. The farm was a 1250 sows site with outside growing gilts- and weaning-units. Weekly clinical investigations were reported and performance data were collected to evaluate and quantify losses. Nine dead piglets and four nasal swabs from sows were submitted to the diagnostic laboratory. Lung homogenates were tested. Clinical specimens were screened for the presence of influenza A viruses by real time RT-PCR (6). Positive samples were further tested for the (H1N1)v by real time RT-PCR (rtRT-PCR), according to the CDC procedure (7). All samples were also cultured for the most common bacterial swine respiratory pathogens and tested for PRRSV, PCV2 and M. hyopneumoniae by using RT-PCR, multiplex PCR and PCR assays respectively (8, 9, 10).

Sera were collected in sows and piglets both when clinical signs were observed and 28 days PI. Specimens were examined by NPA-ELISA and HI tests swine antigen A/H1N1,A/H3N2,A/H1N2 and pandemic A/H1N1.

Results

Figure 1: Total born, born alive and weaned piglets in 2008, 2009, November - January 2008/09 and 2009/10

Sows presented fever, depression, anorexia and agalactia, while 5-10 days piglets diarrhoea and weight loss. The morbidity in sows was approximately 30-50% and the performance sow and piglets data are reported in Figure 1 and 2.

Gross lesions were catarrhal enteritis in 8 piglets and pneumonia with a purple area of consolidation in the apical lobes in one piglet. The latter and one of the two pools of 4 piglets were positive for type A influenza (H1N1)v assay. Only PRRSV European strain was detected from the first pool, whereas other samples resulted negative for the tested pathogens.

Sow sera collected at 28 days PI. were positive by NPA-ELISA and HI tests pandemic A/H1N1.

Discussion

The main clinical signs were depression and agalactia in sows during the first week after farrowing. Different weights were observed in litters and piglets showed wasting and dehydration. The loss interested litters and were quantified in increased mortality in farrowing units, performance reduction in sows consisting in enhanced mortality and fertility rate reduction.

Pigmeat price dynamics: effects of Influenza A H1N1 in Mexico?

Ernesto Bobadilla¹ Angelica Espinoza¹ Maria Trujillo² Giovanna Penuelas¹ Francisco E. Martinez Castañeda¹

¹. Universidad Autonoma del Estado de Mexico, Toluca, MEX, Mexico; ². Universidad Nacional Autonoma de Mexico, Mexico, DF, Mexico

Introduction

Several factors can modify price fluctuations in different magnitude and time. Mexico as all world, experimented a terrible human disease in middle 2009. At the beginning of the disease it was named swine disease, hog fever, and other names that contributed someway to increase fear for these products. Price fluctuations are a discipline that combines historical dynamics and prospective analysis. The aim of these study was to evaluate 2009 pigmeat price fluctuations and identify the effect of A H1N1 Influenza disease.

Materials and Methods

2009 daily pigmeat, hog prices and slaughter were analyzed. Data were collected from Secretaria de Economía. A multiplicative components model with a component separation was used. Y=T*S*C*I, where Y=variable; T=Tendency; S=Seasonality; C=Fluctuations and; I irregular movements.

Results

Both live hog and pigmeat price showed fluctuations around 10% in one year, percentage that destabilized the sector. Live price fluctuation was 12.49% and began a negative dynamic from April 20th to May 31. Pigmeat fluctuation was 11.87% all year but from April 12th to June 10th the variation was 10.70% (Fig 1). Figure 2 showed 2 different negatives tendencies, the first one from March 31 to April 9th and the second from April 17th to June 3rd.

Discussion

Price fluctuation more than 10%, can provoked wrong signals both consumer and producer at different time. When a Pandemic A H1N1 Influenza occurred, live hog price dropped and fluctuated more than 10%, and it happens in a short period of time, 41 days. Mexican Pigmeat cycle is 42 month long (Martínez et al, 2009). That means, the sector needs at least 21 months in order to recover the bad fluctuation or vise versa. The effects that were observed during the Pandemic correspond with the negative live price fluctuation. Some way it had affected Mexican hog production but it surly will have effect when the market it selves recovered or adjust the fluctuation regular movements. Unfortunately, this market arrangements represents the lost of many producers, and the federal policies implemented weren’t made to protect or stimulated pigmeat and Mexican hog sector.

Pigmeat fluctuation ran with the same tendency, but the time registered wasn’t 41 days like live price, it was 10 days more, i.e. 51 days long, almost 2 months. Once price bottom it never recovered, the price average maintained below the no fluctuation value, i.e. CERO.

Slaughter registered two negatives periods, the first one is “regular” performance, because it coincidence with the Traditional Mexican “Seaman Santa” (Eastern break).

**Introduction**

Swine influenza virus (SIV) is a primary pathogen of the respiratory tract of pig (1). The target cells of SIV are the epithelia lining the entire respiratory tract. However, a major pathological significance are those located in the small airways (2). Young pigs are fully susceptible to the swine origin pandemic H1N1 2009 influenza A as it was reported in several countries including Argentina. Experimental infections with this novel virus induced mild clinical signs, however, virus shedding and lung lesions were similar to infection with SIV (3). The present work was aimed to review the histopathology (HP) and immunohistochemistry (IHC) features of lung lesions of naturally infected pigs with the pandemic H1N1 2009 influenza A.

**Materials and Methods**

A total of 21 slide lung samples belonged from 9 naturally infected pigs were examined. Cases were selected by gross lesions and rRT-PCR positive. For each, HP, and IHC studies were done. Morphometric study of changes at level of bronchi, bronchiole, alveoli, blood vessels and connective tissue was performed according with Richt et al (2). For statistical analysis, ANOVA test were used and, post hoc Fisher’s LSD analysis was applied when differences were detected.

**Results**

The histopathological hallmark was a severe necrotizing bronchiolitis. Small and medium sized bronchioles were plugged with neutrophils, necrotic epithelial cell and mucous exudates. Affected airways were denuded or lined by flat epithelium. In few of them focal areas of metaplasia were seen. Bronchi and large bronchiole showed only minor changes. Alveolar inflammation was distributed in a lobular or lobar fashion. In them, two coexisting patterns of response were observed in the same sample. The first, infiltrative non-exudative reaction with the presence of neutrophils and few macrophages within the alveoli or in the alveolar wall. The second was serofibrinous exudates into the alveoli with inflammatory cells such as macrophages and neutrophils, hyaline membranes, capillary thrombosis and in few cases, focal necrosis. In 2 cases, lesions resembled infection by A. pleuropneumoniae. The ANOVA analysis showed significant statistical differences among structure affected (p=0.0000). Bronchiolar lesions were statistically higher than others structures (p<0.05), followed by those seen in the alveoli and bronchi. Marked IHC labelling was observed in the severely denuded epithelial cells of bronchioles, pneumocytes and alveolar macrophages of affected or normal alveoli.

**Discussion**

The spectrum of pathological lesions in pigs appears to vary little among SIV subtypes (4). Epithelial cells necrosis of bronchioles, airway plugging with desquamate cells, neutrophils infiltration and mucus are the features of SIV infection (1,2). Changes such as hyaline membranes, capillary thrombosis and alveolar necrosis observed in the study are not commonly reported in SIV infection as has been in human influenza (5). These differences could be associated with the lack of immune response against this “new” subtype. Neutrophils were the common inflammatory cells seen in the airways and alveoli. It may be the results of high level of cytokines secreted by the infected bronchiolar epithelial cells and macrophages which in turn is related with the virus load on these cells (4). In the examined samples, the higher bronchiolar scores were correlated with the more marked immunolabeling. However, secondary bacterial infection can not be excluded. More extensive studies are needed to evaluate the consistence of the above described lesions of the pandemic H1N1 2009.

Introduction
The Norwegian swine population has been considered free from influenza A virus infection documented through a serological surveillance program running since 1997 (1). The swine population is also documented free from PRRS-virus and Mycoplasma hyopneumonia (1, 2). The first human cases of the pandemic influenza A (H1N1) 2009 virus infection in Norway were detected in early May 2009. The first porcine case was detected in October, and human to pig transmission was suspected (3). This paper describes the lung lesions in slaughtered fattening pigs from herds naturally infected with pandemic influenza A (H1N1) 2009 virus.

Materials and Methods
The slaughtered fattening pigs originated from three herds. The lungs from pigs from herd 1 and 2 had been selected for examination because “new” types of lung lesions were observed at the meat inspection. From these herds, lungs from 9 and 10 pigs, respectively, were examined. Herd 3 had been tested positive for pandemic influenza A (H1N1) 2009 virus two weeks before the pigs were slaughtered, and 10 lungs were submitted for examination. From each examined lung one swab from trachea and one from a bronchus were submitted for virus detection by real-time PCR (4). One sample from the right cranial lung lobe was submitted for bacteriological examination. The gross pathological lung lesions were recorded. One sample from trachea and nine samples from different lung lobes were fixed in 10% buffered formalin for 24 h and then transferred to 70% ethanol. The samples were routinely processed, and 3–4 μm sections were cut and stained with hematoxilin and eosin. Immunohistochemical examinations using monoclonal antibodies to detect influenza A virus (5) and PCV2 in the lung tissues were performed.

Results
In herd 1 and 2 the pandemic influenza A (H1N1) 2009 virus was detected in 17 of 18 examined lungs. In herd 3 influenza virus was not detected in the five examined lungs. The lungs from the three herds showed a multifocal, lobular pattern of atelectasis and dark red discoloration. The lesions were most pronounced in the cranioventral parts of the lungs. The areas with atelectasis were slightly firm compared to the surrounding tissue. In the bronchi there were varying amounts of mucus to mucopurulent exudate. The tracheobronchial lymph nodes were slightly to moderately enlarged. Histological examination of the lungs from pigs from herd 1 and 2 showed comparable lesions but also revealed variation between animals and within the lungs. The main findings in the affected lobules were atelectasis and moderate to intense infiltration of leukocytes in the mucosa of the small bronchi and bronchioles. Attenuation of bronchial and bronchiolar epithelial lining was seen, but acute epithelial necrosis was seldom identified. Large peribronchial and perivascular infiltrates of lymphocytes, and in some pigs, also lymphoid follicles were observed. There were increased numbers of leukocytes in the interalveolar septa, and varying numbers of granulocytes, lymphocytes and few macrophages were seen in the partial collapsed alveoli. In the lungs from pigs from herd 3 the major findings were atelectasis, prominent peribronchial and peribronchiolar lymphoid follicles and thickened interalveolar septa. The bacteriological examination showed sparse to moderate growth of different Streptococcus species or non-pathogenic bacteria from the majority of the lungs. Influenza A virus was detected by immunohistochemical examination in the bronchiolar epithelium, in cellular debris in bronchiolar lumen or in scattered cells in the interalveolar septa in 5 of 9 pigs in herd 1 and in 9 of 10 pigs in herd 2. PCV2 virus was not detected by immunohistochemical examination of the lung lesions.

Discussion
The pandemic influenza A (H1N1) 2009 virus infection induced significant lung pathology in the pigs from the three herds. The primary locations for lesions seemed to be small bronchi and bronchioles. In herd 1 and 2 the duration of the infection may have varied between 5-10 days prior to slaughter, and the lesions in most lungs were significantly different from the lungs from the pigs in herd 3 slaughtered 18 days after the detection of the virus in the herd. The lesions observed in the lungs were similar to the lesions described for “classical swine influenza”.

Introduction and objective
A recently emerged influenza A H1N1 virus (pH1N1) spread globally from human-to-human causing the first pandemic of this century (1). The pH1N1 originated from the reassortment of swine influenza virus (SIV) with human, avian, classical swine and Eurasian swine lineages (2). Since then reports of reverse zoonotic cases in avian species and pigs have been documented in the field (3). These events raise concern of possible reassortment between the pH1N1 and other SIVs that may cause a new virus with zoonotic potential. Rapid detection and differentiation of the pH1N1 virus from swine H1N1 influenza virus (sH1N1) is essential for prompt preparedness for such events. Since the genome of pH1N1 is of swine origin, it is difficult to differentiate pH1N1 from all sH1N1 currently circulating in pigs worldwide. Fortunately, the origin of PB1 gene in the Thai and European sH1N1 isolates are mainly avian-like while that in pH1N1 is human-like (4). In this study, a conventional one-step reverse transcriptase (RT)-PCR assay targeting PB1 gene was developed for detection and differentiation of pH1N1 from other sH1N1 viruses. Additional RT-PCR assay targeting HA and NA genes was also developed and modified for subtyping H1 of classical swine and N1 of European swine viruses.

Materials and Methods
The two pairs of primers, PB1-P and PB1-S, specific for pH1N1 and sH1N1 viruses, respectively were designed based on PB1 gene. Additional H1 and N1 primers (N1 modified from (5)) were designed for subtyping H1N1 viruses from all species. The primers are shown in Table 1. All primers used in this study run with the same condition allowing detection of different genes simultaneously. The conditions are as follow: reverse transcription at 48°C for 45 min, initial denaturation at 94°C for 3 min and 40 cycles of denaturation at 94 °C for 30 sec, anneal at 55°C for 30 sec and extension at 72°C for 1 min, followed by final extension at 72°C for 10 min. The sensitivity of this assay was tested. The specificity of the assay was determined by testing with pH1N1, SIV subtype H1N1, H1N2 and H3N2, avian influenza H5N1 virus, seasonal human influenza H1N1 (huH1N1) virus and other swine respiratory viral pathogens.

Results and Discussion
The results showed that the RT-PCR assay can be applied to detect and differentiate pH1N1 virus from other SIVs, including sH1N1 viruses and huH1N1 virus (Fig 1). This novel assay was sensitive and can detect 0.001 and 0.01 TCID50/ml of pH1N1 and sH1N1 viruses, respectively. They showed 100% specificity and did not amplify genetic material from other subtypes of SIV and other swine respiratory viral pathogens (data not shown). Overall, the results clearly indicated that the novel one-step RT-PCR assay has high sensitivity and specificity to detect pH1N1 virus. The assay can discriminate pH1N1 from huH1N1 virus, Thai sH1N1 and possibly European H1N1 SIVs since the PB1 gene is of the same avian-like origin. Moreover, the RT-PCR assay targeting H1 and N1 genes can be used to subtype the virus using the same PCR condition which allows rapid and simultaneous detection and differentiation of the influenza A viruses. In summary, this cost-effective assay can be used for rapid screening of current circulating SIV isolates for detecting pH1N1 in the swine population.

Introduction
In April 2009, a new influenza A/H1N1 strain circulating in the human population was reported in Mexico. The new H1N1 virus was a triple swine/human/avian reassortant that afterwards spread pandemically. Fortunately, the virulence of the pandemic H1N1 (panH1N1) seems to be low but this episode made clear the need for a better surveillance of influenza A viruses infection. Swine influenza is most often caused by subtypes A/H1N1, A/H1N2 and A/H3N2. Hemagglutination inhibition test (HI) still is the serological assay of reference and it is assumed to be subtype-specific1. The main objective of the present work was to assess to what extent the use of different strains of a same subtype may affect the outcome of HI when examining swine serum samples.

Material and methods
Ninety-four serum samples were selected from a sera bank (2007-2009) corresponding to a cross-sectional study of swine influenza in Spain where sera had been tested in HI using an European avian-like A/swine/Neth/Best/96 strain (NLH1N1)(GD laboratories, Deventer, Netherlands). The group of selected sera included negative and positive anti-NeH1N1 sera (≤1:320) that were re-tested in HI using the Spanish avian-like H1N1 A/swine/Spain/53207/2004 strain (ESH1N1) and the novel pandemic H1N1 (A/Catalonia/S2169/2009) strain (panH1N1) isolated from a human sample. Similarity of the predicted amino acid sequences of H1 were 89.3% between NLH1N1 and ESH1N1; 75.1% between NLH1N1 and panH1N1 and 71.5% between ESH1N1 and panH1N1. Sera were also examined using A/H1N2 and A/H3N2 (A/swine/Gent/7625/99 and A/swine/Neth/St.Oedenrode/96) (GD laboratories, Deventer, Netherlands) strains. Statistical analysis was done with Statdirect 2.7.5.

Results
Figure 1 show the comparative distribution of HI titres using the different H1N1 strains. Comparison of results of sera analyzed with NLH1N1 or ESH1N1 showed that both strains produced fairly similar titres (r=0.79; CI95%=0.70-0.85). In contrast, regression of log-transformed titres for NLH1N1 or ESH1N1 and panH1N1 was non significant, suggesting that antibodies towards panH1N1 did not cross-react with other H1N1. No cross-reactivity between none of the A/H1N1 and either H1N2 or H3N2 was observed (data not shown). Interestingly, in 4 farms animals seropositive (≥1:40) against panH1N1 were found. In one of those farms (analysed in the first quarter of 2009) 8 animals were positive (Table 1); some of them reacted with other swine influenza strains.

Discussion
The present results indicate that panH1N1 has little or no cross-reactivity in terms of HI with other contemporary swine H1N1 viruses. However, the results also showed that, most probably, H1 viruses cross-reacting with the panH1N1 strain already existed before or at the same time of the emergence of that new pandemic strain. Considering the limited virulence of current panH1N1 it can not be discarded that similar or cross-reacting H1N1 virus circulated completely unnoticed in pig herds. Also, raise the question of how to interpret the HI results obtained with a given influenza strain.

Detection of Pandemic H1N1 2009 in swine herds
Yeun-Kyung Shin; Sorah Yoon; Soon-Seek Yoon
National Veterinary Research and Quarantine Service, Anyang, Korea

Introduction
Pandemic H1N1 2009 was first reported in human population in April, 2009 and on the same month, pig infection was also reported in Alberta, Canada. With the increasing number of human death toll and with more cases of swine infections all around the world, Korean government enlisted Pandemic H1N1 2009 in notifiable animal diseases under the Act of ACT ON THE PREVENTION OF CONTAGIOUS ANIMAL DISEASES on August 21, 2009 and started monitoring of Pandemic H1N1 2009 in pig herds. Accordingly, the necessity of rapid and reliable detection method of swine influenza virus or antibodies in pig herds for a number of heads on a regular basis was increased. Here we present one-step M gene multiplex RT-PCR system which detect Pandemic H1N1 2009 from swine samples, one-step HA1/HA3 subtyping multiplex RT-PCR system and one-step NA1/NA2 subtyping multiplex RT-PCR system from swine influenza viruses.

Materials and Methods
Viruses
A human pandemic flu virus (A/Korea/01/2009 (H1N1), isolated in Korea, a pandemic flu virus (A/sw/Korea/J2/2009) isolated from pig, 10 various subtypes of endemic swine influenza viruses, and Reference influenza viruses (from HA subtype 1 to 16) were used. Virus titres were measured by Hemagglutinin assay or Reed-Munch method using MDCK cells. Oligonucleotides design
The matrix (M) genome sequences of Pandemic H1N1 2009 influenza virus (A/California/04/2009), endemic swine influenza viruses and avian influenza A viruses were retrieved from the GenBank database and analyzed to select sites which is specific for pandemic flu. Primers were also selected for the subtyping of HA1/HA3 or NA1/NA2 among endemic swine influenza viruses.

Results
One-step multiplex RT-PCR assay was performed with the RNA extracted from diluted pandemic flu virus (titre of stock: 1 x 106 TCID50/ml) at 10-1 to 10-8. A positive amplification could be visualized up to 10-5-6 dilution, which meant the lowest concentration with positive results was 1-10 TCID50/ml. One-step multiplex RT-PCR assay was also performed with RNA standard prepared to know the exact sensitivity as copy number. The minimum copy number of matrix gene RNA detectable with our system was approximately 101-2 copies of RNA.

Specificity of the system was tested using various endemic swine influenza viruses and reference viruses with different HA subtype. All were negative for the pandemic H1N1 2009 virus specific bands. Bands for influenza A common M gene were only visible.
One-step HA1/HA3 subtyping multiplex RT-PCR system and one-step NA1/NA2 subtyping multiplex RT-PCR system were also tested for the specificity and sensitivity with a panel of influenza A viruses. The limit of detection was 101 TCID50/ml for HA1/HA3 subtyping, and 101-2TCID50/ml for NA1/NA2 subtyping.

Discussion
Pig can be infected with avian, human or swine influenza A viruses, hence, is well known as a mixing vessel. With the advent of swine origin Pandemic H1N1 2009, the importance of national or international level of monitoring of swine influenza viruses is well appreciated. It is important to develop or update the virus or antibody detection method from pigs to know the exact situation of influenza virus infection. It is necessary to have a reliable and highly sensitive swine flu detection method from pig herds since the viruses are cleared rather quickly from pigs. Monitoring of swine flu on regular basis will contribute public health and pork industry at the same time. Our system will be a good tool for monitoring of Pandemic H1N1 2009 in swine herds on a regular basis.

Development of inactivated pig vaccine for Pandemic H1N1 2009

Jae-Young Song1 Yeun-Kyung Shin1 Young-Ki Choi2
1. National Veterinary Research and Quarantine Service, Anyang, Korea; 2. College of medicine and medical research, Choongbook National University, Cheongju, Korea

Introduction
First case of pig infection of Pandemic H1N1 2009 was reported in Canada in April, 2009 and afterward, there were additional cases in more than 10 countries all around the world. Korean government practiced active monitoring of Pandemic H1N1 2009 from May 2009. Approximately 10% of the fattening farms, which meant 10% of the total fattening farms and included 700 farms, all breeding farms and all Artificial Insemination centers (200 locations) were monitored. 18 farms in different places all around the country were found to have infected pigs. Since pigs were well known as a mixing vessel of influenza viruses, it was necessary to develop vaccines which can prevent pigs from being infected or producing reassorted pandemic flu viruses.

Materials and Methods
Generation of vaccine candidate viruses
A/PR8/34 H1N1 influenza A virus, which is a backbone virus of seasonal human influenza vaccine and Pandemic H1N1 2009 virus, A/sw/Korea/SCJ01/2009, isolated from pigs in Korea were co-infected in 9-10 day old embryonated SPF eggs to generate reassorted vaccine candidate virus(CL A/swine/Korea /SCJ01/09 x PR8). Allantoic fluid was harvested and plaque assay was performed to select reassorted virus with 6 internal genes from PR8 virus and with 2 surface glycoprotein (NA and HA) genes from pandemic flu virus. Immunogenicity in mice and pigs
Immunogenicity of recombinant virus in mouse and in pigs was tested using concentrated viruses with 2% alum. Mice were immunized with 3.5ug inactivated vaccine two times with two weeks interval. Pigs were immunized with 7.5ug. Sera were collected 2 weeks after each immunization and Hemagglutination inhibition (HI) tests were performed. Virus challenge and protection test
Two groups of pigs were immunized with different type of vaccines two times. Group I was immunized with endemic swine influenza H1N1 vaccine and Group II were immunized with pandemic flu vaccine candidate. Two weeks after the last immunization, both groups were challenged with 1ml pandemic H1N1 2009 virus in intranasal route at 1x105 TCID50/ml. For transmission studies, new group of pigs were housed aerosol contact with immunized and challenged groups a day after infection. Nasal swabs were collected p.i. 2, 4, 5, 6, 7, and 8 days from all animals to examine the ability of the vaccine to inhibit virus replication.

Results
Immunogenicity in mice and pigs
HI titer of one time immunized mice were 40-80. When immunized two times, the titers were 160-320. In the case of pigs, HI titer of one time immunized pigs were 40-80, and 160-320 with two immunizations. Virus challenge and protection test
Both of the vaccine and challenged group started to shed virus 2 days p.i. Much higher titer of virus was detected from pigs immunized with endemic swine influenza virus vaccine longer time. No virus was detected from contact group with pandemic flu vaccine immunized group while virus was detected from contact group with endemic vaccine.

Discussion
It is well known that vaccination for influenza A virus would be a good way to control transmission of viruses and overcome illness in humans. Vaccination of pigs will add up one more advantage: inhibitions of possible generation of reassorted influenza A viruses by combination of endemic influenza A viruses and Pandemic H1N1 2009. Continuous monitoring of influenza A viruses circulating among pigs and application of right vaccination for the current strains will benefit both public health and pork industry.

Spreading of Actinobacillus pleuropneumoniae in the pig farm. A field case

Kazimierz Tarasiuk1 Marcin Bzdawka2
1. PIC Poland, Warsaw, Poland; 2. Rogóźno Farm, Łasin, Poland

Introduction
Actinobacillus pleuropneumoniae (App) is the etiologic agent of swine pleuropneumonia, a highly infectious, often fatal disease. The main route of spread is by direct contact from pig to pig or by aerosol within short distances. Although some authors (1, 2) reported that airborne transmission between closely located pig units is possible but rare. The objective of this study was to follow up the spreading of App serotype 2 infection within a small pig herd.

Materials and Methods
A high-health multiplying farrow to finish herd (240 sows) was infected with App serotype 2 in August 2009. The herd was free of the major diseases including PRRS, EP and Actinobacillus pleuropneumonia. The farm consisted of two buildings 40 m from each other with no direct connection established between them. One building is devoted to grow-finish pigs managed AIAO by room and the other one is populated with sows and weaning pigs up to 7 weeks of age. The grow-finish building consisted of 4 rooms split, each containing 2 pens with 45 pigs in each. The infection entered into the building in one of the outer rooms which was separated physically from the other part with a solid wall. Once the first symptoms of the infection emerged in pigs (temperature 41.5°C, coughing, lack of appetite) the facility was locked and the possibility to get in from outside was only used. All the animals in this room were treated with tetracycline in the water for 7 consecutive days. Immediately extra biosecurity conditions (different stockperson, separate shower facility, clothes and boots) were introduced into the farm. After the clinical signs declined and antibiotic withdrawn, all the animals from this room were slaughtered. Slaughtercheck was performed and tonsils from 15 randomly selected pigs with lung lesions were taken for PCR. The affected lung tissues were submitted to the laboratory for App culture. The empty pens were first fumigated with 1% Virkon and left for 5 days. The floor was soaked with a glutaryl aldehyde based disinfectant and left until completely dried. After 5 days the entire facility was cleaned, washed, disinfected, dried and left for 30 days before new pigs were introduced. The pigs from the other 3 rooms were observed clinically and were given tetracycline in the water for 7 consecutive days as prevention. From every pen 15 randomly selected pigs were bled for serology. During the next 8 weeks all the animals from the first building were gradually slaughtered. Tonsils from 5 randomly selected pigs / pen were taken for PCR. In the meantime many precautions were undertaken to protect the sow building from contamination. Ten sentinels naïve for App were introduced into the breeding sector of the farm allowing them to have contact nose to nose with the local pigs. All sentinels were tested serologically twice: 1 and 2 months after introduction. After two months from infection the blood from 45 randomly selected sows was taken for serology. For detection of antibodies against App serotype 2, a LC-LPS ELISA was used (Swine-Check App, Biovet, Canada).

Results
App serotype 2 infection was confirmed by culture from lung lesions of pigs from the outer perimeter room. Pigs from this facility were sick with a typical clinical signs of pleuropneumonia. Slaughtercheck revealed typical lesions of App infection (abscess-like nodules present in the diaphragmatic lobes) in 35 of 52 pigs. Two hundred and seventy pigs from the other three rooms gradually slaughtered did not show any lung lesions. The serology carried out in randomly selected pigs from every room revealed that all the results were negative for App serotype 2. In total 90 pigs were bled for serological investigations. No clinical signs of respiratory problems were observed in sows and weaning pigs as well as sentinel animals. Serological investigations performed on 45 randomly selected sows shown all of them to be negative for App serotype 2. Tonsils of 15 pigs from the infected room were tested PCR positive. Tonsils of pigs from the other three rooms of the building were tested PCR negative. Sentinel pigs were tested serologically negative for App serotype 2 either 4 or 8 weeks upon introduction.

Discussion
Results obtained clearly show that App infects naïve pigs if there is direct contact with contaminated material. In this particular case the source of infection there was very likely the stockman (fomites) attending the loading process. Only the pigs in the outer perimeter room became infected with App serotype 2, of course the loaded animals get infected as well. It is worth noting that infection did not spread across the entire building. The swift actions undertaken upon the first signs of infection appeared allowed to protect pigs from the rest of the rooms of this building and other building from the App infection. This confirms previous observations that airborne transmission of App is possible but limited (1, 2).

**Introduction**

Porcine pleuropneumoniae is a worldwide spread disease responsible for severe economic loss to pig producers because of mortality, lower weight gains and increased production costs. Its aetiological agent, *Actinobacillus pleuropneumoniae* (App), has 2 biotypes (I and II) dependent and non-dependent for “in vitro” growth of nicotinamideadeninedinucleotide (NAD), respectively. The species has been classified into serotypes 1-15, according to composition of surface cell walls antigens (LPS). This is important for immunity and protection, since most of the serotypes do not cross-react immunologically, having different pathogenic potential. So that, knowledge on relative prevalence of different serotypes in a particular producing area is important for establishing preventive control strategies. The objective of this work was to classify a collection of argentinean isolates of App into serotype groups, based on PCR amplification of selected sequences belonging to the omlA and apx genes.

**Material and Methods**

Forty eight App cultures isolated from clinical cases of pleuropneumoniae in swine farms from different locations of the country were utilized. The strains were cultured and biochemically classified by conventional bacteriology laboratory works and stored lyophilized. For serotype classification by PCR, bacterial ADN was extracted by a commercial kit (Fermentas™) and ran using primers and conditions reported previously (1).

**Results**

Serotype group classification and percentages can be observed in the following table 1. In figure 1 can be visualized the geographical location within Argentina where the strains were isolated.

**Table 1.**

**Discussion**

It can be observed that the most frequent group of serotypes detected is 1-9-11, since the test does not discriminate among these particular serotypes. It was expected that serotype 1 was the most prevalent since was described as it long ago (2). However, a relative high frequency of serotypes 3-6 was detected, which is not surprising since existence of serotype 3 was previously described (3). This is an important finding, since no conventional vaccines containing App serotypes 3-6-8 exist in the argentine market. Serotype 7 also showed a relatively high prevalence within this collection, which is not surprising either, since it was previously isolated from a clinical case of pleuropneumoniae (4).

In this work, strains from the most important producer areas from Argentina were studied, such as showed in figure 1. In the future a higher number of isolates should be processed, so that a more complete map of App serotype distribution in Argentina will be obtained. This information will allow to improve control and preventive strategies for this disease.

**Introduction**

Swine pleuropneumonia caused by *Actinobacillus pleuropneumoniae* (App) is a contagious disease that may produce important economic losses. Clinical signs of acute disease are dyspnea, coughing, anorexia, depression, fever and sometimes vomiting. In the absence of treatment, the disease can progress very rapidly and death can occur within a few hours. Chronic infections are characterized by coughing and pleuritis in lungs. There are 15 serotypes of App described so far. Serotype 15, the last described serotype, was suggested as being present only in Australia1. In this country, it seems to produce important losses in the swine industry. However, strains have later been isolated in USA, Canada and Argentina2 and, more recently, in Japan3, causing sporadic disease. In the present study, we analyzed sera from naturally infected animals in Australia, as well as, sera from experimentally infected animals with the reference strain HS-143 and with North American strains. In addition, we studied the genetic diversity of within USA App serotype 15 strains.

**Materials and Methods**

Strain and isolates: The reference strain of App serotype 15 (HS-143) was kindly supplied by Prof. J. Frey, Switzerland. Other reference strains came from our own collection. A total of 22 isolates recovered from diseased animals originated from the University of Minnesota Veterinary Diagnostic Laboratory. These isolates were sent to our diagnostic laboratory for serological characterization.

Antigenic and genotypic characterization: Serotyping was carried out by coagglutination, immunodiffusion and indirect hemagglutination tests. Hyperimmune serum against strain HS-143 was produced in rabbits. Toxine profile was performed by PCR. Genotyping was carried out by ERIC-PCR and Random Amplified Polymorphic DNA (RAPD).

Field and experimentally infected swine sera: Field serum samples from two Australian herds clinically infected with serotype 15 strains (kindly supplied by Dr. Patricia Spicer) as well as sera from six experimentally infected pigs with strain HS-143 were tested by LC-LPS ELISA against serotypes 1 to 12. A LPS antigen for serotype 15 was produced as described before4 using the reference strain. Selective immunoblot tests, using different antigens and sera, were also performed.

**Results**

- Serotyping: All field isolated presented a strong and clear reaction with anti-serotype 15 rabbit serum. Most strains presented also cross-reactions with serotypes 3, 6 and/or 8 with most techniques used. Some isolates presented cross-reactions with serotypes 7 or 12.
- Genotyping: A relative degree of heterogeneity, with at least 7 different clusters, was observed.
- Toxine profile: apxIVA, apxIBD, apxICA, apxIIICA and apxIIIBD (production of ApxIV, ApxII and ApxIII).
- Serology:

  Most field sera presented a clear positive reaction with antigens from serotypes 3, 6, 8 and 15. Common LPS epitopes in these serotypes was confirmed by immunoblot.

**Discussion**

- App serotype 15 infection is relatively common in North America.
- LPS from App serotype 15 is antigenically related to that from serotypes 3, 6 and 8, as previously suggested by chemical analysis5.
- A slight cross-reactivity at the capsular level is observed in serotyping, which also can be explained by previous capsular structure analysis5.
- Strains presented in USA are not clonal.
- Serologic diagnosis of herds infected by these strains can be done by the LC-LPS ELISA test using either homologous or serotype 3, 6 or 8 antigen.

Introduction

Swine pleuropneumonia caused by *Actinobacillus pleuropneumoniae* (App) is a contagious disease that may produce important economic losses¹. Clinical signs of acute disease are dyspnea, coughing, anorexia, depression, fever and sometimes vomiting. In the absence of treatment, the disease can progress very rapidly and death can occur within a few hours. Chronic infections are characterized by coughing and pleuritis in lungs. There are two biotypes of App differentiated on the basis of their requirement for nicotinamide adenine dinucleotide (NAD). Biotype 1 strains require NAD, whereas biotype 2 strains can synthesise NAD in the presence of specific pyridine nucleotides or their precursors¹. There are 13 serotypes of biotype I (serotypes 1 to 12 and 15), and 2 serotypes of biotype II (serotypes 13 and 14), based on surface polysaccharide antigens. Some strains belonging to serotypes such as 2, 4, 7 and 9, mainly isolated in Europe, have been described as being either biotype I or biotype II. So far, in North America, serotypes 1 to 3, 4 (Canada), 5 to 8, 10, 12 and 15 have been isolated². We report here for the first time the isolation of serotype 13 strains in USA and Canada. However, these strains are NAD-dependent and antigenically different from the reference strain³.

Materials and Methods

Isolates: Two isolates (003-16 and 15816), from a Canadian and an USA herds, respectively, were characterized. Both isolates were recovered from animals presenting clinical signs and lesions compatible with swine pleuropneumonia. Both strains were shown to be a typical biotype I (NAD-dependant) App. Both strains were shown to be App by two species-specific PCR. Strain characterization: Serotyping was carried out by coagglutination (CoAg), immunodiffusion (ID) and indirect hemagglutination tests (IHA). Toxine profile was performed by PCR. Genotyping was carried out by Amplified Fragment Length Polymorphism (AFLP)⁴.

Field and experimentally infected swine sera: Field serum samples from herds infected with strains 003-16 or 15816 as well as sera from three experimentally infected pigs (with strain 003-16) were tested by LC-LPS ELISA against serotypes 1 to 15 and against the homologous strains. Selective immunoblot tests using different antigens and sera were also performed.

Results

**Serotyping:**

*Sera from 6 different rabbits from 2 laboratories; b By all techniques used; f By ID only (LPS-like reaction); d By all techniques, although weak reaction by IHA was observed (LPS-like reaction by ID); Light cross-reactions with serotypes 5, 6 and 8.**

- Sera from either naturally or experimentally infected animals presented a positive reaction using LC-LPS ELISA when either the homologous (high values) or serotype 10 (intermediate values) LPS antigen was used. Negative results were obtained with LPS from the reference strain of serotype 13. Immunoblot tests clearly indicated a reaction with sera from experimentally infected animals with serotype 10 LPS.
- Toxine profile: *apx*ICA; *apx*IBD (*ApxI* production).
- Genotyping: Both strains clustered together with the same profile, clearly different from the serotype 13 reference strain.

Discussion

- Although slight differences, both Canadian and USA strain are antigenically similar.
- These strains are different from the reference strain: a) biotype I; b) LPS similar to serotype 10 App; c) *ApxI* toxin production; d) a different genetic cluster.
- These strains probably possess a capsular type of serotype 13 and a LPS of serotype 10.
- Serologic diagnosis of herds infected by these strains should be done by the LC-LPS ELISA test using the homologous (preferable) or serotype 10 antigen.

Profiles of Actinobacillus pleuropneumoniae serotypes in Dutch slaughter pigs

Gerard J. Wellenberg1 Øystein Angen1 Eric. van Esch2 Anja Rothkamp1 Frits Bouwkamp1 Tom Duinhof1
1. Animal Health Service, Deventer, Netherlands; 2. National Veterinary Institute, Copenhagen, Denmark

Introduction

Although Actinobacillus pleuropneumoniae (App) infections have been evidenced in The Netherlands, the actual distribution of the different App serotypes in Dutch pigs is unknown and so, it is not clear which types of App should be tested for App control or eradication programmes. Therefore, a study was performed to get:

1. more insights in circulating App serotypes in Dutch herds with unknown history of App by performing a serological survey in slaughter pigs and
2. by characterisation of App strains isolated from clinical cases.

Materials & Methods

500 serum samples from slaughter pigs, originated from 100 ad random chosen herds (n= 5 per herd), were analysed for the presence of App antibodies using 7 different ELISA’s. These ELISA’s were able to detect antibodies directed against lipopolysaccharides (LPS) antigens of App, specific to one or a group of serotypes 1 - 12 (Biovet, Canada). In addition, 24 serum samples collected from a swine herd, positive by Apx-IV Idexx ELISA but without App related clinical signs, were analysed using the LPS antigens ELISA’s. The Bayesian True Prevalence model was used for calculating the App antibody prevalences in Dutch slaughter pigs.

Within the period February – December 2008, 63 App strains were isolated from clinically affected swine after necropsy. The App strains were obtained from other herds than the herds described above. App strains were serotyped by standard coagglutination assay using a panel of type-specific anti-sera against all 15 serotypes (National Veterinary Institute, Denmark). If necessary the serotype of the App strains was further characterised by the immunodiffusion method and/or serotype specific PCR’s. The Apx-toxin profiles were determined by PCR.

Results

Table 1 presents the results of serotype specific ELISA’s, including the calculated App seroprevalences in Dutch slaughter pigs. In 142 (28.4%) of the 500 examined slaughter pigs, no positive reactions were recorded in any of the 7 App antibody ELISA’s. In at least 44% of the examined herds positive reactions were recorded in more than one of the 7 ELISA’s.

Table 1: Results (n= 500 sera) of the App serotype or serogroup specific ELISA’s, and the calculated prevalences with 95% confidence intervals (CI).

In the 24 swine sera of one Apx-IV ELISA positive herd, antibodies directed against App serotypes 3, 6, 8 (n=15), 4, 7 (n=3) and serotype 12 (n=5) were detected.

Sixty (95%) of the 63 App isolates were characterised as serotype 2 (70%) or 9 (25%; Table 2). The Apx-toxin profiles of 61 (97%) of the 63 examined App isolates were similar to one of the serotypes that were detected too by serotyping and/or App type-specific PCR.

* NAD dependent App strain from the heart of a clinically affected pig.

Discussion

This study shows that Dutch slaughter pigs have:

- Rather high App antibody prevalences against serotypes 3, 6/8, 4/7 and 12, and low antibody prevalences against serotypes 1/9/11, 5a/5b and 10.
- Herds could be positive for antibodies against more than one App serotype.
- Antibodies against App serotypes 3/6/8, 4/7 and serotype 12 were found in one herd without clinical signs related to App infections.
- The serological profile of App serotypes in slaughter pigs differs from the App serotype profile found in clinically affected pigs. In 95% of these pigs, originated from other herds, App serotypes 2 and 9 were found.
A case control study of on-farm risk factors for acute pleuropneumonia in fatteners

Nils Holmgren1, Nils Lundeheim1, Sivert Johansson2, Leif Göransson1, Gösta Gustafsson1, Johan Ehlorsson3

Introduction

Actinobacillus pleuropneumoniae causes pleuropneumonia (PP) in swine throughout the world and can cause severe economic losses (3). Acute outbreaks often appear unpredictable at the end of the fattening period (1). On average 0.6% of slaughter-pigs in Sweden show acute PP, but the variation between herds is substantial 0-60% (5). Limited options are available to prevent the disease. Improvements in barn climate have not been evaluated as preventive measures. Experiences made by practitioners indicate that feeding may influence on PP. Therefore, the aim of the present study was to look for climatologic and nutritional risk factors for PP.

Material and Methods

The trial was conducted as a case-control study in 25 barns with documented high, and in 25 barns with low prevalence of PP at slaughter. Averages by quarter of PP-prevalence (n=8) before, during and after the trial were in case-barns 4.6% (SD=0.2%) and in control-barns 0.2% (SD=0.1%). Case- and control-barns were matched for slaughter plants, and season at visit (April – Sept).

Measurements of climate and environmental factors were performed in a standardised way by an engineer specialised on climate in pig houses. Measurements taken at herd visits (pig age 20-24w) were: max. ventilation rate; air inlet capacity; under-pressure (Dwyer type Mark II); air velocity in the resting zones at different ventilation rates (0-100%); balance between exhaust and inlet air; heat balance; sectioning between barns; air contamination; functioning of climate regulation equipments; pen hygiene; concentrations of CO₂ and NH₃. The release (amount) of NH₃ in relation to animal density (CR) was calculated (4).

Composition of feeds and feed allowances during the fattening period was recorded at farm visits. The statistical analyses were performed by Students t-test and logistic regression, using the SAS software (PROC TTEST; PROC GENMOD; PROC GLIMMIX).

Results

On average, PP barns had more deficiencies in air inlet and in air outlet capacities compared to control barns. These differences were however not significant. There was a tendency for better control of air in- and outlet in control herds (p=0.07).

Analysed differences between case-control barns are presented in Table 1. In total, 9 possible risk factors differed significantly between the two group of barns. When including all these risk factors as explanatory variables in the logistic regression, 3 of these factors had a p-value =<0.15 (Table 2).

Discussion

Climate in barns had unexpected low impact on the occurrence of PP. However, a more intense feeding plan (+1MJ/pig/d) and use of many alternative feed-stuffs had negative impact on pen hygiene. In the final model there were tendencies for alternative feeds and intense feeding to be risk factors for PP. If this is due to an increased metabolic stress in fast growing pigs is unknown and has to be elucidated by further investigations. The number of fatteners in herds had a strong impact on the occurrence of PP. The same risk factor has also been identified for pleurisy in slaughtered pigs (2).

Acute-phase responses following repeated infections with *Actinobacillus pleuropneumoniae* in the presence and absence of medical treatments

Marie Sjölund1, 2 Caroline Fossum2 Per Wallgren1, 2

1. SVA National Veterinary Institute, Uppsala, Sweden; 2. SLU Swedish University of Agricultural Sciences, Uppsala, Sweden

**Introduction**

Acute-phase proteins mirror the magnitudes of primary *Actinobacillus pleuropneumoniae* (APP) infections (1) which are influenced by early initiated antimicrobial treatments, and also correlated to the efficacies of such treatments (2). However, little is known about the acute-phase response following re-infections, especially how it is influenced by responses following previous treatments. Therefore we studied the acute-phase response after a re-challenge with APP in pigs treated with drugs of different efficacies following the first exposure.

**Materials and Methods**

30 nine week old SPF-pigs were allocated to 5 groups and housed in separate rooms with a high level of biosecurity. After acclimatisation, 4 groups were inoculated intranasally with 10^{11} CFU of APP serotype 2 (APP2). At the onset of clinical symptoms, 20 hours pi, the groups were either treated with enrofloxacin, tetracycline or penicillin. One group served as an inoculated control and did not receive any treatment and one group served as an un-inoculated control group.

On day 28, all 5 groups were challenged with 10^{11} CFU of APP2. No treatments were carried out this time (3).

Blood was collected once daily following inoculations and thereafter once or twice weekly (Fig 1). Haptoglobin and Serum amyloid A (SAA) in serum were analysed using commercial assay kits (PHASE^{TM} RANGE, Tridelta), according to the manufacturer’s instructions.

**Results**

Results regarding clinical signs, antibody responses and post-mortem findings are well documented and published (3). Acute phase responses mirrored serology and clinical manifestations well (3). Following the first inoculation, both haptoglobin and SAA-levels increased in all inoculated pigs while no changes were observed in the un-inoculated pigs (Fig. 1). Acute-phase responses were not observed in any of the previously inoculated groups except the enrofloxacin treated group following the re-challenge. In contrast, increased levels were recorded in the previously un-inoculated control group and in the enrofloxacin treated group (Fig. 1).

**Discussion**

Early medication with enrofloxacin has proven very effective in treating acute actinobacillosis, preventing seroconversion (4). However, these pigs were unprotected upon re-challenge, despite the initiation of an acute-phase response after the primary exposure to APP2 (3). This implies that early treatments with very effective antimicrobials prevent any immunological memory to develop. Consequently, an acute-phase response appears following re-challenge of such animals.

Innate immune parameters in the respiratory tract after infection with *Actinobacillus pleuropneumoniae*

Isabel Hennig-Pauka¹ Doris Hoeltig¹ Ruediger Koch² Hagen Gasse² Frank Blecha³ Karl-Heinz Waldmann¹ Gerald-F. Gerlach⁴

1. Clinic for Swine and Small Ruminants, Hannover, Germany; 2. Department of Anatomy, University of Veterinary Medicine, Hannover, Germany; 3. Department of Anatomy and Physiology, College of Veterinary Medicine, Kansas State University, Kansas City, USA; 4. IVD GmbH, Hannover, Germany

**Introduction**

The severity of respiratory tract disease is essentially determined by the quality of immediately activated reactions of the innate immune system as the first line of defense, which is also responsible for naturally occurring disease resistance in breeding lines (1). Understanding local innate mucosal immune responses of the upper and lower respiratory tract will be the basis for the development of new control strategies against disease. The tissue distribution of the antibacterial peptid PR-39 which has been found to be a local respiratory disease marker in BALF has been observed as an example for the constitutive defense readiness of the upper and lower respiratory tract. In addition systemic disease markers as acute phase proteins are involved also in local immune defense mechanisms in the lung (2); they have been examined in this study in healthy pigs; and in pigs infected with *Actinobacillus pleuropneumoniae* (*A.pp*).

**Materials and Methods**

The immunhistochemical examination of tissue samples was performed in three healthy mock-infected pigs and six pigs infected with different serotypes of *A.pp* in the acute (n=2) and chronic (n=4) stage of infection. Subsequently samples from the Concha nasalis, Tonsilla pharyngea, Trachea, Lung (Lobus cranialis, Lobus caudalis as well as from altered lung tissue at other locations) and the Lymphonodi tracheobronchiales craniales were sampled. For the demonstration of PR-39, sections were stained with a monoclonal mouse anti-PR-39-antibody and a second-ary peroxidase-coupled polyclonal goat-anti-mouse antibody. The determination of acute phase proteins Haptoglobin (Hp), C-reactive protein (CRP), pig major acute phase protein (pig MAP), serum amyloid A (SAA) and the LPS binding protein (LBP) in BALF and serum was performed prior to and at days 4 and 20 after aerosol infection with an *A.pp* serotype 7 strain AP76.

**Results**

PR-39 was detected in all tissue samples of healthy and pneumonic pigs. In healthy lung tissue a homogenous distribution of the peptide was found while a high increase of positive cells could be detected in pneumonic areas (Fig. 1a and b).

Hp, CRP and pigMAP were significantly increased in BALF and serum at day 4 after infection, while HP concentrations in BALF further increased to day 21 after infection (Fig 2). SAA was only increased in serum at day 4 after infection, while LBP concentrations showed no significant changes.

**Discussion**

According to the tissue and cell distribution of PR-39 not only neutrophils but also other cells might be responsible for PR-39 expression or uptake. An increase of Haptoglobin in BALF supports the hypothesis of a local production in lung cells, so that it can be considered also as a respiratory disease marker reflecting lung tissue alterations. Day 4 after infection might have been too late to detect early changes in the LBP concentration as a proximate effector molecule of the innate immune system.

Actinobacillus pleuropneumoniae exotoxin ApxI induces expression of proinflammatory cytokines in porcine alveolar macrophages

Graduate Institute of Microbiology and Public Health, College of Veterinary Medicine, National Chung Hsing University, Taichung, Taiwan

Introduction
Actinobacillus pleuropneumoniae (AP) causes fibrinous, hemorrhagic, necrotizing pleuropneumonia in all ages of pigs. The Actinobacillus pleuropneumoniae exotoxins (Apx) are one of the major virulence factors of AP. Previous studies had revealed that pigs endotracheally inoculated with live AP bacteria resulted in the expression of proinflammatory cytokines in lungs, including IL-1, IL-8 and TNF-α; however, what types of cells and bacterial components involved in this process remained unidentified (1, 2). Therefore, the objective of this study was to examine whether AP serotype 10-derived exotoxin, ApxI, caused proinflammatory cytokines expression in porcine alveolar macrophages (PAMs), one of the first line defense cells in lung.

Materials and Methods
PAMs were obtained from 3- to 6-week-old healthy piglets through lavage. ApxI was harvested from the culture supernatant of AP serotype 10. For experiments, PAMs were treated with 0.5–1 CU/ml or heat-inactivated ApxI (ΔApxI) in the presence of polymyxin B for 2–4 h. The mRNA and protein levels of cytokine expression were determined by real-time reverse-transcriptase PCR (RT-PCR) and quantitative ELISA (Quantikine®, R&D system), respectively. Proinflammatory cytokines examined included IL-1β, IL-8 and TNF-α.

Results
To examine the protein expression level of cytokines under treatment with APP serotype 10 derived ApxI, cytokines IL-1β, IL-8 and TNF-α were determined by quantitative ELISA. Significant elevation of IL-1β, IL-8 and TNF-α were found in culture supernatants of PAMs at 4 h after stimulation with ApxI (image1). Levels of these cytokines in ΔApxI-treated group did not differ significantly from untreated control group, suggesting that the induction of cytokines was attributable to the bioactivity of ApxI.

To further examine the transcription levels of IL-1β, IL-8 and TNF-α genes expression, PAMs treated with ApxI were subjected to RT-PCR analysis. The results indicated that ApxI induced significantly higher mRNA levels of IL-1β, IL-8 and TNF-α in PAMs than that in ΔApxI or control group (image2). These data are consistent to the findings in quantitative ELISA and indicate that AP-derived ApxI induces IL-1β, IL-8 and TNF-α expression in PAMs.

Discussion
Overproduction of proinflammatory cytokines has been implicated in the AP-induced lung damage (1). In this study, we demonstrated that ApxI, in addition to its hemolytic and cytotoxic activities, induces the expression of IL-1, IL-8 and TNF-α in PAMs that might have a role in the pathogenesis of AP.

Introduction
Respiratory tract infections in pigs pose a severe economic problem to farmers due to immense costs for antibiotic treatments and increased mortality rate among piglets. Vaccines developed so far only alleviate clinical symptoms but do not prevent colonisation by the pathogens. Therefore there is a strong interest in the identification of genes which modulate the susceptibility of pigs to respiratory tract infections. This work was performed under the auspices of the project FUGATO-IRAS and the ongoing project RePoRI. The aim of the project is the development of genetic markers to predict resistance. By means of these markers a pre-selection of animals with reduced susceptibility to respiratory tract infections shall be enabled in breeding programs.

Materials and Methods
Highly informative microsatellite markers have been developed for 35 candidate genes. These genes belong either to the innate immune system (e.g. toll-like receptors) or are supposed to be directly related to an infection with A. pleuropneumoniae. For identification of suitable microsatellite motifs within or in proximity of the target gene genomic porcine sequences available in the NCBI database or shotgun genomic sequences from porcine BAC clones have been used. Genotyping was carried out using standardized PCR-techniques with subsequent direct-blotting and chemiluminescence detection of the products. By means of these markers two different objectives were pursued. The first aim was the investigation of the current gene pool in different pig populations in Germany. The second aim was the comparative genotyping of pigs from four different breeding lines with a mild or severe course of disease after infection with A. pleuropneumoniae in order to identify loci which modulate the susceptibility of the animals to respiratory tract infections. For the diversity study 74 samples from rare and / or old pig breeds and 69 samples from a consumer study (meat samples bought in supermarkets and butcheries in 30 cities all over Germany) were taken. For the association study 100 animals with defined phenotype after infection have been genotyped (infection model standardized by the Tierärztliche Hochschule Hannover).

Results
The diversity study revealed large differences of the allele distribution among the examined cohorts. The largest allele diversity was observed in the consumer study gene pool whereas the allele pool in the tested breeding lines showed less variation. Unique alleles were only observed in the wild boar population whereas the gene pools of the examined breeding lines represented parts of the consumer study gene pool at each marker locus.

The analysis of the association study data revealed statistically significant differences concerning the genotype distribution of the mildly and severely infected pigs at 7 marker loci mainly belonging to the interferon receptor and tumor necrosis factor receptor superfamilies.

Discussion
The next step will be the comparative sequencing of homozygous carriers of risk or resistance alleles respectively at the pre-selected loci to enable the identification of SNPs. With these data a haplotype analysis will be performed to minimize the genomic region responsible for the association.

Involvement of Mitogen-Activated Protein Kinases p38 and JNK in Actinobacillus pleuropneumoniae exotoxin ApxI-Induced apoptosis in porcine alveolar macrophages

Chi-Ming Wu1 Maw-Sheng Chien1 Nai-Yun Chang1 Zeng-Weng Chen1 Chih-Ming Liao2 Joey Yu3 Jiunn-Wang Liao1 Wei-Cheng Lee1 Shih-Ling Hsuan1
1. Graduate Institute of Veterinary Pathobiology, Taichung, Taiwan; 2. Animal Health Division, Bayer Taiwan Co., Ltd., Taipei, Taiwan; 3. Animal Health Division, Bayer Taiwan Co., Ltd., Taichung, Taiwan

Introduction
Actinobacillus pleuropneumoniae (AP) is the causative agent of fibrinous, necrotic and hemorrhagic pleuropneumoniae in swine. Actinobacillus pleuropneumoniae exotoxins (Apx) are one of the major virulence factors of AP (2). Our previous study has demonstrated that native ApxI at low concentration causes apoptosis in porcine alveolar macrophages (PAMs), one of the first line defense cells in lungs (1). However, the molecular mechanisms underlying ApxI-induced apoptosis are not well understood. Therefore, the aim of this study was to elucidate the signaling pathways mediating ApxI-induced apoptosis in PAMs with focuses on the effect of ApxI on mitogen-activated protein kinase (MAPK) and the role of MAPK in ApxI-induced apoptosis of PAMs.

Materials and Methods
PAMs were obtained from 3–6-week-old healthy piglets through lavage. The exotoxin ApxI of A. pleuropneumoniae serotype 10 was prepared from bacterial culture supernatant. For experiments, PAMs were treated with 0.5–1 CU/ml ApxI in the presence of polymyxin B for 0–6 h. The levels of active, phosphorylated MAPKs p38 and JNK were determined by Western blot analysis. PAMs were pretreated with a p38 inhibitor (SB203580) or JNK inhibitor (SP600125) for 1 h, followed by ApxI stimulation, Hoechst dye staining, and scored for apoptosis.

Results
To evaluate the potential role of MAPKs in ApxI effect, the phosphorylated p38 and JNK were assessed by Western analysis for the indicated time periods. The levels of phospho-p38 increased substantially and reached a plateau between 0.5 and 2 h post ApxI stimulation (Fig. 1A). The phospho-JNK isoforms were observed at 1 h post-treatment with ApxI and persisted to 4 h (Fig. 1B).

To further determine the involvement of p38 and JNK in ApxI-induced apoptosis, selective inhibitors was used to pre-treat PAMs prior to stimulation of ApxI and scored for apoptosis. The results indicated that addition of p38 inhibitor and JNK inhibitor caused a ~45% and ~35% reduction in ApxI-induced apoptosis, respectively (p < 0.05; Fig. 2). Co-administration of SB203580 and SP600125 prevented PAMs from ApxI-induced apoptosis almost completely (p < 0.001). These results demonstrated that p38 and JNK both contributed to apoptosis of PAMs in response to ApxI.

Discussion
In this study, it was demonstrated that both p38 and JNK were activated in PAMs stimulated with ApxI. Blocking activities of these two kinases rescued PAMs from apoptosis by ApxI. These findings suggest a crucial role of MAPK signaling in ApxI-mediated apoptosis.

Figure 1. ApxI activated MAPKs p38 (A) and JNK (B) in PAMs. PAMs were treated with 1 CU/ml of ApxI or left untreated for 0 to 6 h and subjected to Western blot analysis for phosphorylated p38 (p-p38) and JNK (p-JNK). Beta-actin served as a loading control.

Figure 2. p38 and JNK inhibitors attenuated ApxI-induced apoptosis in PAMs. PAMs pre-treated with 20 μM of p38 inhibitor SB203580 (SB), JNK inhibitor SP600125 (SP), or both were stimulated with ApxI for 6 h, followed by apoptosis scoring. * p < 0.05; *** p < 0.001. V, vehicle DMSO used to dissolve inhibitors.

Characterization of apxIVA of Actinobacillus pleuropneumoniae Korean isolate
Min-kyoung Shin; Seung-Bin Cha; Won-Jung Lee; Ji-Hyun Sung; Yu-Mi Roh ; Han-Sang Yoo
Department of Infectious diseases, College of Veterinary Medicine, Seoul National University, Seoul, Korea

Introduction
Actinobacillus pleuropneumoniae (APP) causes a highly contagious pleuropneumonia in pigs with major economic losses in pig farming worldwide. The four major RTX toxins ApxI, ApxII, ApxIII and ApxIVA are secreted by the different serotypes in various combinations. Compared to ApxI, ApxII and ApxIII, ApxIV is produced by all serotypes of APP, highly specific to APP and expressed only in vivo but not in vitro conditions. Based on the information in GenBank, apxIVA gene was sequenced after PCR amplification from A. pleuropneumoniae serotype 2 Korean isolate. ApxIVA of Korean isolate was analyzed and characterized using determined amino acid sequences after sequencing of the gene.

Materials and Methods
Primer sequences of apxIVA were designed according to the reference strain (GenBank accession No. AF021919). Primer walking method was performed for nucleotide sequences of unknown region of ApxIVA Korean strain. Extended PCR amplification and sequencing except apxIVA were performed to confirm sequences. ApxIVA of Korean isolate was determined amino acid sequences. Analyzed sequences of apxIVA were compared with the reference strains. In addition, the phylogenetic analysis was performed based on nucleotide and amino acid sequences compared with 5 different APP reference strains (GenBank accession No. AF021919, AF030511, CP000569, GQ332268 and CP000687) using MEGA 4.0 program. The regions of similarity between Korean isolate and the reference strains is represented by a dot-plot. The percent identity was performed based on nucleotide sequences and amino acid sequences compared with reference strains using MegAlign 5.0 DNASTAR. The determined amino acid sequences were analyzed to characterize bioinformatics of ApxIVA Korean isolate using ProtScale, emboss polydot and Hphob. / Kyte & Doolittle program.

Results
The full length nucleotide size of apxIVA was 5,856bps and confirmed by nucleotide sequencing. ApxIVA of Korean isolate was determined amino acid sequences with a predicted molecular mass of 218,124.77 Da and a theoretical pl of 4.76. ApxIVA Korean isolate gene is preceded immediately upstream by a ORF1. Upstream of ORF1, there is a stem loop structure. This stem loop structure is preceded the C-terminal end of mrp gene. LacZ gene is present the C-terminal of apxIVA. Stem loop structure is located between C-terminal of ApxIVA and LacZ. ApxIVA of Korean isolate was closely related to 5 different reference strains, showing 96.4, 96.1, 96.4, 96.8 and 98.4% nucleotide homology. ApxIVA Korean isolate showed 100, 95.2, 95.3, 96.2 and 98.2% homology compared with China(CP000569), Switzerland(AF030511), Canada, China(GQ332268) and Switzerland(AF021919) in amino acid level. Conserved region and repeats are easy to see in ApxIVA Korean isolate by dotplot program. The C-terminal part of ApxIVA Korean isolate contains 30 glycinerich nonapeptides with the consensus sequence L/V-X-G-G-X-G-N/D-D-X. The hydropathy plot of ApxIVA Korean isolate was shown by Hphob. / Kyte & Doolittle program. This analysis revealed a hydrophobic region at the N-terminus and a hydrophilicity in general region.

Discussion
The amplified apxIVA Korean isolate from A. pleuropneumoniae serotype 2 was confirmed and analyzed by sequencing. Nucleotide and amino acid sequences of whole apxIVA of Korea isolate were similar to the reference strain. Conserved region and repeats are shown in ApxIVA Korean isolate by dotplot program. There are 30 glycinerich nonapeptides with the consensus sequence in the C-terminal part of ApxIVA Korean isolate. The hydropathy plot of ApxIVA Korean isolate revealed a hydrophobic region at the N-terminus and a hydrophilicity in general region.

Efficacy of Protective Immune Response for Surface expressed Actinobacillus pleuropneumoniae ApxIIA in Saccharomyces cerevisiae in pig

Min-kyoung Shin1 Myung Hwan Jung1 Seung-Bin Cha1 Won-Jung Lee1 Yu-Mi Roh1 Jung-Mi Kim2 Ji-Eun Cho3 Dae-Gun Choi3 Dae-Hyuk Kim2 Han-Sang Yoo1

1. Department of Infectious diseases, College of Veterinary Medicine, Seoul National University, Seoul, Korea; 2. Research Center of Bioactive Materials, Chonbuk National University, Jeonju, Korea; 3. CTCBIO INC., Hwasung, Korea

Materials and Methods
Porcine alveolar macrophages were obtained from 8-week-old healthy piglets through lavage and isolated using previously described procedures (Iglesias et al., 1989). The cells were dispensed at a concentration of 1 x 106 cells/ml in 24 well microplates. The cells were stimulated with 4 x 105 cells/ml of vector control- and surface-displayed ApxIIA in S. cerevisiae and 1 μg/ml of LPS. After stimulation, the concentrations of secreted nitric oxide (NO), TNF-α and IL-6 were measured with ELISA (R&D SYSTEMS).

Three-week-old piglets were used in this study. Each experimental group consisted of 5 pigs was degminated into four groups; non-treated group, vector control group, oral vaccinated groups with surface-displayed ApxIIA in S. cerevisiae. This was followed by three-time administrations with gradually increasing amount of the vaccines with 1 week intervals. After last boosting, pigs were challenged by intra-tracheal and intra-nasal injection with A. pleuropneumoniae serotype 5 Korean isolate. ApxIIA-specific immune responses were measured in sera, nasal wash and fecal samples by ELISA. Protective activity was investigated by comparing clinical signs, pathological lesions and histopathologic analysis after challenge with A. pleuropneumoniae serotype 5 Korean isolate.

Results
The amount of secreted NO, TNF-α and IL-6 in the supernatant of porcine alveolar macrophages were measured after stimulation with vector control- and surface-displayed ApxIIA in S. cerevisiae, and LPS. While IL-6 and NO were not measured, the production of TNF-α from porcine alveolar macrophages increased time-dependently after exposure.

Discussion
The secretion of TNF-α was evaluated as a parameter of macrophages stimulation. Higher secretion of TNF-α was showed in the supernatant of macrophages exposed to surface-displayed ApxIIA in S. cerevisiae. Porcine alveolar macrophages did not produce any NO after stimulation. Present result lends support to the theory that porcine macrophage are not able to produce NO in vitro. Although the secretion of IL-6 was not almost induced after 24h of stimulation, supplementary experiment needs such as arrangement of experiment schedule and the amount of stimulants for confirmation of this conclusion.

Pigs immunized orally with surfaced-ApxIIA in S. cerevisiae maintained a higher ApxIIA-specific IgG response than the non-treated and vector control group in serum. ApxIIA-specific IgA titers of the vaccinated groups were a little higher than the non-vaccinated groups in serum and fecal sample. After challenge with A. pleuropneumoniae serotype 5 Korean isolate, scores of clinical signs and pathological lesions of vaccinated pigs were lower than those of the control group. Survival rate was high in the vaccinated group.

Biofilm formation in field isolates of Actinobacillus pleuropneumoniae

Corina Pascu; Luminita Costinar; Viorel Herman
Faculty of Veterinary Medicine, Timisoara, Romania

Introduction
Actinobacillus pleuropneumoniae is the causative agent of swine pleuropneumonia, a highly contagious and often fatal respiratory disease that affects pigs worldwide. Biofilms play a key role in the pathogenesis of many bacterial infections. As a first step toward understanding the mechanism of A. pleuropneumoniae biofilm formation and the role it may play in the pathogenesis of swine pleuropneumonia, we sought to develop methods to observe the biofilm phenotype in the laboratory, and to determine the prevalence of biofilm formation among various A. pleuropneumoniae field isolates from Romania. In this report we show that A. pleuropneumoniae forms biofilms in glass tubes. This phenotype is stable when A. pleuropneumoniae is cultured on agar but is rapidly lost when cells are cultured in broth.

Material and Method
All field isolates (30 strains) were from the lungs of pigs with swine pleuropneumonia. All isolates were tested for gram stain reaction and requirement for NAD. Bacteria were grown on BHI agar and broth or in Mueller Hinton broth. The media were supplemented with 0.1% of NAD. Cultures were incubated in air at 37ºC for 24 hours.

Results and Discussions
Strains formed thick biofilms at the air–liquid interface when cultured in glass tubes with agitation. The biofilm formation phenotype was maintained indefinitely when cultures were passaged on agar but was lost after one or two passages in broth. Our findings indicate that biofilm formation is a prevalent phenotype among A. pleuropneumoniae field isolates, and that this phenotype may have been previously overlooked because of its tendency to be lost upon subculturing in broth. Biofilm formation may have relevance to the colonization, pathogenesis and transmission of this bacterium.

Conclusions
Considering the ability of A. pleuropneumoniae strains to produce biofilm on the walls of test tubes in which they had been cultivated in BHI broth, as a defining indicator of adhesin production linked pathogenicity, there were found differences among the strains we isolated, only 56% of our strains had the ability to produce micro-colonies adherent to the tube walls, although all strains were hemolytic.

Loop-mediated isothermal amplification for detection of Actinobacillus pleuropneumoniae

Yang Wang; Pin Chen; Yang Chen; Hui Liu; Qiqai He
State Key Laboratory of Agricultural Microbiology, Huazhong Agricultural University, Wuhan, China

Introduction
Porcine contagious pleuropneumonia is a severe infection caused by Actinobacillus pleuropneumoniae (APP). Timely implementation of effective antimicrobial treatment depends on rapid diagnosis. The apxIVA gene was showed highly specificity in Actinobacillus pleuropneumoniae and does not exist in other species that closed to A.pleuropneumoniae. But not all the strains of A.pleuropneumoniae have high virulent. The strains that product APXI toxin were high virulent strains. Loop-mediated isothermal amplification (LAMP) method was a novel nucleic detection method with high specificity and sensitivity. Using the LAMP method targeting the apxIVA gene and apxl gene, we could rapidly and correctly detect A.pleuropneumoniae infection and the high virulent strains of A.pleuropneumoniae within 1 hour which is more rapid than conventional PCR.

Material & Methods
LAMP was carried out in 25 μL reactions containing 1.6 μM of each inner primer (FIP and BIP), 0.2 μM of each outer primer (F3 and B3), 0.4 μM of each loop primer (LF and LB), 1.4 μM deoxy-nucleoside triphosphates, and 1 M betaine (Sigma). Each LAMP reaction also included 20 mM Tris-HCl (pH8.8), 10 mM KCl, 10 mM (NH4)2SO4, 6 mM MgSO4, 0.1% Tween 20, 8 U of Bst DNA polymerase large fragment (New England Biolabs), and 1 μL of template DNA. The mixture was incubated at 63°C for 30 min in a water bath and heated at 80°C for an additional 10 min to terminate the reaction.

Results
The LAMP assay amplified the target gene within 30 minutes, and required only a laboratory water bath for the reaction to occur. The apxIVA LAMP and apxl LAMP respectively successful amplified all serovars of A. pleuropneumoniae and serovars of 1,5,9,10,11 which were high virulent strains of A. pleuropneumoniae. A total of 100 lung samples were collected from 100 pigs with apparent respiratory problems. The LAMP and PCR methods were also compared in field trials. Eighteen lung tissue samples tested positive for A. pleuropneumoniae by both apxIVA-nested PCR and apxIVA-LAMP methods. We also use apxl PCR and apxl LAMP for the 18 samples. Six samples were test positive by both apxl PCR and apxl LAMP. The PCR and LAMP have a great agreement.

Discussions & Conclusions
The LAMP is a novel nucleic detection method with high specificity and sensitivity. In our sensitivity test, we found that the sensitivity of LAMP assay is about 10 times more than that of conventional PCR. In the field trail, ApxIVA-LAMP picked up 10 additional positive samples that were missed by nested-PCR (p<0.0001, chi-square test). Based on the apxIVA gene and apxl gene, LAMP assay could detection of A. pleuropneumoniae infection and high virulent strains of A. pleuropneumoniae with 1 hour which is more rapid than conventional PCR. So the LAMP method is a alternative method for detection of A. pleuropneumoniae.

2. Utrecht University, Faculty of Veterinary Medicine, Dep. Infectious Diseases and Immunology, Utrecht, Netherlands

Introduction

Quantitative detection of Actinobacillus pleuropneumoniae (App) in live pigs is usually done by laborious and relatively non-specific selective bacterial examination techniques (SBE). PCR techniques for identification of App, described so far, are used for qualitative rather than quantitative detection. In this study we describe the design, development and validation of a quantitative real time PCR (qPCR) for the detection of apxIVA DNA, using previously described primers and a newly designed probe.

Material and Methods

BLAST homology search was performed in development of a probe sequence. A real time PCR protocol was developed for use in a iQ5 PCR machine. Commercially available hot start mix was combined with primers earlier described (APXIVANEST1-F and APXIVANEST1-R1) and a newly designed Taqman probe (with a 5’ FAM fluorescent group and at the 3’ end a BHQ group), dissolved in TE-buffer. DNA from pure App cultures and samples from pigs infected with App were isolated according to Instagene™ Matrix protocol2. Negative and process controls of DNA isolation and qPCR reaction were included to detect possible contamination. App species specific reactions were determined by testing DNA from pure cultures of 15 reference App serotypes, several field isolates of App and other Pasteurellaceae and bacterial swine pathogens. The analytical detection limit was determined with DNA from a 10-fold serial dilution of App serotype 1536 in saline, ranging from 1 – 5.0x10⁶ CFU/ml. The influence of target clinical material was tested in spiking experiments using the same App1536 dilution series and added to tonsil scrapings. Intra- and inter-assay reproducibility was determined by testing duplet dilution series in triplets on different plates (n=6). For validation with samples from pigs, material from live pigs was obtained from S. suis and App experimentally infected pigs using cotton swabs for samples from the ventral nasal meatus and toothbrushes for tonsil scrapings. Correlation of quantitative detection between SBE on CGVA plates3 and PCR was studied in samples from App infected pigs. DNA samples. Freezing (-20°C) of spiked samples before DNA isolation showed to be essential to prevent PCR inhibition. Optimalization and standardization of protocols have to be performed to minimize inter assay variability. Results from the correlation between qPCR and quantitative SBE of tonsil scrapings of App infected animals will be presented.

Results

The qPCR product was 377 base pairs. In non App species 26/26 PCR reactions were negative and in App reference serotypes 15/15 PCR reactions tested positive. The analytical detection limit was 1-5 CFU/reaction. Analysis of linearity showed that the regression coefficient of the slope = -3.30 (CI -3.36 - -3.25) and the intercept=42.77 (CI 42.5 – 43.0), with R²=0.99, corresponding to a PCR efficiency of 100% (CI 98.4 – 103.1%). Statistical analysis showed no significant intra-assay variability. An effect of inter-assay variability is observed on the intercept, showing the need to incorporate reference samples in each new assay. Small but non-significant inhibitory effects were found for testing spiked DNA samples. Freezing (-20°C) of spiked samples before DNA isolation showed to be essential to prevent PCR inhibition. Optimization and standardization of protocols have to be performed to minimize inter assay variability. Results from the correlation between qPCR and quantitative SBE of tonsil scrapings of App infected animals will be presented.

Discussion

The apxIVA qPCR could be a valuable alternative for quantitative SBE for the detection of App in samples from pigs. Strict compliance to sample handling and DNA isolation protocols is a prerequisite for reproducibility. Future experiments have to provide more data on optimal sampling sites in live pigs to provide an appropriate estimate of the App infection status of a pig. Sensitivity and specificity of the qPCR have to be determined in field validation experiments before implementation as a diagnostic assay can be considered.

Intervet-Schering Plough, Boxmeer, the Netherlands and Central Veterinary Institute, Lelystad, the Netherlands are greatly acknowledged for providing bacterial strains.

Identification of strain specific marker genes for Actinobacillus pleuropneumoniae infection in pig

Mario Drungowski1 Doris Höltig2 FUGATO consortium RePoRI2
1. ATLAS Biolabs GmbH, Berlin, Germany; 3. University of Veterinary Medicine Hannover, Hannover, Germany

Introduction
Bacterial respiratory tract infections cause severe losses to the pig industry in the European Union and worldwide. Genetic traits associated with porcine host resistance have not been identified to date. The aim of this project is the identification of strain specific genetic markers, putatively associated with resistance to infection caused by the bacterial respiratory tract pathogen Actinobacillus pleuropneumoniae (APP).

Materials and Methods
For the identification of candidate genes a well established aerosol infection model with APP was used. Pigs of three different strains (German Landrace, Pietrain and Hampshire) were infected, clinically monitored during the stages of infection and probed on day 4 (acute phase) post infection.

The samples were used for transcriptome analysis using the Affymetrix Gene Chip Porcine Genome Array enabling a genome wide analysis of porcine gene expression.

Results
In the course of the analysis we performed an intensive re-annotation of Affymetrix probe sets since the incomplete sequence of the pig genome still poses a challenge in genome wide data interpretation. We then applied analysis of variance (ANOVA) in order to identify potential strain specific marker genes. The genes identified as being strongly regulated post infection show important differences in the pig strains indicating strain-specific responses to APP lung infection. The candidates were further functionally characterised with enrichment analysis in order to identify affected molecular pathways. Here, we identified predominantly pathway components of immune response related mechanisms.
Improvement of APP vaccine through adjuvant selection

Introduction

Actinobacillus pleuropneumoniae (APP) is a gram negative bacterium responsible of severe respiratory disease in growing and in finishing pig. This disease is causing significant loss to farmers particularly when finisher pigs are involved. Improvement of existing vaccine can be safety and/or efficacy improvements but also to provide longer lasting protection allowing single vaccine procedure for a lifetime pig protection. Our studies demonstrate the ability of various adjuvants from Montanide™ range to improve the both safety and efficacy profile of pig APP vaccines.

Materials and Methods

Experimental vaccines: All experimental vaccine formulations were done by simple dilution of the antigenic media in the adjuvants under a gentle stirring. Various Adjuvants technologies were studied: oil in water emulsified formula (Montanide™ ISA 15 A VG), Polymeric adjuvant (Montanide™ Gel 01) and several nanoparticles based formula (Montanide™ IMS range). Two trials were performed to assess the safety and efficacy of experimental vaccines.

Trial 1: Montanide™ Gel, Montanide™ ISA 15 A VG, Montanide™ IMS 1335 VG, Montanide™ 2215 VG and Montanide™ IMS 251 C VG. A commercially available vaccine was used as positive control (oil in water emulsified adjuvant) as well as an aluminum salts based formula. The antigen media injected in saline buffer was the negative control. APP seronegative (PCR and ELISA-test) pigs weighting 10 to 15 kg were vaccinated intramuscularly in the neck twice with 1ml dose, 28 days apart. Groups of 7 pigs were used except for the negative control group where 9 animals were inserted.

Trial 2: Montanide™ Gel, Montanide™ ISA 15 A VG and Montanide™ IMS 1335 VG. The adjuvant ratio was reduced compared to trial one. APP seronegative pigs weighting 40 to 45 kg were vaccinated with 1ml intramuscularly in the neck and injection site dissected 14 days after injection. Groups of 4 pigs were used.

Data collected: Rectal temperature and behavior of the animals were followed during 3 days after each injection. Loins were dissected at the slaughterhouse in order to look for intramuscular local reactions. An internal scale was created allowing the scoring of observed local reactions. Blood samplings were performed before injection, 14 and 28 days after vaccine delivery. ELISA test on individual sera were performed at each sampling date to detect antigen specific IgG antibodies induced after vaccine injection. An infectious challenge was performed 38 days after first injection to assess the protection induced by the vaccines. Lung scoring was used to assess the level of protection in surviving pigs.

Results and Discussion

Trial 1: Pyrogenic reactions observed after vaccine delivery were insignificant whatever the vaccine (less than 1°C). Nevertheless, pigs showed a transient anorexia during 2 days after each injection. Two kind of local reactions were at the injection site observed: fibrosis and sterile abscess. Montanide™ IMS 251 C VG and aluminum based formula induced large local reactions while other formulation presented a low occurrence or even no local reaction. When comparing the ELISA results no significant differences could be observed in between groups whatever the sampling date. On the opposite, the challenge demonstrated that only two formulations were able to protect at 100% the animals: those formulas were based on Montanide™ IMS 1335VG and ISA 15 AVG.

Trial 2: Pyrogenic reactions observed after vaccine delivery were unmodified compared to trial 1. Injection site dissection showed that as early as 14 days post injection, the muscle presented a normal aspect at dissection for Montanide™ ISA 15 A VG and IMS 1335 VG group while small granulomatus fibrosis was observed for the Montanide™ Gel based formulation.

Montanide™ based formulations showed different behavior; best results were obtained with Montanide™ IMS 1335 VG and ISA 15 A VG reaching a 100% of protection without any impact on the animal welfare or meat quality. Surprisingly, compared to previously published data, the Gel based formulation induced local reactions in the injected muscle. These findings highlight the crucial importance of the antigenic media composition upon the vaccine performance.

Conclusion

Our study allowed identifying promising vaccine candidate compared to the existing vaccine available for pig farmers. The efficacy performances of our experimental formulations were identical to marketed vaccine while the local and general reactions were reduced these improvements of animal welfare also means a reduced risk of carcass blemish linked to vaccine adverse effect. Field experiments upon larger number of animal will now allow assessing the benefits of the new vaccine in terms of long term protection.
Sensitivity of Actinobacillus pleuropneumoniae biovars to three cephalosporins

Jaime Maldonado1 Laura Valls1 Susana Colomer1 Marta Fernandez2 Jesús Navas2
1. Laboratorios Hipra, Amer, Spain; 2. Facultad de Medicina, Universidad de Cantabria, Santander, Spain

Introduction
Swine pleuropneumonia (SP) caused by Actinobacillus pleuropneumoniae is traditionally controlled through antibiotic treatment. However, antibiotic resistance against widely used drugs like β-lactamics and tetracyclines has emerged (1). Currently, three generations of cephalosporins are recommended for the empirical treatment of SP. However, little is known about the quantitative activity of these compounds against A. pleuropneumoniae biovar 1 [nicotinamide adenine dinucleotide (NAD) dependent] and even less against biovar 2 (NAD-independent) strains, which are prevalent in some regions (2). We aimed to compare the in vitro activity of cephalexin, ceftiofur and cefquinome against clinical isolates of A. pleuropneumoniae, representing most prevalent serovars in biovars 1 and 2.

Materials and Methods
Minimum Inhibitory Concentration (MIC) determinations were performed by the macrodilution broth method with twenty-nine A. pleuropneumoniae clinical isolates belonging to biovar 1 (n=19) serovars 2, 4, 5, 9 and 11, and biovar 2 (n=10) serovars 2, 7 and NT (non-typable). Isolates (2002-2008) came from pneumonic lungs of pigs housed in fattening units located in seven Spanish provinces.

Bacterial inoculums (5 x10^5 UFC/ml) were grown on Veterinary Fastidious Medium broth supplemented with 0.025% of NAD at 37°C, 5% CO2 for 24-48h (3). The MIC value of each drug tested corresponded to the lowest concentration of the compound that completely inhibited the visible growth of the tested isolate under the established conditions. The cut-off for resistance of A. pleuropneumoniae to cephalexin and ceftiofur/cefquinome were MICs ≥32 μg/ml and ≥8 μg/ml, respectively.

Results and Discussion
Overall, cephalexin was the drug against which a higher number of isolates showed resistance and susceptible ones exhibited higher MIC values (always ≥1 μg/ml) (Table 1). Although only one strain was resistant to ceftiofur and cefquinome, when CMI values were compared at the strain level for these two compounds (data not shown) lower MICs were obtained in 15 isolates susceptible to ceftiofur, while cefquinome showed higher activity only against two isolates. The remaining 12 isolates that were susceptible to both drugs showed identical CMI.

We tested few samples in each biovar to establish differences in sensitivity between them in a reliable way. However, we observed a trend towards a higher average MIC values for biovar 1 isolates (data not shown). Ongoing work is focused on testing more isolates, particularly of the biovar 2 that seems to emerge as an important swine pathogen in some areas.

All together, these findings indicate that ceftiofur is the most active antibiotic against A. pleuropneumoniae compared to cephalexin and cefquinome.

Antimicrobial susceptibilities of Canadian isolates of *Actinobacillus pleuropneumoniae*

Marie Archambault; Julien Gouré; Josée Harel; Mario Jacques

*Université de Montréal, St-Hyacinthe, QC, Canada*

**Introduction**

*Actinobacillus pleuropneumoniae* is the causative agent of porcine pleuropneumonia, a severe and highly contagious respiratory disease responsible for economic losses in the swine industry worldwide. To date, 15 serotypes have been described based on capsular antigens (1, 2). Although antimicrobial resistance in *A. pleuropneumoniae* has been recently reported in Europe (3-5) and in Japan (6), the current situation in Canada is unknown. The aim of the present study was to determine the antimicrobial susceptibility patterns of 43 strains of *A. pleuropneumoniae* isolated in Canada.

**Materials and Methods**

Bacterial isolates and growth conditions. A total of 43 isolates were recovered from swine herds in Saskatchewan, Ontario and Québec (Table 1). Isolates were cultivated overnight on chocolate agar plates supplemented with PolyVitex at 37˚C with 5% CO₂.

**Table 1.** Distribution of the 43 clinical isolates by serotypes and provinces.

Antimicrobial susceptibilities. The antimicrobial susceptibilities of the isolates were determined by the micro-dilution method using the commercial BOPO1F Sensititre 96-well microtitre plates (Trek Diagnostic Systems Inc., UK) in Veterinary Fastidious Medium in accordance with the guidelines provided by the Clinical and Laboratory Standards Institute (CLSI, M31-A3). The plates were incubated for 20-24h at 35˚C in 5% CO₂. The minimal inhibitory concentration (MIC) value was considered to correspond to the first dilution at which no bacterial growth was detectable. The MICs that inhibited 50% (MIC₅₀) and 90% (MIC₉₀) of the isolates were also recorded. Resistance breakpoints were used according to the CLSI document M31-A3.

PCR detection of resistance genes. PCR amplification of resistance genes was performed using Taq DNA polymerase and specific oligonucleotide primers.

**Results and Discussion**

All isolates were susceptible to ceftiofur, florfenicol, tilmicosin and trimethoprim/sulfamethoxazole (Table 2). The mean % of resistance to penicillin and ampicillin was 16% based on the presence of the gene *blaROB-1*. Since there are no specific breakpoints for *A. pleuropneumoniae* for these drugs, we observed a high level of resistance to chlortetracycline (88.4%) and oxytetracycline (90.7%). The strains showing resistance to tetracycline antimicrobials contained at least one of the following tet genes: tetB, tetO, tetC, or tetH. The high level of resistance to tetracyclines is similar to what was previously reported in Spain (3). A low level of resistance was observed toward tiamulin (7%). Five isolates showed multi-resistance to β-lactam, aminoglycoside and tetracycline antimicrobials.

**Table 2.** MICs obtained for the 43 clinical isolates.

**Actinobacillus pleuropneumoniae (APP) Elimination with injectable Enrofloxacin and early weaning**

Hans Rotto¹ John Swart²

¹. IAS LLC Veterinary Clinic, Ames, IA, USA; ². Exemplar Genetics, Sioux Center, IA, USA

**Introduction**

*Actinobacillus pleuropneumoniae* (APP) is an economically significant pathogen in the swine industry.¹ The control of APP associated disease through feed medication and delivery can be difficult for some herds. The trial group was a 75 head sow herd farrow to finish operation composed of APP positive gilts, sows, and boars. The objective of this report was to eliminate APP serotype 3, 5 and 7 from the off-spring of an APP positive sow herd using only injectable antibiotics and early weaning. The APP negative off-spring would then be used to establish a new herd.

**Materials and Methods**

The APP elimination medication plan is as follows:

The first step was a whole herd (sows, gilts, boars and growing pigs on site) injection with Baytril at 1 cc/29.4 lbs. (7.5 mg/kg). The whole herd injection with Baytril was repeated five days later. Sows and gilts were injected again using the same dose two days prior to their projected farrow date throughout the duration of the elimination program. Piglets were given Naxcel (ceftiofur) per label dose at birth in combination with iron. Piglets were given 0.5 cc of Baytril at eight days of age and again at weaning. All piglets were weaned off-site by fourteen days of age into clean environments with limited risk for APP exposure. The first two nursery diets had Denagard / CTC in the ration post weaning. The feed was non-medicated after the first two rations.

The APP diagnostic test plan was as follows:

The first diagnostic tests were a serological examination of the herd prior to purchase. Following purchase, tonsil scrapings were pooled in groups of three and submitted for APP PCR testing to establish the current prevalence of positive pigs within the population. This same testing method was used for APP PCR testing of medicated early weaned pigs post-weaning. At maturity gilts and boars were serologically tested using the Multi-APP test to monitor for potential APP infection and/or spread.

**Results**

Before implementation, the initial screening of the herd using APP serotype testing showed positive pigs for APP 3, 5 and 7. Post purchase 24/26 pools of sows, boars and gilts were positive for APP by PCR. Two of five tonsillar pools from growing pigs, (6 to 14 weeks of age) were also positive. Approximately 30 days after the second whole herd medication treatment, nine random tonsil scrapings were pooled in groups of three from the resident herd and were negative by PCR. The first medicated early weaned pigs were sampled at approximately five weeks post wean and were individually negative by APP PCR and APP culture on tonsillar scrapings. Three tonsils from adult breeding stock were submitted and were negative by APP PCR and for APP culture. Later, eight pools of tonsil scrapings from growing pigs were submitted for APP PCR and were negative. Five months after the first pigs were weaned, serology was used to screen the oldest gilts. One positive test to the Multi-APP screen was found. Roommates were tested and 4/14 were serologically positive. The positive gilts were found to be positive for APP serotype 5 on further testing. PCR testing of ten pooled tonsil scrapings were negative in growing pigs. Due to the lack of spread between pen-mates and limited positive gilts on serology and APP PCR, it was determined that all breeding age gilts would be screened using the Multi-APP test. Any suspects or positives were not used for the re-population of the new herd. Serological testing of the gilts at six to eight months of age using the Multi-APP test determined that 4/61 gilts would not be used. No antibodies have been detected in recent tests of gilts at 6 to 7 months of age.

**Discussion**

APP negative gilts and boars were produced from the positive herd to establish an APP serotype 3, 5 and 7 free sow herd. Gilts have remained negative by PCR and culture of tonsillar scrapings for APP. The Multi-APP screening test detected some antibodies suggesting exposure in few individual gilts; however, there was no evidence of APP spread in pens, rooms or barns. On previous APP elimination trials Multi-APP serological screening has shown cross-reactivity with other APP serotypes.³ Test results indicate the herd has eliminated the APP 3, 5 and 7 from retained gilts and boars. The use of injectable Enrofloxacin and early weaning was successful in limiting the vertical spread of APP.

Efficacy of COGLAPIX® in susceptible piglets against a challenge with Actinobacillus pleuropneumoniae; evaluation of post-mortem findings, clinical data and immune response

Miklos Tenk1 Georges Országh1 János Benyeda2 Imre Bíksí3 Tamás Kis4 István Alapi1 József Herczeg1 Jérôme Thevenon1 Bálint Kupcsulik1 Botond Siklódi1 Benaouda Kadra1

Introduction
Actinobacillus pleuropneumoniae is a major pathogen of pigs causing porcine pleuropneumonia, which generates significant economical losses for the swine industry. Among other virulence factors, the APX toxins belonging to RTX toxin family play a significant role in the pathogenesis of A. pleuropneumoniae. The combination of bacterins and inactivated APX toxins have been shown to be cross-serotype protective. The bacterin-toxoid vaccine, Coglapix®, using the optimal combination of somatic antigens together with Apx toxins (ApxI, ApxII & ApxIII) has been developed to provide effective protection against infection caused by various serotypes of A. pleuropneumoniae.

Materials and Methods
Coglapix® and a competitor vaccine was injected to 9-week-old A. pleuropneumoniae sero-negative piglets 2 times 3 weeks apart, using the recommended dose of the vaccines. A group of non vaccinated animals was also included. Each group consisted of 8 animals. Seven weeks after the 2nd vaccination, the animals were challenged intranasally with a broth culture of a virulent serotype-2 A. pleuropneumoniae strain in a dose of 5*10^6 colony forming units per animal. Serum samples were taken on day (D) 0, D21, D35, D69 and D76. The animals’ immune response was followed with Swinecheck APP 2, Swinecheck APP 1, 9, 11 (Biovet, Canada) and ApxI, ApxII and ApxIII in-house developed monoclonal-antibody based ELISAs. After the challenge (D69), the animals were monitored daily for the presence of general and respiratory symptoms. The rectal temperatures were also measured on a daily basis from D69 to D76. The body weight gain was recorded between D69 and D76. After 1 week, (D76) the animals were slaughtered and necropsied. The lung changes were scored according to EP:1360. The App bacteria were recovered from the lungs using suitable culture methods. The microscopic lung lesions were observed in paraffin-embedded, haematoxylin-eosin stained sections.

Results
In this study, both Coglapix® and the Competitor vaccine showed similar protection in terms of preventing from lung lesions. The cumulative results of clinical and pathological observations are presented in Table 1.

</tbody>
</table>

The serological titers before vaccination have proven the seronegativity by all of the 5 ELISA systems used. The negative control group remained sero-negative until the date of challenge. Both vaccines induced high titers already with first vaccination, which was boosted by the second one. In general, the Competitor vaccine induced higher antibody titers against somatic antigens. Overall, the Competitor induced higher anti-ApxI titers, the anti-ApxII titers were similar whereas Coglapix® induced higher anti-ApxIII titers. The bacteriological culture results showed higher recovery rate from the Competitor-vaccinated group than the Coglapix®-vaccinated one, with a 2.25 times higher odds ratio.

Discussion
Coglapix® vaccine has proven to have similar protective features as the Competitor in this challenge. Further studies needed involving more challenge strains to prove the broad-range protective efficacy of the vaccine, which has already been shown under field conditions.

Clinical field trial of COGLAPIX® (App vaccine) in pigs in The Philippines

Romeo Sanchez2 Eric Brunier3 Georges Országh1 Miklos Tenk1 Benouda Kadra1 Jérôme Thevenon1
1. CEVA-Phylaxia Veterinary Biologicals Co. Ltd., Budapest, Hungary; 2. College of Veterinary Medicine, University of the Philippines, Los Banos, Philippines; 3. CEVA Animal Health Asia Pacific, Malaysia, Selangor, Malaysia

Introduction
A new Actinobacillus pleuropneumoniae (App) vaccine has been developed. The formulation of this new App vaccine was optimized to obtain a good balance between safety and efficacy. The vaccine was thoroughly evaluated in field conditions, in pigs in The Philippines, using competitor vaccines for the comparison.

Materials and Methods
Coglapix® contains inactivated, native Apx antigens (ApxI, ApxII & ApxIII) and somatic antigens of App. The vaccine is adjuvanted with aluminium hydroxide gel. It is administered by IM route (2 ml/pig) and two injections are given at 6 and 9 weeks of age.

This trial was carried out in The Philippines, in one farrow-to-finish farm, positive for App. Altogether, 300 pigs were allocated in 5 treatment groups (1 control and 4 vaccinated groups, Table 1.).

The vaccines were applied at 6 & 9 weeks of age. Precise clinical observations were performed on 15 pigs / group: general reactions and rectal temperatures. The bodyweights of all pigs were measured regularly (5 times) and feed conversion rate (FCR) was also calculated.

The seropositivity for App was tested before vaccination on 15 sows and 15 marketed hogs (5-6 months of age), using IDEXX CHEKIT APP-ApxIV ELISA kit.

From each group, 20 pigs were examined at slaughter where lung lesions were recorded using a scoring system of a maximum of 28/lung (4/lobe).

Results
Out of the 15 sampled sows 12 (80%), whereas from the 15 sampled hogs 5 (33%) was seropositive.

The average rectal temperature increase values by vaccine group are presented in Table 2.

Coglapix® vaccinated pigs have shown a better productivity performance than the other groups.

Coglapix® vaccinated pigs have had the lowest average lung lesion score at slaughter.

Discussion
In this trial, Coglapix® has shown an improved safety with no adverse reactions in minimum age piglets as well as the best trend of economical parameters.

Introduction
A new Actinobacillus pleuropneumoniae (App) vaccine has been developed. The formulation of this new App vaccine was optimized to obtain a good balance between safety and efficacy. The vaccine safety of a dose and of an overdose was thoroughly evaluated in susceptible piglets in laboratory conditions, in Hungary.

Materials and Methods
Coglapix® contains inactivated, native Apx antigens (Apxl, ApxxII & ApxIII) and somatic antigens of App. The vaccine is adjuvanted with aluminium hydroxide gel. It is administered by the IM route (standard dose: 2 ml/pig) and two injections are given from the age of 6 weeks to protect piglets as early as possible for the duration of the fattening period.

Safety of a maximum LPS content Coglapix® batch was evaluated at the youngest age (6 weeks) recommended in susceptible piglets as presented in table 1. The serological status of the animals was tested with Swinecheck APP 2, Swinecheck APP 1, 9, 11 (Biovet) and the CHEKIT APP-ApxIV (IDEXX) ELISA kits. Every pigs were observed for general and local reactions for 14 days after each injection. The rectal temperature was measured 3 days before vaccination, 2, 4, 6 hours after each injection and on the 4 consecutive days. Performance measurements were recorded (weight gain, appetite). The injection sites of each pig was palpated and examined at post-mortem, 2 weeks after the last injection (D28).

*AWG: average body weight gain

In laboratory conditions, the maximum rectal temperature increase after vaccination with Coglapix® was not higher than 1.5°C as required by the EU Ph even after the overdose administration. No general adverse reactions were observed after the administration of Coglapix® in both standard and overdose administrations.

Discussion
Coglapix® has shown a good safety even with a maximum LPS content batch in laboratory conditions.

Study on preventive effects of garlic on pigs experimentally infected with *Actinobacillus pleuropneumoniae* serotype 2

Norbert Stockhofe-Zurwieden¹ Henk J. Wisselink¹ Monique F. Mul² Petra M. Becker² Carola van der Peet-Schwering²

1. Central Veterinary Institute of Wageningen UR, Lelystad, Netherlands; 2. Wageningen UR Livestock Research, Lelystad, Netherlands

**Introduction**

*Actinobacillus pleuropneumoniae* (App) can induce severe (per)acute pleuropneumonia, but certain serotypes as serotype 2 are more known to cause chronic disease resulting in pleuritis or focal pleuropneumonia, often without overt signs of clinical disease (1).

Garlic is alleged to have antimicrobial properties (2) and antimicrobial in vitro effects on App from garlic-derived volatile allyl methyl sulfide (AMS) has been shown (3). In this study we wanted to investigate the possible preventive effect of garlic on the occurrence of clinical disease and pathology of a mild course of an experimental infection with App in pigs.

**Materials and Methods**

In two different studies pigs of about 7 weeks old from a herd free of App were used. Pigs were fed with a commercial freeze-dried garlic powder (Enteroguard™garlic). Garlic was added to the diet in increasing concentrations during 6 days with finally 5% or 10% at the day of challenge (Table 1).

During the aerosol inoculation three pigs were housed per run for 20 (Study I) or 30 minutes (Study II) in a 0.6 m³ stainless steel chamber. Aerosols of App serotype 2 reference strain 17399 were introduced with an Aeroneb™Pro micropump nebulizer (Aerogen Ltd., Ireland) from 5 ml inocula containing 10⁷, 10⁸ or 10⁹ CFU/ml (Table 1). During each inoculation run viability of bacteria was controlled by passing air from the aerosol chamber through an Anderson stage sampler. During the post infection phase of 4 days, pigs were monitored for occurrence of clinical signs, fever and changes in WBC. After euthanizing, pigs were examined pathologically and bacteriologically. In study II the relative lung weights were determined, comparisons were made between the treatment groups by using the Wilcoxon-Mann-Whitney two sample rank sum test.

**Results**

In the first study no clinical signs of an App infection were observed, fever was observed in 2 pigs from the garlic fed group and in 3 pigs of the control group. In 4 of 10 pigs of the control group and in 1 of 10 pigs in the garlic fed group small focal (pleuropneumonia) was found at necropsy. In the second study one pig of the control group died 24 hours after inoculation due to a severe pleuropneumonia. No differences were found in clinical signs between the two treatment groups. At necropsy small focal lung lesions were found in 7 of 15 pigs in the control group and in 5 of 15 pigs of the garlic fed group. The relative lung weight was increased in the control group compared to the garlic fed group (p = 0,06).

¹Fever ≥ 40°C; ²Relative occurrence of WBC of > 20G/L; ³Pathology lung; ⁴Re-isolation of App by culture

**Discussion**

A mild clinical course of infection was introduced in this aerosol challenge model of App. No clear differences in clinical signs were observed between the groups. A trend for an effect of garlic on pathology findings was observed.

It has to be emphasized, that the used concentrations of Enteroguard™garlic 5% to 10% far exceeded the concentrations applied in practice of 1%.

Study of some Actinobacillus pleuropneumoniae strains’ susceptibility at antimicrobials

Corina Pascu; Luminita Costinar; Viorel Herman; Ioana Vaduva; Bogdan Faur
Faculty of Veterinary Medicine, Timisoara, Romania

Introduction

The sensitivity of A. pleuropneumoniae to antibiotics and chemotherapics we studied showed a various and unstable behavior of this species, very different in time and place, dependent on the area and time of isolation, reason why the antibiogram represents an indispensable tool before a treatment is established in pig pleuropneumonia.

The goal of our research was to determine actual sensibility to antimicrobials of A. pleuropneumoniae strains isolated from farms situated in the west part of country, used NCCLS methodology.

Materials and Methods

The A. pleuropneumoniae strains studied were isolate from animal with clinical symptoms of pig pleuropneumonia from wean to finish and fattening farms.

All 40 strains were identified according well knowing methodology.

After completion of the susceptibility testing of the test strains and the quality control strain, we record the obtained results using zone-diameter in millimetres and categorize each of the tested strains as either “resistant” (R), “intermediate” (I) or “susceptible” (S) against each tested antimicrobial agent.

Results and Discussions

In all the 40 strains we examined in this study, the best results we found with fluorphenicol, tulathromycine, penicillin and tilmicozin. To be noticed that 3 of these belong to a newer class of antibiotics and only 66.6% of the strains were very sensitive to tilmicozin and 87.5% were very sensitive to fluorphenicol. Toward lincozamide (lincomycin), some blactamine (amoxicillin), aminoglycosides (gentamicin, streptomycin) the strains we studied had a moderate sensitivity, while they had a noticeable resistance toward amoxiklav, ampicillin, oxitetraciscin, enrofloxacin and cephalosporins, fact that urge us to contraindicate these antibiotics and chemotherapics (enrofloxacin) in the absence of an antibiogram which shows their sensitivity.

To be noticed that 20-30 years ago seemed an unquestionable truth the fact that all A. pleuropneumoniae strains are sensitive to penicillin, including the strains isolated in this area of the country, while nowadays 30% of the strains isolated by us are resistant to penicillin and it seems that is because of the excessive usage of this antibiotic in time. In this matter our results are similar to those of other authors.

Conclusions

Our studies show that an excessive usage of some antibiotics and chemotherapics in order to prevent or treat pig pleuropneumonia, especially using medicated food may have negative results, as the selection of resistant strains which in time may replace the sensitive strains to a certain antibiotic or chemotherapeutic that is used at random, without knowing the sensitivity of germs from the population.

Also it is worth mentioning that changes of sensitivity toward some antibiotics – tetraciclins and chemotherapics – quinolons were revealed during the present investigation, comparing the results obtained on strains isolated from the same population at an interval of about 6-7 months in which the antibiotics were administered continuously.

Introduction

The objective of the presented study was to describe different dynamics of humoral immune reply to intradermally (ID) administered gradually diluted antigen and find out the lowest dose of antigen, administered ID, able to invoke measurable humoral immune reply.

ID vaccination is known to be a very practical method of vaccination especially in pigs, able to save a lot of antigen and could increase the number of available doses of vaccine (1), easy to mass administer and without residual changes and/or abscedation in the meat of food animals, and transmission of infectious diseases (2).

An experimental vaccine against APP was used and gradually diluted. The lowest dose of antigen APP was not disclosed. In concentration 3.10^4, decided as very low, the IgG and IgM reply was measured in levels comparable to higher concentrations of APP antigen.

Material and Methods

Seven groups of SPF piglets were used (n=6) at age of 6 weeks of life. Experimental vaccine, based on commercial toxoid vaccine Suivac APP ID (Dyntec, CZ) was used and gradually diluted. Group 1 was vaccinated by full ID dose of vaccine, containing 6.0ug of equal mixture of APX toxoids, OMP and LPS. Groups 2 to 5 were vaccinated and revaccinated three weeks later by gradually diluted antigen in the vaccine – 3x, 9x, 27x and 81x. Group 6 was vaccinated by standard IM dose of Suivac APP IM (positive control, containing the same amount of antigen as ID dose), and group 7 was negative control group. Piglets were blooded weekly for 6 weeks after prime vaccination. Specific antibodies to APP APX were determined in blood serum using indirect isotype-specific ELISA procedure. Statistical software Statistica 9.0 was used for evaluation of the data. The results of serological examinations were expressed as arithmetic mean values of optical densities obtained by ELISA test. Significance of between-group changes detected by ELISA were assessed with Kruskal-Wallis nonparametric test.

Results and Discussion

The very low dose of antigen (27x dilution) administered by intradermal route induced comparable immune reply either in fast immune response of IgM, either of more permanent IgG antibody response. All dilutions of antigen, used in the trial, involved measurable and mostly strong immune reply. The lowest dose of APX antigen was not disclosed. In concentration 1:81, expected as very low, the IgM (data not shown) and IgG response (Figure 1) was measured in levels still comparable to higher concentrations of APP antigen.

Intradermal administration of vaccines was found not only involving measurable humoral protection (IgG and IgM) after administration of highly diluted dose, it was very effective in promoting a cytotoxic T cell response (data not shown). Attempts to dissect the mode of action of some intradermally administered vaccines by cytometric flow analysis of lymphocyte populations from the spleen, lung, liver and thymus revealed an effect of route of vaccine delivery upon the composition of specific lymphocyte subsets in these various organ compartments (3). In some cases lower dose of antigen in ID vaccination dose seems to be more effective in compare to standard IM dosage(4). The very low concentration, 1:81 dilutions, seemed to be too low to stimulate any reply after single administration of very low dose of antigen, but booster vaccination of the same thin dose involved measurable IgG and IgM response.

Introduction

The modern pig industry is managed by practices geared for maximum production efficiency. Strategies to reduce the impact of diseases and to promote welfare of animals are essential to ensure business survival. Mycoplasma hyopneumoniae (Mh) is the most important respiratory pathogen in the Brazilian pig industry. It impairs production efficiency and increases production costs. Better understanding of these costs associated with Mh outbreaks will assist Veterinarians and producers to come up with cost-effective biosecurity and health assurance programs, aiming to avoid or at least to minimize potential losses associated with outbreaks.

Considering the economic impact of Mh on pig industry worldwide and understanding that controlling important diseases is cost-effective, the objective of this work was to estimate the economic losses of a Brazilian farm that experienced an outbreak of enzootic pneumonia, disease caused by Mh.

Materials and Methods

This study was conducted from September to December 2009 in a 170 sows farrow-to-finish herd, located in the State of Goias, Brazil. This farm was free of Mh based on absence of clinical signs and routine serology monitoring. The clinical signs were first recognized on August, when diagnosis was established by clinical examination, gross pathology and histopathology. The analysis and economic evaluation were based on the mean change of death rates of farrowing, nursery and growing/finishing pigs, as well as the expenses of additional drugs, vaccines and feed intake. The periods used for comparison were (1) the average from April to July, when the farm was serologically free of Mh and (2) the average from September to December, period post infection.

Results and Discussion

The death rate of farrowing piglets rose from 7.2% to 12.37%. At nursery, the change was from 1.33% to 25.17% and at growing-finishing period, the death rate jumped from 2.9% to 5.85%. The mortality rates before the outbreak were in accordance with the expected losses for Brazilian pig farms as suggested by Sobestiansky et al (2007).

The phase that had the higher spike in mortality was the nursery, what was expected and can be explained by the fact that piglets probably got infected at the farrowing barns by their dams. The increase of mortality in preweaning piglets was higher than usual in a Mh outbreak and can be explained by the fact that the average weaning age of this farm was 30 days of age. We believe that interaction of other pathogens such as Circovirus and Pasteurella with Mh infection have contributed to the increase of mortality rates.

The expenses from September to December 09 with Mh-vaccines, anti Mh-drugs and with ration that was fed to animals that died with Mh clinical signs was computed US$ 33,600. When we consider that these extra animals that died after the outbreak could have been sold to slaughter at weight of 95 kg, after discounting the cost with feeding, the lost value was US$ 15,800. Combining both costs, the total loss with this outbreak from September to December was US$ 49,400.

Conclusion

The high economic losses associated with an outbreak of enzootic pneumonia, in the form of deaths and cost of therapy, corroborates the need for establishing effective preventive measures. Biosecurity protocols can prevent the entry of pathogens especially by the introduction of positive animals in the herd and control of fomites and transit of vehicles, since these pose potential risk of disease transmission.

Colonization, serologic and parity state to Mycoplasma hyopneumoniae in vaccinated sows and their piglets

Pablo J. Tamiozzo; Alicia I. Carranza; Bibiana R. Pelliza; Carlos Goñi; Arnaldo Ambrogi
Universidad Nacional de Rio Cuarto, Rio Cuarto, Cordoba, Argentina

Introduction
Mycoplasma hyopneumoniae (Mh) is the etiologic agent to Enzootic Pneumonia (EP). The transmission can occur horizontally from infected pigs to naïve pigs or vertically from sow to its piglets (1). It has been suggested that sow-to-piglet transmission may be influenced by sow parity (2-4) but the results are controversial. Due the fact sow vaccination did not affect piglets’ colonization (5) and the different results about serologic and colonization status of sow and piglets according to parity distribution the objective of this study was to determinate colonization, serologic and parity status on Mh multiple-vaccinated sows and their piglets.

Materials and Methods
A 4100-sow, multiple-site herd was selected to carry out this study. Mh vaccination was used in sows, gilts and boars (at least with five doses of vaccines against Mh ((RespiSureONE, Pfizer, Argentina)). This vaccine scheme had been adopted since 3 years before. A longitudinal study was performed. Eighty-two sows were selected (being 15% of the weekly farrows). All parturition distribution was considered in each sampling time (1st- 9th). From each sow two piglets were randomly selected; (one hundred and sixty-four piglets). None of these piglets were cross-fostered. Blood samples for ELISA (HerdChek® Mycoplasma hyopneumoniae, IDEXX, Maine, USA) and nasal swabs for nPCR (6) were taken in the sows, at 0 day of gestation, at 8 weeks pre-farrowing and 2-5 days post-farrowing, and on the piglets at 2 weeks old. In order to study the effect of parity number, sows were divided into the following groups: A- low parity number (1-2), B- intermediate parity number (3-4), C-high parity number (5-6) and D- Very high parity number (7 or higher). The median Optical Density (OD) values of sera were calculated to compare seropositive sows and piglets according to different parity distribution and to compare seropositive sows at different sampling time.

Results
The results are shown in tables 1 and 2.

Table 2. Median and range of Optical density (OD) according to parity distribution in sows and their piglets.

Discussion
The percentages of seropositive sows were higher than the obtained in previous studies (6, 5). However, seronegative sows were found. This, may be explained by the fact that vaccine efficacy is not 100%, in addition to the existence of subpopulations of susceptible animals (7), and/or different responses to vaccination (8). Through different sampling time, the proportion of seronegative sows in group B was greater than the others groups, these result are according to previous studies (2, 4) and would indicate that young sow group B are more likely to transmit Mh to their piglets. The highest level of nPCR positives was found at 8 weeks pre-farrow and in this sample the OD value (from seropositives sows only) was lowest. That suggests that while protective antibodies decreased, exists a major shedding of Mh due to the decline in vaccine antibodies (9) or the protective antibodies are transferred from the blood to the udder in agreement with previous studies (10). At post-farrowing sampling time, the OD values increase according to parity number of sows (and their piglets). This suggests that the increased maternal antibodies concentration is not completely due to vaccination but also the repeated exposure of sows to Mh under field condition.

Respiratory diseases – Mycoplasma hyopneumoniae
Retrospective study on *Mycoplasma hyopneumoniae* infections in suckling and nursery pigs

Heiko Nathues1 Rene Kubiak2 Regina Tegeler1 Elisabeth Grosse Beilage1
1. Field Station for Epidemiology in Bakum, University of Veterinary Medicine Hannover, Bakum, Germany;
2. Boehringer Ingelheim Pharma GmbH & Co KG, Ingelheim am Rhein, Germany

Introduction

*Mycoplasma hyopneumoniae*, the causative agent of porcine enzootic pneumonia, is predominantly transmitted through nose to nose contact between animals and more infrequently by aerosol, maintaining horizontal spread of the agent from infected to naive pigs of the same age, or via vertical transmission from sows to their offspring (2). If the latter occurs frequently, it is suggested that vaccination of suckling piglets during their first days of life may assist *M. hyopneumoniae* control (1). However, only a few studies have surveyed the infection of suckling and nursery pigs under field conditions and the results are inconsistent. The main objective of our study was to evaluate the occurrence of *M. hyopneumoniae* infections in suckling and nursery pigs originating from a broad range of farms located in a region with intensive pig production and a high pig density.

Material and Methods

A retrospective analysis was applied to data obtained by routine diagnostics over two consecutive years from a laboratory working as specified in the ISO/IEC 17025:2005. Herd parameters were amended on the basis of enquiries with the herd-attending veterinarians. A correlation between the detection of *M. hyopneumoniae* in lung tissue on one hand and the vaccination history of the herd, the lung and pleura lesions examined during necropsy, and the detection of other respiratory pathogens on the other hand was tested during further data analysis. The list of parameters was divided into suitable subsets and each individual parameter was considered initially by conducting a Chi-Square analysis to examine the independence of the respective parameter levels and the occurrence of a *M. hyopneumoniae* infection. A linear logistic regression model was then used to examine the relationship between the binary response of *M. hyopneumoniae* detection and a set of explanatory variables which were defined by all infectious agents that were found to be significant (P<0.05) in the individual considerations. The log odds function (LOGIT) was used as a link function.

Results

The occurrence of *M. hyopneumoniae* infections in young pigs was surveyed on 1,122 datasets, where either suckling or nursery pigs were examined for *M. hyopneumoniae* in lung tissue. Findings were correlated with lung lesions, detection of other respiratory pathogens, vaccination history and parameters describing the herd of origin. The prevalence of *M. hyopneumoniae* in lung tissue from suckling pigs (n=201) was 2.0% and, thus, significantly lower than in lungs from nursery pigs (n=921), which was 9.3%. Previous use of antimicrobials and vital status of the pigs when delivered for necropsy did not influence the detection of *M. hyopneumoniae* infection. The presence of PRRSV-EU genotype, *Pasteurella multocida*, *Haemophilus parasuis*, *Mycoplasma hyorhinis* or *Streptococcus suis* was correlated with a higher probability of also finding *M. hyopneumoniae*. Positivity for *H. parasuis*, *M. hyorhinis* and *S. suis* strongly indicated the presence of *M. hyopneumoniae*. Neither vaccination (yes/no), the time of first/second application nor type of vaccine (one-shot vs. two-shot) influenced the detection of *M. hyopneumoniae*. Correlation between “type of herd” and presence of *M. hyopneumoniae* was statistically insignificant and no effect of farrowing rhythm could be confirmed.

Discussion

The model of a retrospective study is, on one hand, lacking in the possibility of standardisation in sampling, e.g. number and age of animals, and, moreover, the possibility to further examine the samples. On the other hand, the analysis of datasets from routine diagnostics can provide representative data from the field, if inclusion and exclusion criteria are well chosen to rule out a selection bias (3). For the present analysis 1,122 dataset entries from a nationwide operating laboratory were included, representing 27.5% of all examined pigs over a period of two entire years. This study corroborates the infrequent occurrence of *M. hyopneumoniae* infection in suckling and nursery pigs under field conditions. It also underlines the low prevalence and rules out any significant impact of vaccination on the frequency and time of the infection.

Cloning and expression of pyruvate dehydrogenase E1-α subunit from Mycoplasma hyopneumoniae in Escherichia coli

Chung-Nan Weng
Animal Technology Institute Taiwan, Taipei, Taiwan

Introduction
Mycoplasma hyopneumoniae is the causative agent of swine enzootic pneumonia (SEP), one of the most important chronic respiratory diseases that affects swine production worldwide. The pathogen results in considerable economic losses through retarded growth, poor food conversion and increased susceptibility of pigs to infections by other organisms. Prevention of SEP may be achieved by improving hygiene and management in pig farms. In addition, vaccination is an effective strategy for control and prevention of SEP [1]. Commercial M. hyopneumoniae vaccines were prepared from killed bacteria (bacterins). However, mass production of M. hyopneumoniae vaccine employing the complicated cultivation method is expensive and time consuming. The use of specific immunogenic proteins as subunit vaccines produced by recombinant DNA technology may be a preferable alternative to the use of killed bacteria. In our previous research, 19 immunogenic proteins of M. hyopneumoniae PRIT-5 were identified using an immunoproteomic approach [2]. These immunogenic proteins are potential subunit vaccine candidates. In order to evaluate the immunogenic proteins as subunit vaccines, cloning and expression of genes encoding immunogenic proteins in heterologous expression systems is needed. In this report, we describe the cloning and expression of a gene encoding immunogenic pyruvate dehydrogenase E1-α subunit (PdhA) from M. hyopneumoniae PRIT-5 in Escherichia coli.

Materials and Methods
The pyruvate dehydrogenase E1-α subunit gene (pdhA) was amplified by polymerase chain reaction (PCR) from M. hyopneumoniae PRIT-5 genomic DNA template followed by TA-cloning. In order to replace mycoplasma-specific TGA (Trp) codons in the cloned pdhA gene, which did not allow its full length expression in E. coli, by the universal TGG codon, the overlap extension-PCR method was used. The silent mutated pdhA was cloned into pET29a-D. The resulting plasmid, pET-DPdhA, was transformed into E. coli BL21 (DE3) for expression of PdhA. Protein expression was induced with 1 mM isopropyl-β-D-thiogalactopyranoside. The cell pellet of E. coli was collected and analyzed by SDS-PAGE and western blot. Recombinant PdhA produced by the E. coli expression system was purified from cell pellet by immobilized metal-ion affinity chromatography (IMAC).

Results
The pdhA gene was cloned by PCR. DNA sequence analysis showed that the pdhA consists of an open reading frame of 1,125 bp coding for a 374-amino acid residues and contains 8 TGA codons. The deduced amino acid sequence of M. hyopneumoniae PRIT-5 PdhA showed high degree identity (99%) compared with PdhA from other strains including J, 232 and 7448. In order to correctly express the PdhA in E. coli, all the TGA codons carried by pdhA were mutated in TGG. The mutated pdhA was further cloned into E. coli expression vector and expressed in E. coli as a recombinant fusion protein containing a hexahistidine N-terminal sequence and λ capsid protein D in insoluble form. Recombinant PdhA could be purified from E. coli by IMAC (Figure 1).

Discussion
In this study, we reported the successful cloning, expression and purification of pyruvate dehydrogenase E1-α subunit from M. hyopneumoniae PRIT-5. The purified recombinant PdhA will be further used for the purpose of immunobiological studies.

**Introduction**

Enzootic pneumonia (EP), also called mycoplasmal pneumonia, is recognized as one of the most economically significant swine respiratory diseases. The etiological agent of this disease, \textit{M. hyopneumoniae} (Mh), attaches to the ciliated epithelial lining of the respiratory tract, resulting in impairment of the mucociliary mechanisms, predisposing to secondary bacterial infections. Vaxsafe\textsuperscript{®} MHP is a live temperature sensitive Mh strain that is being developed by Bioproperties Pty Ltd (Australia) as the first live vaccine against EP.

**Materials and Methods**

Forty (40) SPF pigs 3 weeks of age were used in this study. All pigs were ear tagged with an individual number, weighed and assigned to 4 study groups each containing 10 pigs housed under the same conditions in negative pressure isolation rooms. Pigs were acclimatized for 3 days before treatment.

Group 1 was the Negative control. Pigs within this group were administered vaccine diluent. Group 2 was vaccinated with Vaxsafe\textsuperscript{®} MHP. Pigs within group 3 were vaccinated with an inactivated commercial vaccine. Group 4 was the positive control. Vaccination day was designated as “days post vaccination-zero” (DPV-0). Vaccination with Vaxsafe\textsuperscript{®} MHP was performed by intranasal spray and the commercial vaccine was administered by intramuscular injection. Vaccinated pigs were allowed to develop immunity over a period of 22 days, and subsequently they were challenged on two occasions with live culture of Mh IOWA strain 194 administered by aerosol at a dose of \textasciitilde 106.0 ccu/mL/45 minutes in a chamber specifically designed for pigs. On the first round pigs were challenged three times at 4 days apart ie. DPV 22, 27 and 32. All groups were then subjected to a second round of challenge with a similar live culture of Mh administered on 3 consecutive days (DPV-84, -85 and -86). Post-mortem examinations were performed 19 days after the second round of challenge (DPV-105). A number of parameters were employed in order to achieve the objectives of this study including assessment of clinical signs, nasal swabs (nPCR) at post-mortem, gross lung lesions typical of Mh infection were recorded on lung lesion diagrams employing the planimetric method.

**Results**

The planimetric scoring method was used to determine the average percentage area of affected lungs for each group. Small lesions (unrelated to Mh as demonstrated by nPCR results) were found in the negative control group. Pigs in the positive control group showed lesions affecting an average of 10.98% of the lung (Table 1).

A significant reduction in the severity of lung lesions (1.34%) was observed in the pigs vaccinated with Vaxsafe\textsuperscript{®} MHP. By comparison a higher lesion score (6.93%) was detected in the pigs vaccinated with the commercial inactivated vaccine. There were significant differences (P≤0.05) in the severity of lung lesions between groups vaccinated with Vaxsafe\textsuperscript{®} MHP and the positive control group. However, there was no significant difference (P≥0.05) between group vaccinated with a commercial vaccine and the positive control group.

<table>
<thead>

</tbody>
</table>

No significant difference in the incidence of lung lesions was observed between the Vaxsafe\textsuperscript{®} MHP and the commercial inactivated vaccine groups.

ELISA tests performed on the two vaccinated groups showed 78% positive for the inactivated vaccine but only 12.5% positive for the live Vaxsafe\textsuperscript{®} MHP vaccine.

Conclusions: Following challenge, Vaxsafe\textsuperscript{®} MHP provided a significantly higher level of protection against severity of lung lesions compared with an inactivated commercial vaccine. This study also showed that ELISA (commercial) assay is not a good indicator for protection provided by this live vaccine.

**Introduction**

Enzootic pneumonia (EP) of swine, also called mycoplasmal pneumonia, is recognized as one of the most economically significant swine respiratory diseases. The etiological agent of this disease *M. hyopneumoniae* (Mh) attaches to the ciliated epithelial lining of the respiratory tract, resulting in impairment of the mucociliary mechanisms, predisposing to secondary bacterial infections. Pigs affected with the disease show poor conversion and thus low weight gain. Vaxsafe® MHP is a temperature sensitive Mh strain that is being developed by Bioproperties Pty Ltd (Australia) as the first live vaccine against EP.

**Materials and Methods**

Forty (40) SPF pigs 3 weeks of age were used in this study. All pigs were ear tagged with an individual number, weighed and assigned to 4 study groups each containing 10 pigs. All groups were housed under the same conditions in negative pressure isolation rooms. Pigs were acclimatized for 3 days before treatment.

Group 1 was the Negative control. Pigs within this group were administered vaccine diluent. Group 2 was vaccinated with Vaxsafe® MHP. Pigs within group 3 were vaccinated with a commercial vaccine. Group 4 was the positive control. Vaccination day was designated as “days post vaccination-zero” (DPV-0). Vaccination with Vaxsafe® MHP was performed by intranasal spray and the commercial vaccine was administered by intramuscular injection. Vaccinated pigs were allowed to develop immunity over a period of 22 days, and subsequently they were challenged on two occasions with live culture of Mh. IOWA strain 194 administered by aerosol at a dose of ~106.0 ccu/mL/45 minutes in a chamber specifically designed for pigs. On the first round pigs were challenged three times at 4 days apart. DPV 22, 27 and 32. All groups were then subjected to a second round of challenge with a similar live culture of Mh administered on 3 consecutive days (ie. DPV 84, 85 and 86). Post-mortems were performed 19 days after the second round of challenge (DPV-105). A number of parameters were examined in order to achieve the objectives of this study including assessment of growth performance.

**Results**

Vaccinated groups showed increased weight gain compared to the positive control group. However, analysis of variance for weight gain between the positive control group and the vaccinated groups indicated that the increase was significant (P≤0.05) only for Vaxsafe® MHP and the negative control group (see Table 1).

</table>

P values in parenthesis

No significant difference (P≥0.05) in weight loss was observed between the vaccinated groups and the negative control group. Only the positive control group showed a significant (P≤0.05) weight loss due to challenge (Table 1).

**Conclusions**

Vaxsafe® MHP showed a significant difference with respect to weight gain in comparison to the commercial vaccine. An average increase in weight of 7.5 kg was observed for the group vaccinated with Vaxsafe® MHP compared to the positive control. The group vaccinated with a commercial vaccine on the other hand did not show any significant difference in weight gain when compared to the positive control group. Compared to the negative control, the group vaccinated with Vaxsafe® MHP lost only 2 kg while the group vaccinated with a commercial vaccine lost 3.9 kg following challenge.

1. Laboratorio Avimex, Mexico City, DF, Mexico; 2. FES-C UNAM, Cuautitlan, MEX, Mexico; 3. CENASA, Tecamac, MEX, Mexico; 4. Bioproperties Pty Ltd, Victoria, VIC, Australia

**Introduction**

*M. hyopneumoniae* (Mh) is the etiological agent of enzootic pneumonia (EP). The organism attaches to the ciliated epithelial lining of the respiratory tract, resulting in impairment of the mucociliary mechanisms, predisposing the lungs to secondary bacterial infections. Vaxsafe® MHP a temperature sensitive Mh strain that is being developed by Bioproperties Pty Ltd (Australia) as the first live vaccine against EP.

**Materials and Methods**

Forty (40) SPF pigs 3 weeks of age were used in this study. Group 1 was the Negative control. Pigs within this group were administered vaccine diluent. Groups 2, 3, 4 and 5 were vaccinated with Vaxsafe® MHP at 103, 104, 105 and 106 ccu per dose, respectively. Group 6 was vaccinated with a commercial inactivated vaccine. Group 7 was the positive control. All the details concerning the vaccination and challenge processes are included in other papers of the series. Representative lung samples were collected and fixed in 10% buffered formalin. Routine paraffin inclusion and HE stains were performed.

**Results**

Histopathological examination of lesions showed typical bronchopneumonia with mononuclear and polymorphonuclear cell infiltrate and BALT hyperplasia. A clear correlation was observed between the vaccine dose administered and the severity of the lesions. Increasing doses of vaccine resulted in milder manifestation of lesions with the highest vaccine dose resulting in a severity score of 1.34% (Table 1). The lowest dose of Vaxsafe® MHP resulted in a severity score of 4.38%. However, this will still lower than the severity of lung lesions observed for the inactivated vaccine (6.93%) which was delivered at the commercial dose. Negative control showed lung lesions unrelated to Mh infection as shown by nPCR test results.

**Conclusions**

The use of Vaxsafe® MHP resulted in a notable reduction of severity of lung lesions (explained as percentage of lung area affected), but not in the absence of lesions. This is in direct relation to the vaccine dosage.

Simultaneous vaccination of pigs with SPRINTVAC® and PESTIFFA®

H.C. Lim¹ B.K. Lim² P.Y. Choo³ Henry Too⁴
1. Rhone Ma Malaysia (M) Sdn Bhd, Selangor, Malaysia; 2. Vet Food Agro Diagnostic (M) Sdn Bhd, Selangor, Malaysia; 3. Asia Pacific Special Nutrients (M) Sdn Bhd, Selangor, Malaysia; 4. Merial Asia Pte. Ltd, Selangor, Malaysia

Introduction

The administration of different vaccines simultaneously often gives rise to concerns about safety and efficacy. A previous study on the simultaneous use of Merial vaccines in sows showed no adverse effects on safety and similar immune responses (1). However, there has been no study on the simultaneous use of mycoplasma vaccines with swine fever vaccines in piglets. The present study was conducted to evaluate the safety and serological response induced by the two vaccines, SPRINTVAC® and PESTIFFA™ (Merial) used for the control of swine enzootic pneumonia (SEP) and classical swine fever (CSF) respectively following simultaneous administration to piglets.

Material and Methods

Twenty four 4-week old weaners from farm known to be free of Aujeszky’s disease, Porcine Respiratory and Reproductive Syndrome (PRRS) and CSF were randomly allotted to 3 groups (Table 1), i.e. vaccinated intramuscularly (IM) in the neck with SPRINTVAC and PESTIFFA on the same day (Group S), vaccinated IM with PESTIFFA 5 days after SPRINTVAC (Group NS), and not vaccinated (Control group). When simultaneous vaccination was performed, the vaccines were injected on opposite sites on the neck region. All pigs were housed in adjacent pens and managed in same manner throughout the trial period.

Weekly serum samples from 4 to 10 wks of age and at 12 and 20 weeks of age were tested for antibodies to M. hyo and CSF using IDEXX test kit, and Hipra CIV swine fever test kit respectively. The effects of local site reactions and anorexia were observed for up to 3 weeks after vaccination.

Results and Discussion

The serological profiles for mycoplasma and swine fever antibodies are shown in Figures 1 and 2.

Seven (87.5%) of pigs from Group S seroconverted to PESTIFFA 2 weeks post vaccination. Only 25% of pigs from NS group seroconverted at three weeks post vaccination. CSF antibodies were detected in all pigs at 4 weeks (Group S) and 5 weeks (Group NS) post vaccination.

Three (37.5%) of the pigs from NS group seroconverted two weeks following SPRINTVAC vaccination while all but one (87.5%) of the pigs from S group seroconverted 3 weeks post vaccination. Seroconversion rate for both groups at 5 weeks post vaccination remain above 90% until the age of 20 weeks old. Seventy-five per cent of pigs from control group were seroconverted at the age of 20 weeks old. This is ascribed to field challenge of Mycoplasma hyopneumoniae.

There were no adverse local reactions to the vaccinations or anorexia observed post-vaccination.

Conclusion

In this study, no adverse local reactions or anorexia were observed with the simultaneous vaccination SPRINTVAC and PESTIFFA. The serological responses were similar in both simultaneous vaccination and non simultaneous group.

Safety and Efficacy of a novel live vaccine for Mycoplasma hyopneumoniae: Vaxsafe® MHP

Youssef Abs EL-Osta; David Tinworth; Rima Youil
Bioproperties Pty Ltd, Bundoora, VIC, Australia

Introduction

Vaxsafe® MHP is a live temperature sensitive vaccine developed by Bioproperties Pty Ltd for the protection against Mycoplasma hyopneumoniae (Mh) infection in pigs. Vaxsafe® MHP has been developed in two formats: wet frozen (WF) and freeze dried (FD). A number of in vivo studies have been completed which assessed safety, efficacy and colonization of Vaxsafe® MHP in target animals following intra-nasal administration. In this paper two regulatory based studies will be presented.

Materials and Methods

Study 1: Six-week-old healthy Mh free commercial pigs were used in this study. A dose of 109.3 ccu/mL of Vaxsafe® MHP (WF) was tested for safety. The regulatory guidelines for live vaccines stipulate that safety of a 10 times (10X) overdose should be tested. The dose of 109.3 ccu represents a significant overdose of the vaccine surpassing the established 10X overdose by 1000 fold. This study also investigated efficacy of Vaxsafe® MHP (WF) at doses of 105.7, 106.9 and 108.0 ccu/mL. Positive and negative control groups were included. At 22 days post vaccination (DPV), all groups except the negative control group were challenged by intra-nasal spray with Mh wild type strain.

Study 2: Three-week-old healthy Mh free commercial pigs were used in this study. A dose of 105.0 ccu/mL of both the WF and FD formats of Vaxsafe® MHP were tested for efficacy. A group of pigs given a commercial inactivated vaccine as well as positive and negative control groups were also included in this study. Groups vaccinated on DPV-0 as well as the positive control group, were challenged by intra-nasal spray on two occasions (DPV-24 and -67) with Mh wild type strain. Post mortem was conducted at DPV-102. Safety of Vaxsafe® MHP (FD) was also investigated at a dose of 108 ccu/mL. This dose was at least 10-fold higher than the expected maximum release titre (MaxRT) of the vaccine.

Results & Discussion

Study 1: The safety profile indicated that despite the high overdose, Vaxsafe® MHP did not result in any deaths. Analysis of data revealed that no significant difference in body temperature and weight gain existed between the vaccinated (safety group) and negative control group. At post-mortem, 2/10 pigs had a small lung lesion (not significant (P>0.05) compared with the negative group). Also, the lesions did not translate to any adverse effect on weight gain nor on any clinical signs. At post mortem 4/10 pigs in the unvaccinated, challenged control group presented with significant lung lesions (~30% of the lung). No pigs in either the 105.7 or the 106.9 ccu/dose vaccinated groups showed any lesions. In the 108.0 ccu/dose vaccinated group, 1/10 pigs presented with a minor lung lesion (~7% of the lung). PCR analysis of nasal swabs taken at DPV-21 prior to challenge showed presence of live Vaxsafe® MHP in 60% to 70% of pigs from each of the vaccinated groups. Tracheal colonization was investigated by taking swabs from the upper, middle and lower regions of the trachea at post-mortem (DPV-59). Swabs were only collected from the safety (unchallenged) group. Therefore, Mh detected would be due to Vaxsafe® MHP. Results obtained from PCR analysis showed that Vaxsafe® MHP was present in the trachea of 60% of pigs in this group. This indicates that Vaxsafe® MHP is capable of colonizing the respiratory passages of vaccinated pigs for at least 8 weeks post vaccination.

Study 2: The unvaccinated challenged group presented with lung lesions in 100% of pigs with a lung lesion score (planimetric method) of 9.2%. At a dose of 105.0 ccu lung lesions were detected in 30% (WF) and 10% (FD) of vaccinated pigs post-challenge with average lesion scores of 0.7% and 1.7% respectively. Presence of lung lesions in the commercial inactivated vaccine group was detected in 60% of pigs with an average lesion score of 8.5%. A direct comparison between the commercial inactivated vaccine group and the 105.0 ccu/dose Vaxsafe® MHP group showed a significant reduction in both the incidence of lung lesions (60% to 10%) and in the severity of lung lesions (8.5% to 1.7%), in the Vaxsafe® MHP vaccinated group. The 105 ccu/mL dose of Vaxsafe® MHP (FD) provided a protective index of 90% (incidence) and 81% (severity) of lung lesions. The commercial inactivated vaccine provided a protective index of 40% (incidence) and only 8% (severity) of lung lesions. All indices were calculated in comparison to the positive control group.

Administration of an overdose of Vaxsafe® MHP did not result in pig mortalities, any adverse clinical signs, nor any significant increase in the incidence or severity of lung lesions compared to the negative control group. A comparative study with a commercial inactivated vaccine showed Vaxsafe® MHP to offer a higher level of protection following challenge. Overall, these two studies indicate that Vaxsafe® MHP to be a safe and efficacious live vaccine against M. hyopneumoniae infection.

**Efficacy of SPRINTVAC® (Merial) vaccination in piglets affected by swine enzootic pneumonia, *Mycoplasma hyopneumoniae*, in Brazilian field conditions**

Edson Bordin¹ Ronie Pinheiro² Flavio Barcelos¹

1. Merial Animal Health Ltda., Campinas, SP, Brazil; 2. Integrall - Soluções em Produção Animal Ltda, Patos de Minas, MG, Brazil

**Introduction**

*Mycoplasma hyopneumoniae* is considered one of the most important agents associated with chronic diseases in swine herds, and the primary agent of swine enzootic pneumonia (Meyns et al., 2006). Moreno et al. (1999) found a prevalence of 59.9% of farms affected by *Mycoplasma hyopneumoniae* in several Brazilian states.

The objective of this study was to evaluate the efficacy of vaccination of piglets with the vaccine SPRINTVAC®(Merial) compared with the vaccine RESPISURE ONE®(Pfizer Animal Health), combined with strategic medication in pulses, by measuring the weight gain, prevalence and extent of lesions in the respiratory tract, rates of occurrence of coughs and mortality rate.

**Material and Methods**

The experiment was conducted in a growing and finishing unit of a commercial farm, with a system of all in/all out. A total of 32 pens with about 60 animals (i.e., 1,980 animals) were randomly divided into two groups:

- **T1**: 16 pens vaccinated with SPRINTVAC at 21 days of age.
- **T2**: 16 pens vaccinated with RESPISURE ONE at 21 days of age.

Pulses with strategic medication occurred at the same time and same intensity for all groups.

The cough index was determined throughout the experimental period, according to standard, scientifically validated methodology (Mores et al., 1999).

At slaughter 120 animals of each treatment were submitted to a lung lesion evaluation according to the methodology of Piffer & Brito (1991).

The software package statistical analysis for genetic epidemiology (S.A.G.E.) was used for variance analysis and mean comparison. Chi²-test and non-parametric tests like Kruskal-Wallis were used.

**Results**

As shown in table 1 no significant difference in the weight output termination (p>0.05) and for GPD phases analyzed. Table 1 also presents the prevalence of lesions of pneumonia, in addition to objective index to assess the extent of these lesions (IPP Index Pneumonia) and no significant difference was observed between both groups (Chi²-test; p>0.05).

No significant difference was found in mortality rates for the entire experimental period: 2.6% for animals vaccinated with SPRINTVAC and 2.85% for those with RESPISURE ONE (p> 0.05).

As shown in table 2 related to the rate of cough there was no significant difference between treatments (Chi²-test; p>0.05).

Safety evaluation of SPRINTVAC® by measure of piglet body temperature in a commercial farm in Brazil

J. Sarubbi1, 5 Edson Bordin2 D. Jorge De Moura3 F. Oliveira3 Andrea Delvecchio4 François Joisel4

1. FEAGRI UNICAMP, Campinas, SP, Brazil; 2. Merial Animal Health Ltda., Campinas, SP, Brazil; 3. MULTIPLAVET, Campinas, SP, Brazil; 4. Merial S.A.S., Lyon, France; 5. UFSM, Palmeiras das Missões, Brazil; 6. UNICAMP, Sao Paulo, Brazil

Introduction

Mycoplasma hyopneumoniae (M. hyo) is considered to be one of the most economically important pathogens in the swine industry. The effectiveness of vaccination in reducing the economic impact of M. hyo has been shown previously (1, 2). The objective of this study was to evaluate the safety of SPRINTVAC® vaccination in piglets by the measure of piglet body surface temperature compared to body surface temperature of piglets treated with another current vaccination protocol.

Material and Methods

A total of 140 piglets from a 400-sow farrow-to-finish herd located in Brazil were used in this study. Piglets were randomly divided into 2 treatment groups: group T1 vaccinated with one dose of SPRINTVAC (2mL, IM), group T2 vaccinated with one dose of Suvaxyn® Respifend MH (Pfizer Animal Health).

Piglet body surface temperature of piglets was measured with an infrared thermographic camera Testo® (figure 1).

Figure 1: Infrared thermographic camera used to verify the distribution of temperature on piglet skin

All piglets were photographed at 5 timepoints: before vaccination, 30 min, 45 min, 24h and 48h after vaccination. Acquired images were processed and analyzed using the IRTesto® software to calculate average surface temperature.

To compare piglets from both treatments, a polygon was drawn to cover the regions of their neck, flank and hind legs. From these regions, the average surface skin temperature of the left profile of each piglet was extracted. The average temperatures were compared by Tukey’s test, after verification of normality of the data distribution.

Results

Thirty minutes after vaccination, the average skin temperature of T1 animals was the same as the temperature measured before vaccination. The average temperature of T2 animals increased by 1.6°C. Forty-five min after vaccination, the average temperature of T1 animals increased by 0.8ºC compared to the average temperature found before vaccination but stays 0.4ºC lower than in T2 group. Twenty-four hours after vaccination, the average skin temperature of T1 animals decreased by 1.3ºC compared the previous measurement. Piglets of T2 showed a decrease of a similar value (1.4ºC). At this point, animals from T2 kept their average temperature (0 3ºC) a little higher than T1 animals. Forty-eight hours post-vaccination, piglets in both treatment groups showed an increase in their average temperature, being the highest increase in the animals from T2 (0.9°C against 0.5°C from T1).

At all time points, pigs from group T2 showed a numerically higher average temperature than in group T1, although, statistical differences were found only at 30 minutes and 48h post-vaccination (Table 1).

Table 1: comparison of average surface temperatures of piglets from T1 and T2

</tbody>
</table>

(a,b) different letters in the same line indicate significant statistical difference.

Discussion and Conclusion

Measure of piglet body surface temperature with an infrared thermographic camera seems to be a good tool limiting labour and pig stress. For a more precise evaluation, it would be necessary that the piglets would be under an efficient climatization system, that more piglets would be studied and during more days.

It is believed that SPRINTVAC adjuvant gives a smoother response compared to the other studied vaccine, explaining the behavior of the lower surface temperature of the piglets vaccinated with this bacterin These results confirm the safety of SPRINTVAC vaccine.

Efficacy of a combined vaccination schedule with RHINIFFA® T in sows and SPRINTVAC® in piglets versus another commercial protocol

J. Sarubbi1, Edson Bordin2, D. Jorge De Moura3, F. Oliveira4, Andrea Delvecchio5, François Joisel5
1. FEAGRI UNICAMP, Campinas, SP, Brazil; 2. Merial Animal Health Ltda., Campinas, SP, Brazil; 3. UNICAMP, Sao Paulo, Brazil; 4. MULTIPLAVET, Campinas, SP, Brazil; 5. Merial S.A.S., Lyon, France

Introduction

Atrophic rhinitis (AR) and enzootic pneumonia (EP) are two diseases afflicting swine herds worldwide. The vaccines against (EP) provide protection to swine by the reduction of lesions and improvement of the productivity indexes, although they do prevent neither the colonization by mycoplasma nor the establishment of carrier swine (1). AR in swine is characterized by a deformation of snouts and a turbinate atrophy (2). Vaccination of sows is among the effective strategies used for the prevention and control of AR in piglets (3).

The objective of this study was to evaluate a combined vaccination schedule with RHINIFFA® T in sows followed by SPRINTVAC® in piglets, compared to another currently applied protocol.

Material and Methods

Farm: A 400-sow farrow-to-finish herd located in Brazil and selected on its previous historic of lung lesion condemnations was used in this study.

Experimental design: 3 replicates of 120 commercial pigs, housed in 3 separate pens, were used in the study. Each repetition was divided into 2 treatment groups. In the first group (T1) piglets born from sows vaccinated with 2 doses of RHINIFFA T (MERIAL, 2mL, IM 6 to 8 weeks before farrowing and the 2nd dose was performed at 2 to 3 weeks before farrowing) received SPRINTVAC (MERIAL - 2mL, IM, at 3 weeks of age). In the second group (T2) piglets born from sows vaccinated with RINIPRAVAC DT® (2mL, IM, 1st dose at 6 to 8 weeks and the 2nd dose at 2 to 3 weeks both before farrowing) were vaccinated with 2 doses of MYPRAVAC Suis® (2mL, IM, 1 dose at 7 to 10 days and the second dose at 28 days of age).

Efficacy parameters: Pneumonia Index (PI) and Progressive Atrophic Rhinitis Index (ARI) were used to evaluate the vaccines protocols (4). PI is the numeric representation of the severity level of the pneumatic lesion incidence in examined animals, while ARI is based on the weighted average score of changes and lesions in nasal turbinates. The assessment of lung lesions and nasal turbinates was done by visual appreciation.

Statistical methods: Chi-square Yates-corrected test for concordance of lung and turbinate lesions between the two treatment groups was performed.

Results and Discussion

The prevalence of lung lesions was numerically found slightly higher in T2 animals (Table 1).

<table>
<thead>
<tr>
<th>Treatments</th>
<th>Prevalence of lung lesions (%)</th>
<th>Pneumonia Index (PI)</th>
<th>Prevalence of nasal turbines lesions (atrophy) (%)</th>
<th>Atrophic Rhinitis Index (ARI)</th>
</tr>
</thead>
<tbody>
<tr>
<td>T1</td>
<td>39.9</td>
<td>0.44</td>
<td>42.1</td>
<td>0.52</td>
</tr>
<tr>
<td>T2</td>
<td>44.9</td>
<td>0.57</td>
<td>57.9</td>
<td>0.82</td>
</tr>
</tbody>
</table>

PI and ARI average scores were 0.13 and 0.30 lower in the T1 animals than in the T2 animal, respectively. It is usually admitted that PI scores are indicative of PI<0.56: herds pneumonia free; 0.56< PI <0.89: Pneumonia is not a threat; PI > 0.90: there is a significant pneumonia incidence (4).

All repetitions show an about 16% higher prevalence of lesions in the nasal turbinates in T2 animals (close to a statistical trend). It is interesting to note that in the T2 animals, some batches showed purulent lesions in the nasal turbinates.

Conclusion

Numerical differences between the results of the two protocols were not found statistically significant. Considering the lung lesion and nasal turbinate prevalence, in this study, T1 treatment provided a good protection against the two diseases.

Comparative efficacy of single dose M+PAC® vaccination schedule and another single dose vaccine in a high M. hyopneumoniae infection pressure environment

Enric Marco1 Joan Escobet2 Miquel Collell2 Jesus M. Bollo3 Rut Menjon3 Marta Jimenez3 Jesus V. Lopez3
1. Marco y Collell, St Paulí de Nola, 6. 08004 Barcelona (Spain), Madrid, Spain; 2. Marco y Collell, St Paulí de Nola, 6. 08004 Barcelona (Spain), Barcelona, Spain; 3. Intervet Schering Plough. c/ Cantabria 2, Edificio Amura 28.108 Alcobendas, Madrid, Spain

Introduction
The objective of the study was to evaluate the safety and efficacy of a single dose M+PAC® vaccination schedule compared with another single dose vaccine for prevention of M. hyopneumoniae (M. hyo) in a high infection pressure environment, to assess the real efficacy of both products.

Materials and Methods
The study was performed in a farm with 450 sows, using 3 week batches, which did not vaccinate for M. hyo before the study and presented a moderate level of pulmonary affection due to M. hyo: average score 0.91, using a 0-5 scoring system (1).

The piglets were divided into 4 groups, and the first 3 ones were randomized according to the sow and piglet gender and weight (weights were comparable at the start of the study (p<0.05), Table 1:

- a) M+PAC® (Intervet Schering-Plough), single 2 mL dose given at 3 weeks of age (121 animals).
- b) Vaccine A, single dose vaccine, 2 mL given at 3 weeks of age (122 animals).
- c) Control, 2 mL saline given at 3 weeks of age (236 animals).
- d) Control A, not included in the study, with no individual animal identification, used to increase the environmental infectious pressure (250 animals).

The 4 groups were commingled in the same pens, keeping the same ratio of each group both during growing and finishing, so that the 2 vaccinated groups represented only 35% of the animals in each pen.

Statistical evaluation was performed using analysis of variance, together with the Levene test, Pearson’s chi-square test, Fisher’s exact test and Mann-Whitney-U test.

Results

Table 1

Concerning ADG during fattening (Table 2), the animals of the M+PAC® group presented higher growths than the control group (+42 g/day, p=0.02), and than the Vaccine A group (+16 g/day, p=0.658). On the contrary, Vaccine A did not present a significant statistical difference with the Control group (p=0.656).

The M+PAC® group showed statistically significant higher average end of fattening weights (157 days of age) than the Control group (+4.62 kg, p=0.027), and than the Vaccine A group (+1.77 kg, p=0.659). Vaccine A did not attain significant statistical differences vs the Control group (p=0.25).

The analysis of variance of both the ADG during fattening and the average end of fattening weights indicated better results of the group vaccinated with M+PAC® compared to the Control group (p=0.002 and p=0.011, respectively) but vaccine A did not present a statistical significant difference vs the non-vaccinated animals (p=0.050).

No differences concerning mortality were found among the groups (p=0.835).

a, b, c: values with different superscripts in the same file present statistically significant differences: a, b: p<0.05, a, c: p<0.001.

M+PAC® produced the highest reduction of pulmonary lesions ascribed to M.hyo and pleuritis.

When grouping together the grade 0-3 scores and the grade 4-5 ones (highest score lesions), the average ADG was 709 and 492g/day, respectively (p=0.012), with the ADG during fattening relating with the severity of the pulmonary lesions which were found.

Discussion
Animals vaccinated with M+PAC® showed the highest reduction of pulmonary lesions, and both a higher ADG during fattening and end of fattening weight compared to the Control group, not occurring in the group vaccinated with Vaccine A.

Analysis of variance showed that the animals vaccinated with M+PAC® presented a more uniform growth and end weight than the Control group, which was not found for the Vaccine A group.

**Efficacy of Suvaxyn® MH-One under field conditions**

Florence Pillet\(^1\) Mathieu Couteau\(^1\) Olivier Roy\(^3\) Paolo Doncecchi\(^2\) Patrick Bourguignon\(^4\) Geoffrey Labarque\(^2\)

**Introduction**

Respiratory disease is the most important pathology in modern swine husbandry in Europe. Mycoplasma hyopneumoniae (M. hyo) is a key player in the porcine respiratory disease complex (PRDC), a multi-factorial disease syndrome caused by several bacteria, viruses, management and husbandry factors. To control the clinical expression of this syndrome and its negative impact on pigs’ performance, vaccination with M. hyo vaccines is a wide-spread practice in European swine farms. Vaccines against M. hyo are by far the most widely used swine vaccines in Europe.

Suvaxyn® MH-One (Fort Dodge Animal Health) is a one-shot vaccine against M. hyo to be administered by intramuscular injection in piglets starting from 3 weeks of age. The efficacy of this vaccine has been confirmed under experimental conditions (1). The present study aimed to confirm the efficacy of this vaccine under field conditions by comparing its performance with another commercially available one-shot Mycoplasma vaccine.

**Materials and Methods**

The study was conducted in a closed breeding-fattening herd in France. Before the start of the study, piglets were vaccinated against M. hyo with a commercially available one-shot vaccine at 35 days of age (i.e. one week after weaning). Two consecutive batches with a three weeks interval were included in this study. The piglets of each of the two batches were divided into two groups: one group (n=182 in total) was vaccinated with Suvaxyn® MH-One at 5 weeks of age and the other group (n=170 in total) was vaccinated at the same age with another commercially available one-shot Mycoplasma vaccine (designated vaccine A), following the manufacturers’ instructions. The piglets did not receive any other vaccine throughout the study.

The efficacy of both vaccines was evaluated using clinical parameters (morbidity (signs of respiratory disease), mortality, number of treatments if required), growth performance parameters (average daily weight gain (ADWG), feed conversion ratio (FCR)) and the results of post-mortem lung examinations at the slaughterhouse. Lung lesions were scored from 0 to 4 per lung lobe. A final score was obtained by adding the scores given to each lung lobe (between 0 and 28) (2). Pleurisy lesions were scored from 0 to 2. The mean lung lesion scores and the percentage of animals having lung lesions were statistically compared using a one-way analysis of variance (ANOVA) and a Chi^2 test, respectively.

**Results**

The results of the field study are summarized in Table 1. No signs of respiratory disease were observed throughout the study. The mortality was the same in both groups (3 pigs in both vaccinated groups).

There were no differences in the growth performance parameters ADWG and FCR between both groups.

There were no differences in the mean lung lesion scores between both groups (0.7 for the Suvaxyn® MH-One group and 0.9 for the vaccine A group) (P>0.05). The percentage of animals with lung lesions (i.e. animals having a score of >0) was somewhat lower in the Suvaxyn® MH-One group (23.5%) when compared to the vaccine A group (26.9%). However, this difference was not significant (P>0.05). Five animals presented pleurisy at slaughter: 2 in the Suvaxyn® MH-One group and 3 in the vaccine A group.

**Discussion**

As no respiratory disease occurred throughout the study, the efficacy of Suvaxyn® MH-One could only be evaluated using growth performance parameters and the results of the post-mortem lung examinations at slaughter. The analysis of these parameters did not reveal any differences between the Suvaxyn® MH-One-vaccinated pigs and the pigs vaccinated with the competitor vaccine. The percentage of pigs presenting lung lesions and pleurisy was somewhat lower in the Suvaxyn® MH-One group, but these differences were not statistically significant.

Department of Obstetrics, Reproduction and Herd Health, Faculty of Veterinary Medicine, University of Ghent, Merelbeke, Belgium; 5. Deceased author, Thessaloniki, Greece; 6. Foundation of Biomedical Research, Academy of Athens, Athens, Greece

Introduction
Mycoplasma hyopneumoniae (M. hyo) is the etiologic agent of mycoplasma pneumonia. The term enzootic pneumonia (EP) describes the epidemiological pattern of the disease in combination with other etiological agents or lesions involved, (high morbidity including clinical respiratory signs such as prolonged non-productive coughing and areas of lung adjacent to normal tissue) (1, 2). The aim of this study was to determine the efficacy of a single dose of an aqueous inactivated M. hyo vaccine against EP, on the basis of reduction of frequency and severity of lung lesions and improvement of growth performance. The study was financed by Intervet SPAH through the Research Committee of Aristotle University of Thessaloniki.

Materials and Methods
The study was carried out in a commercial farrow-to-finish pig farm, (900 sows under production) with confirmed M. hyo infection. The intradermal vaccination was performed with an inactivated aqueous vaccine containing M. hyo strain 11 inactivated M. hyo cells with a light paraffin oil and dl-α-tocopheryl acetate based adjuvant (Porcilis® M. Hyo one shot IDAL, Intervet SPAH, Boxmeer, The Netherlands). A total of 700 healthy suckling piglets at the age of 28±3 days were ear tagged and randomly assigned to one of two experimental groups: 346 piglets in treatment group (IDAL) which received a single vaccination at 4 weeks of age (start of the trial period), and 354 in control (C) group which received a placebo (dl-α-tocopherol-acetate based adjuvating solution). The efficacy of Porcilis M Hyo IDAL® one shot was assessed on the basis of the reduction of lung lesions and improvement of lung performance as compared to the controls. Pleuritis lesions, medication and mortality were evaluated as secondary parameters of efficacy. The statistical evaluation was performed with SAS® version 9.1.

Results and Discussion
The severity of lung lesions and pleuritis at slaughter were reduced significantly in the IDAL group (Table 1) as compared to the controls.

No difference in medication was observed in the nursery, but during the finishing phase significantly less (chi-square test: p<0.001) IDAL vaccinated pigs were treated (5.1%) than controls (15.5%). Three quarters of all treatments during the finishing phase were given for the control of respiratory signs. Also the mortality was significantly lower (Chi-square test: p=0.0208) in the IDAL vaccinated pigs (4.7%) as compared to the control group (9.0%). It is concluded that a single intradermal vaccination of piglets with Porcilis® M Hyo IDAL at the age of around 4 weeks is effective against Enzootic Pneumonia in a farrow-to-finish swine unit infected with M. hyo. The prevalence and severity of lung was improved and the performance was improved.

Evaluation of peripheral lymphocytes after Weaning and vaccination for Mycoplasma hyopneumoniae

Glen W. Almond1 Andrew Kick1 Martin Liebstein1 Patricia A. Routh1 Mark J. Hammer2

Introduction
An early report indicated that vaccination against Mycoplasma hyopneumoniae (MHYO) or pathogen challenge failed to induce a nonspecific change in peripheral lymphocyte populations; however, interferon-γ (INF-γ) secreting cells were important to the protective response (1). Overall, a local mucosal humoral and a systemic cell mediated immune response are important to controlling mycoplasmal pneumonia in pigs (2). The porcine immune system is unique in the expression of CD4+CD8+ lymphocytes, which may be involved in the immune response to MHYO. Therefore, the primary aim of the study was to investigate immune cell populations following intramuscular injection with an one-dose MHYO vaccine and novel adjuvant.

Materials and Methods
The animal phase of the study was conducted at the Swine Teaching Unit, College of Veterinary Medicine. The unit has a high health status and approximately 40 sows. Based on previous serology, animals seroconverted to MHYO two months after placement in the finishing barn. Pigs (n=24 barrows) were selected at weaning (~3 wks of age) and ear tagged for identification. Eight pigs served as controls and 16 pigs were vaccinated with MYHO bacterin (PneumoSTAR™ Myco) at placement in the nursery. Blood samples were collected immediately before injection, and 3, 7, 14, 30, and 60 days after injection. Whole blood was used for complete blood counts (CBC's) and preparation for the flow cytometry analysis. In addition, serum was collected to assess the humoral response to the vaccine or natural infection. Lymphocytes evaluated with flow cytometry included CD3+, CD4+, CD8+, CD4+CD8+, and CD21+ cells. Also, CD25+ cells, and cells expressing IgG and/or IgA were evaluated, but not included in the results. The statistical analyses used an analysis of variance for repeated measures and Tukey’s test to compare means.

Results
Following vaccination, there were no apparent adverse effects in any of the pigs. The CBC’s did not differ between the groups within day; however, total WBC, neutrophils, and lymphocytes increased (P<.05) from day 0 to day 30 (7.2±5 to 16.5±7 x 103/ul, 3.1±.3 to 6±.2 x 103/ul, 3.3±.3 to 9.3±.7 x 103/ul, respectively). An initial increase in CD4+ (Fig 1), CD3+ and CD21+ cells occurred from day 0 to day 3 in both groups of pigs. The number of CD8+ and CD4+CD8+ lymphocytes increased during the initial 3 days in the control group, but not in the vaccinated pigs (Fig 1). The SP ratios for MHYO remained at 0 for control pigs, whereas the titers increased to 1.4 at Day 30 in vaccinated pigs.

Discussion
It was expected that the total WBC counts increased with age of the pigs. The increase in the three lymphocyte populations likely reflects antigenic challenge resulting from the changes in diet and environment. The lack of change in the CD8+ and CD4+CD8+ lymphocytes in vaccinated pigs was surprising; however, it could be partially attributed to lymphocyte trapping in the lymph nodes and lymphatic system, and thus the number of these cells failed to change in the peripheral circulation. The differences between immune cells were observed shortly after vaccination (weaning) and prior to the increased ELISA titers. It is likely that the antigenic challenges associated with weaning confounded the response to vaccination.

**Effect of vaccination against Mycoplasma hyopneumoniae on its transmission under field conditions**

Iris Villarreal; Dominiek Maes; Katleen Vranckx; Frank Pasmans; Freddy Haesebrouck

Faculty of Veterinary Medicine, Ghent University, Merelbeke, Belgium

**Introduction**

Mycoplasma hyopneumoniae (Mh) is the primary agent of enzootic pneumonia (EP), a contagious respiratory disease with major economical impact for the pig industry. Vaccination of piglets is widely practiced as a control strategy for this disease. However, the currently available vaccines do not induce a complete protection against colonization and transmission (2). Virulence differences (3) and protein variability (1) between Mh strains may indicate that vaccination efficacy could vary depending on the strain. The aim of this study was to assess the effect of vaccination with a commercial bacterin vaccine against low and highly virulent Mh strains at 4 and 8 weeks post infection (PI).

**Materials and Methods**

Ninety, 3 week-old, cross-bred (Rattlerow Seghers), Mh and PRRSV free, weaned piglets were moved to the experimental facilities of the Faculty of Veterinary Medicine, Ghent University, Belgium. After one week acclimatization, they were randomly allocated to 10 different groups housed in absolute filters (HEPA U15) to avoid spread of the pathogen between groups. Forty piglets were vaccinated (v) with a one-shot vaccine (Stellamune One, Pfizer), 40 were left unvaccinated (nv) and 10 were assigned to the negative nv and non-challenged (NC) control group. The experimental design is summarized in Table 1. One low (LV) and one highly (HV) virulent Mh strain were used for experimental infection. After anesthesia, the pigs were inoculated intratra- cheally with 7 x 10^7 CCU of Mh in 7ml inoculum or with 7ml of sterile culture medium. Half of the piglets were euthanized at 4w PI and the other half at 8w PI. The severity of coughing was assessed daily using a respiratory disease score (RDS) (values from 0 to 6). At necropsy, macroscopic lung lesions were quantified using the lung lesion score diagram of Hannan et al. (1982), ranging from 0 to 35. Additionally, lung tissue samples were taken from each pig to assess the severity of histopathological lesions (score from 0 to 5). Nasal swabs and bronchoalveolar lavage fluid (BALF) were collected after euthanasia and analyzed using nPCR to confirm presence of Mh.

**Results**

At 4w PI, the vHV group showed significantly milder respiratory symptoms and significantly lower macroscopic and microscopic lesion scores than the nvHV group (P<0.05). The vLV group showed no significant differences for RDS, macroscopic and microscopic lesions scores, compared to the nvLV group. At 8w PI, both vHV and vLV groups had significantly lower RDS scores in comparison to the nvHV and nvLV groups, respectively (P<0.05). Only the vHV group showed significantly lower macroscopic lesions in relation to the nvHV group. Results are summarized in Table 2. As expected, all pigs, except for the nvNC group, were positive by nPCR on BALF and nasal swabs.

**Discussion and conclusions**

The results confirm the difference in virulence between the two strains (3), when measured during a period of either 4 or 8 weeks PI. Vaccination significantly reduced the severity of disease in the vHV group at 4 or 8 weeks PI for most parameters. Vaccination was also beneficial in the LV groups, but the effects were less pronounced and depended on the measured parameter. Further research is warranted to assess the precise effect of vaccination on individual strains under field conditions, since combined infections might lead to more severe clinical disease in a pig herd (4).

Efficacy of Econor® (valnemulin) for the treatment of mycoplasma pneumonia of swine under field conditions in Japan

Nobuo Nakanishi² Koji Ishii¹ Hiroshi Otaki¹ Ulrich Klein³

Introduction

Mycoplasma pneumonia of swine (MPS) caused by Mycoplasma hyopneumoniae (Mhp) is one of major respiratory diseases in pigs all over the world. The susceptibility of Mhp field isolates from Japan against valnemulin, the active ingredient of Econor®, has been confirmed recently (1). The objective of this study was to evaluate the clinical efficacy of Econor® 1% premix for pigs affected by MPS under field conditions in Japan as part of routine post-approval regulatory requirements.

Materials and Methods

This study was conducted from October 2006 to November 2007 at two different farms in central part of Japan (Aichi Prefecture). Two farms were historically known as MPS-positive farms. Prior to the study, two pig farms were randomly selected for necropsy to confirm the presence of typical macroscopic MPS lesion in the lung and isolation of Mhp. Isolation of M. hyorhinis, Actinobacillus pleuropneumoniae and Pasturella multocida was also confirmed. In total 105 crossbred pigs (80 to 100 days of age; 45 pigs at Farm A, 60 pigs at Farm B) were randomly allocated to the following three groups: negative control (T1), Econor® 50 ppm (T2) and Econor® 200 ppm (T3). Econor® was medicated in-feed for 7 consecutive days in accordance to the label in Japan. Body weight was measured at the start of study (Day 0), at the end of the treatment (Day 7) as well as 7 and 14 days after the end of the treatment (Day 14 and 21) to determine the weight gain. Twelve pigs (two pigs per group in each farm) were randomly selected at Day 9, two days after the end of treatment, for necropsy, and lungs were carefully examined to score the macroscopic lesion (score 0-4, 0=no lesion to 4=severe). Also, the area of MPS lesion in the lung was carefully measured to calculate the MPS-lesion ratio (%) in a whole lung surface. In addition, Mhp, M. hyorhinis, A. pleuropneumoniae and P. multocida were isolated when found.

Results and Discussion

The weight gain of pigs in the two Econor groups were significantly higher than the gain of control group during Day 0-7 (T3: 6.0 kg vs. T1: 4.4 kg) and Day 7-14 (T2 and T3: 5.6 kg and 6.0 kg vs. T1: 4.4 kg) (Table 1). With regard to the lung lesion score and MPS-lesion ratio, there were no significant differences among the groups, although there was a trend that values for those at Econor groups were smaller than those of the control group (Table 1). At the necropsy before study onset, Mhp was isolated from all four pigs, and M. hyorhinis, A. pleuropneumoniae and P. multocida were also isolated from some pigs due to secondary infection, which is not unusual under field conditions (Table 2). At Day 9, the control group had similar frequency and distribution of bacteria concerning, whereas Econor® groups had tendency to reduce those bacteria from the level of Day 0. In the case of Mhp, reduction of isolation in three groups was dose dependent. It has to be noted that M. hyopneumoniae, A. pleuropneumoniae and P. multocida were not found and isolated from the lungs of pigs treated with Econor® 200 ppm for 7 consecutive days (Table 2).

Conclusion

In a MPS-positive farm, Econor® has proven its clinical efficacy based on the improvement of body weight gain, the reduction of the bacterial load (Mhp) in the lung and the reduction of the MPS-lesion ratio.

In vitro susceptibility of Porcine Mycoplasmas to antimicrobial agents during 2008-2009

Pacharee Thongkamkoon\textsuperscript{1} Nuvee Prapasarakul\textsuperscript{2} Metta Makhanon\textsuperscript{2} Sasiwimon Talummuk\textsuperscript{3} Ulrich Klein\textsuperscript{4}

**Introduction**

Porcine Mycoplasma including Mycoplasma hyopneumoniae (MH) and M. hyorhinis (MHR) concurrently cause respiratory problems as well as polyserositis/arthritis and lameness from fattening to breeder. Antigenic variation of the bacteria can lead to variation of the immune response and acquired resistance can cause failure in disease treatment and control. MIC (minimum inhibitory concentration) data are a trustworthy tool for the evaluation of antibiotics and their effect against Mycoplasma pathogens (1,2,4,6,7). The objective of this study was to determine the MIC of seven antimicrobials: tiamulin, valnemulin (pleuromutilins), lincomycin (linosamides), tyllosin (macrolids), enrofloxacin (fluoroquinolones), doxycycline (tetracycline), florfenicol – against Thai porcine Mycoplasma strains isolated during 2008-2009.

**Materials and Methods**

Twenty field isolates of MH and MHR, were collected in 2008/2009 from lungs, heart, brain or joints of pigs with lameness and pneumonia. Mycoplasmal identification was done by PCR detection. Mycoplasmal isolates were diluted to a concentration of 5x10\textsuperscript{5} CFU/ml and were incubated at 35\textdegree C for 2 hours. MICs were carried out using microdilution protocol based on CLSI guidelines. The concentration of antimicrobials were serially two-fold diluted, from 0.006-12.5 μg/ml for doxycycline, florfenicol, lincomycin, tiamulin, valnemulin and tyllosin, and from 0.024-50 μg/ml for enrofloxacin. Mycoplasma growth was confirmed by media indicator and microscopic observation. The lowest concentrations of each antimicrobial showing inhibition of visible color change were interpreted as the MIC values at 5th PI for MHR and 7th PI for MH.

**Results**

The MIC values of the tested antimicrobials are shown in Tables 1 and 2.

**Discussion**

Low MIC90 values indicate high susceptibility of MH strains to valnemulin, tiamulin and tyllosin. In contrast, high Tylosin MIC90 values show low sensitivity of MHR strains. Resistance to enrofloxacin might be caused by the widely use in piglets to control E.coli. (7) MIC90 of florfenicol against MH and MHR was detected in a resistant range (breakpoint <2 μg/ml) and was higher than in previous studies (1,2,5,8). Increase of MIC values might be induced from the other antimicrobials that result in mutation at the 50s ribosomal subunit of bacteria (3). Valnemulin showed the lowest MIC values against all tested Mycoplasmas and is considered as the most effective antibiotic in this study. Tiamulin inhibited MHR and MH at MICs lower than 0.1 μg/ml - no trend of MIC increase was found. In conclusion, the Pleuromutilin antibiotics show the lowest MICs and are considered to be the most efficacious therapeutics for the control of Mycoplasmas in Thai pig farms.

**Efficacy of Denagard® 10 (tiamulin hydrogen fumarate) in-feed antibiotic in a Mycoplasma hyopneumoniae infection model study**

J. M. Hammer; Stephen King; Elizabeth Roberts; Linda Roycroft

*Novartis Animal Health, US, Greensboro, NC, USA*

**Introduction**

*Mycoplasma hyopneumoniae* (*M. hyo*) is a highly prevalent insidious respiratory disease in pigs. Although mortality is low morbidity can be high. It is a component of enzootic pneumonia and is also considered an initiator in secondary bacterial pneumonia of pigs which can cause increased mortality and decreased performance with associated higher production costs. Controlling *M. hyo* infections in pig herds should improve respiratory health and performance in growing pigs leading to lower production costs.

**Objective**

To evaluate Denagard® 10 in-feed antibiotic at 137.5 ppm or 165 ppm for a 14 day treatment period to control (*M. hyo* in an induced infection model.

**Materials and Methods**

Approximately 8 week old pigs (11 to 36 kg) serologically negative for *M. hyo* were endotracheal challenged with a *M. hyo*-homogenate containing at least 109 organisms per mL. Once a minimum of four animals on a given day showed 5% or greater lung involvement through necropsy confirmation, the treatment phase was initiated. Pigs were allocated to one of three treatment groups (Control 0 ppm Denagard, 137.5 ppm Denagard for 14 days, or 165 ppm Denagard for 14 days). The pen was the experimental unit. The primary variable ‘total lung lesion percentage’ was transformed and analyzed using an analysis of variance with ‘Treatment’ as the classification variable. Secondary clinical variables (depression score, respiratory score, and cough score), overall treatment success, production parameters (average daily gain, feed intake, efficiency), and mortality were also determined and statistically analyzed.

**Results**

The primary variable for efficacy determination of Denagard was the total lung lesion percentage at necropsy 72 hours post cessation of the Denagard application. Statistically significant differences in favor of the Denagard treatment groups were noted in total lung lesion percentage when compared to the control (Table 1).

a statistical difference from control (p<0.05)

As coughing is a primary clinical sign associated with *M. hyo* infection, the number of pigs coughing was further examined by time of day (Figure 1). Cough in the morning was differential between treatment groups with lower rate of increase in the Denagard groups over the trial period.

**Discussion**

Denagard when administered as an in-feed antibiotic at 137.5 and 165 ppm for 14 days provides control of *M. hyo* infection based on the reduction in lung lesion percentage at 72 hours after in-feed antibiotic removal. Pigs that received Denagard had a lower rate of increase in the number of coughs in the morning over time when compared to control animals. The Denagard 165 ppm group showed a lower rate of increase in coughing in the morning than the Denagard 137 ppm group.

**Conclusion**

Denagard 10 (tiamulin in-feed antibiotic) at a dose of at least 137.5 ppm reduced rates of coughing which is a positive clinical benefit in pigs infected with *M. hyo*. Feeding Denagard 10 at either level significantly decreases lung lesions resulting in improved lung health.
Mycoplasma hyopneumoniae elimination in a 3800 sow, multi-site system

Jerome O. Geiger1 Doug Groth2
1. PIC-NA, Hendersonville, TN, USA; 2. Carthage Veterinary Service, Carthage, IL, USA

Introduction

Mycoplasma hyopneumoniae (Mh) was successfully eliminated from a 3800 sow multi-site system. Several elements were considered important to the successful elimination: stabilization of the sow herd's immunity, segregation of all nursery/finishing animals, strategic use of antibiotics in the sow herd and neonates, complete depopulation of the nursery/finisher facilities, one-directional pig flow, and strict control of people traffic.

Materials and Methods

A 3800 sow multi-site production system was stocked and operating >5 years as Mh negative based on monthly serology, clinical signs and post-mortem examinations. The system was also negative for Porcine Reproductive and Respiratory Syndrome (PRRS). Breeding, gestation and farrowing occurred on Site 1. A gilt development unit (GDU) was also contained in Site 1. Except for the internal replacement gilts in the GDU, the weaned pig flow rotated around three facilities, 18-60 miles from the sow herd.

In Jan.08, clinical signs indicated a change of health status in the sow herd. Mh was diagnosed by Dako ELISA serology and histopathology in the sow herd and followed normal flows through the nursery/finisher system. All animals in the internal GDU and sow herd were infected by natural exposure. The breeding herd and GDU were vaccinated against Mh (M+PAC, Intervet) in late Jan.08 and again in Feb.08.

In Oct.08, efforts began to eliminate Mh, starting with depopulation of the GDU. The entire reproductive herd was vaccinated against Mh in Dec.08 (M+PAC, Intervet) and again Jan.09 (RespiSure, Pfizer). During Jan.09, the breeding herd received Lincomycin (Lincocin, Pfizer) through the water system and piglets received a weight-appropriate dose of injectable tulathromycin (Draxxin, Pfizer, 2mg/kg) at birth and 11 days later. During Jan.09, weaning occurred at >18 days of age (average weaning age was 20.6 days). By Feb.09, all females in Site 1 breeding herd were >11 months of age.

Starting in Feb.09, naïve replacement gilts entered the GDU and weaned pigs flowed into depopulated facilities. Each site of the post-weaning facilities were empty >2 weeks, though individual rooms were empty much longer.

Starting one month after the first negative replacement gilts (sentinels) entered Site 1, random sentinels were serologically tested monthly. Random pigs were tested monthly in the downstream flow as well, allowing for maternal antibody degradation. Mh IDEXX ELISA was used as the screening test. Mh Dako ELISA was used as the differential/confirmatory test on any positive IDEXX samples.

Results

Although sows infected naturally still exist in the breeding herd, shedding of Mh has apparently not occurred, based on continued monthly serologic sampling of sentinel animals and pig flow after the nursery depopulations. The absence of clinical signs and lack of Mh lesions on slaughter checks and routine necropsies (including Mh cultures, PCRs and histopathology) support this position. At the time of writing, serologic testing of sow herd sentinels at Site 1 has been Mh negative 12 months (>350 samples) and the off-site finishers have provided Mh negative slaughter-aged pigs six months (>100 samples). Tissues from >25 animals have been submitted for complete Mh analysis. Three slaughter checks from two finisher sites (n=90 pigs total) have shown no Mh lesions.

Discussion

In this case, Mh was eliminated with the following key factors:

- Mh vaccination of the entire sow herd shortly after initial exposure and at end of elimination.
- Continuous matings and farrowings throughout elimination process.
- Youngest Mh positive animals were >11 months of age and in their second parity before introduction of Mh naïve replacements and weaning of Mh (suspected) negative piglet flow.
- Lincomycin in water medication to breeding herd at end of elimination at Site 1.
- Tulathromycin injection of piglets at birth and 11 days later.
- Depopulation of nursery and finisher facilities before receiving Mh negative pigs.
Antimicrobial susceptibilities and molecular typing of Canadian isolates of Mycoplasma hyopneumoniae

Marie Archambault1 Audrey Charlebois1 Pierre Hélie1 Marcelo Gottschalk1 Carl A. Gagnon1 Corinne Marois2 Marylène Kobisch2
1. Université de Montréal, Saint-Hyacinthe, QC, Canada; 2. AFSSA, Ploufragan, France

Introduction
Mycoplasma hyopneumoniae is present in the majority of swine herds around the world. It is the causative agent of porcine enzootic pneumonia. Its importance is also linked to its ability to increase the severity of infections caused by viruses (1, 2), as well as bacteria (3). However, little is known about this microorganism in Canadian herds. The aim of this study was to evaluate the genetic diversity of M. hyopneumoniae and to determine their antimicrobial susceptibilities.

Materials and Methods
Bacterial isolates, growth conditions and PCR. A total of 160 swine lungs with lesions suggestive of enzootic pneumonia were recovered from two slaughterhouses. They were cultured in Friis medium and tested by PCR or real-time PCR for M. hyopneumoniae and M. hyorhinis (4) as well as PRRSV (Tetracore, USA), influenza and PCV2 viruses (5). Samples were also cultured for other commonly encountered swine pathogenic bacteria.

Antimicrobial susceptibilities and resistance genes. Antimicrobial susceptibilities were determined by minimum inhibitory concentration (MIC) for 18 antibiotics using the Sensititre® plates (#BOPO6F, Nova Century Scientific, Ontario, Canada) as described previously (6) without the use of M. hyorhinis antibodies. PCRs were performed for previously described antimicrobial resistance genes tetM and ermB, and point mutations in L4, L22 and 23S rRNA genes were investigated.

MLVA and RFLP. PCR-RFLP analysis, primers and conditions for locus P97-RR1 and locus P97-RR2 were used as previously described (7). Primers and conditions for locus 1 and 2 were provided as a personal communication from C. Marois, Agence française de sécurité sanitaire des aliments (AFSSA), France.

Cluster and data analysis. Digital images of PCR-RFLP gels and MLVA profiles were imported in the BioNumerics software (Applied Maths, USA) The Student “t” test was performed to evaluate significance (p<0.05; SAS software v.9.1).

Results and Discussion
Ninety percent of the samples were positive for M. hyopneumoniae (Real-time PCR) while 5.6% were positive only for M. hyorhinis (PCR). Within the 25 selected M. hyopneumoniae positive lungs (culture or real-time PCR), 10 were in co-infection with P. multocida, 12 with S. suis, 9 with PCV2 and 2 with the PRRS virus. MLVA and PCR-RFLP analyses of M. hyopneumoniae showed a high diversity among field isolates. However, there seem to be more homogeneity within the same herd. The MLVA analysis also demonstrated that almost half of the field isolates had less than 55% homology with the vaccine and reference strains used in this study. The absence of amplification of one locus (locus 1) of M. hyopneumoniae was significantly associated with a reduced concentration of bacteria and a lower severity of the lung lesions. All M. hyopneumoniae isolates had low to intermediate MICs against the antimicrobial tested (Table 1). Cultures with intermediate MICs for tetracyclines, macrolides and lincosamides were tested for the presence of previously described resistance genes tetM, ermB and L4, L22 and 23S rRNA point mutations. None of these genes were found but one point mutation, G2057A, was identified. This mutation is responsible for the intrinsic resistance of M. hyopneumoniae against 14-membered macrolides. These results indicate that there is no acquired antimicrobial resistance within these isolates.

Mycoplasma eradication using Draxxin® (Tulathromycin), Lincomix 44 Premix® (Lincomycin), and Respisure® in a 2750 sow isowean facility

Timothy P. Snider
Snider Veterinary Services, Steinbach, MB, Canada

Introduction

Mycoplasma hyopneumoniae is a primary contributor to the Porcine Respiratory Disease Complex (PRDC). (1) Its impact on the cost of finisher pig production makes eradication a serious alternative for profitable production. The possibility of producing effectively negative pigs following any one of several different eradication procedures has been well documented.(2) Mycoplasma eradication procedures commonly involve steps that have a negative impact on efficient breeding herd productivity. Examples include: 1) restrictions on replacement gilt flows to allow for Mycoplasma exposure and cessation of shedding, and 2) periods with no farrowing or ultra early weaning to prevent the infection of and shedding from piglets. (3) This paper describes a Mycoplasma eradication program that avoids these traditional pitfalls while rapidly achieving negative piglet production utilizing sow herd treatment with injectable Draxxin®, feed grade Lincomix 44®, and Respisure® vaccine. The Draxxin® application to sows and piglets was a modification of the protocol described by Yeske(4). The duration of Draxxin® application to piglets was extended in order to address the potential that recently exposed animals may continue to shed the organism for up to eight months. (5)

Materials and Methods

A Mycoplasma outbreak was confirmed in one of two naïve sow herds that combined their piglet production to produce marketable groups of weaned piglets. The outbreak occurred following the introduction of infected replacement breeding stock.

At the time of the outbreak, these herds were about to change from commercial weaned piglet sales to retained ownership into several large continuous flow wean to finish facilities. These wean to finish facilities were well isolated from other pig production and had a high likelihood of maintaining a Mycoplasma negative status.

The eradication protocol included the following steps:

- Piglets were weaned at 18 – 21 days. No piglets were held on the farm beyond 24 days of age.
- All weaned piglets received Respisure® vaccination in the nursery for 5 months following the eradication procedure.
- Mycoplasma naïve gilts entered the herd immediately following the second breeding herd treatment. Monitoring occurred using serology in Mycoplasma negative sentinel gilts. Post mortem sampling and the monitoring of clinical signs for Mycoplasma were also utilized.

Results

Piglets from the treated herd have been comingled with naïve piglets from another sow herd for 8 months. No Mycoplasma has been detected clinically or through other diagnostic methods.

Discussion

Although the cost of treating the complete sow herd was significant, the shareholders immediately recognized the value of rapidly achieving Mycoplasma negative piglet production to the profitability of the wean to finish system. Following the sow Draxxin® protocol, there continued to be a concern of shedding of Mycoplasma from parity 1 sows that entered the herd late in the process. The cost of a Mycoplasma outbreak in the large finisher operations would have been significant. With the assumption that Mycoplasma negative piglets can be produced using Draxxin® therapy in the event of shedding from their dams, all piglets were treated with Draxxin® for a period of 8 months after the last breeding animal was estimated to have been infected.

The Norwegian program for eradication of *Mycoplasma hyopneumoniae* is successfully completed

**Bjørn Lium**1, 2 **Anne Jørgensen**2 **Mona Gjestvang**2

1. National Veterinary Institute, Oslo, Norway; 2. Animalia, Oslo, Norway

**Introduction**

In the early 1990s The Norwegian Pig Health Service conducted successful eradication programs for *M. hyopneumoniae* in several pig herds based on age-segregation and medication (1). Preliminary serological surveys indicated that about 15% of the pig herds in Norway were infected with *M. hyopneumoniae*. Based on this knowledge it was decided to initialize a program to systematically reduce the occurrence of, and from year 2000, to totally eliminate *M. hyopneumoniae*-infection in the Norwegian pig population.

**Materials and Methods**

**Organization.** The nation-wide eradication program was decided in a co-operation between the pig breeders’ and the slaughter-house industry in 2000, and the Norwegian Pig Health Service was appointed to lead the operation. The program was based on voluntary participation, with some financial support from the pork industry and an agricultural tax fund. The pig producers’ economic benefit was a higher market price on live pigs in addition to an improved economic production yield on farm.

**Classification of herds.** The nucleus and multiplier herds were classified as free from *M. hyopneumoniae* if all of respectively 60 and 40 blood or colostrum samples were negative for antibodies against *M. hyopneumoniae*. For conventional herds the initial classification was based on blood or colostrum samples from at least 20 pigs (sows or slaughtered pig). Herds with 1 or 2 positive samples were retested. To maintain status as free from *M. hyopneumoniae*, the nucleus and multiplier herds are tested annually (at least 10 pigs per herd). The conventional herds were also tested annually in the first years of the program. The surveillance of these herds is now based on clinical signs and control of lung lesions at slaughter. Herds with respiratory symptoms are tested serologically.

**Laboratory methods.** The serum and colostrum samples have been analysed for the presence of antibodies to *M. hyopneumoniae* by a monoclonal blocking ELISA (DAKO®, Denmark), which has a very high sensitivity and specificity (2).

**Eradication programs.** Most of the infected breeding and breeding to finishing herds performed an eradication program based on a combination of age-segregation and medication (1). Finishing herds and some breeding herds were depopulated and restarted with pigs free from *M. hyopneumoniae*, and some herds gave up the pig production.

**Results**

During the years 1994 to 2009 samples from 138 635 pigs from 3247 different herds were tested for antibodies against *M. hyopneumoniae*, 5538 (4%) of the samples and 389 (12%) of the herds were declared as positive. The prevalence of positive herds differed from 5.8 in the South region to 19.2% in South-West region, Table 1. In 2009 all 9612 pigs tested from 839 herds were negative for antibodies against *M. hyopneumoniae*.

**Discussion**

A fundamental decision in our project was to start with establishing freedom from *M. hyopneumoniae* in all the nucleus and multiplier herds. With exception of the South-West region, which has a high density of pig farms, re-infections with *M. hyopneumoniae* has not been a problem in Norway. This may be explained by many small farms, long distances between farms, hilly landscape and a well-organised market for fatteners and gilts. In areas with a dense pig population we experienced that a strict regionalization of the eradication is crucial to succeed. Similar programs for eradication of *M. hyopneumoniae* have been implemented in Switzerland and Finland (3, 4). It is roughly estimated that freedom from *M. hyopneumoniae* means a benefit of 1-2.5 million euros per year for the Norwegian pig industry with a total of 1.5 million pigs slaughtered per year.

**Table 1.** Screening for *M. hyopneumoniae* antibodies in Norwegian pigs during the years 1994 to 2009.

Serotype distribution of A. pleuropneumoniae and H. parasuis in the Czech Republic

Linda Czanderlova; Marek Zizlavsky; Dita Kellnerova; Marcela Gambova; Svetlana Odehnalova; Jiri Odehnal
Sevaron Counselling, Brno, Czech Republic

Introduction
Actinobacillus pleuropneumoniae and Haemophilus parasuis cause health problems in pigs with a worldwide economic impact on industrialized pig production. Precise serotype identification is important for studying the epidemiology of these diseases, because the virulence and the prevalence of specific serotypes vary with geographic location (1). The knowledge of the predominant serotypes will facilitate the control of these diseases by vaccination, as strains can be then formulated in vaccines that will contain antigens homologous to those prevalent in the field.

Materials and Methods
The study conducted in the year 2008 and 2009 included 203 strains of Actinobacillus pleuropneumoniae and 53 strains of Haemophilus parasuis. All strains were isolated from the lungs of pigs showing clinical symptoms of respiratory diseases. A. pleuropneumoniae and H. parasuis were cultivated on chocolate agar based on Müller Hinton agar with 10% of ovine blood. The isolates of A. pleuropneumoniae and H. parasuis were serotyped by a standard coagglutination assay. The accuracy of the test was confirmed using reference strains for each serotype. Serotyping of H. parasuis was carried out by the Veterinary Research Institute, Brno, Czech Republic.

Results
Table 1 shows the proportion of A. pleuropneumoniae isolates detected and typed in this study. Serotype 9, identified in 129 strains, i.e. in 63.5% of all examined strains, was found to have the highest prevalence. Serotype 2 was detected quite frequently (51 strains, 25.1%), serotype 11 was less frequent (13 strains, 6.4%). Serotype 7 was identified in 5 strains, all detections of this serotype were recorded in the year 2009. The isolation of serotypes 3 and non-typable (NT) was sporadic. Other serotypes of A. pleuropneumoniae were not recorded.

Results of serotyping of H. parasuis are presented in Table 2. Serotype 4 was found to have the highest prevalence followed by serotypes 5 and non-typable strains. Serotypes 1, 2, 12 and 13 were detected less frequently. The isolation of serotypes 3, 7 and 9 was sporadic. Other serotypes of H. parasuis were not recorded.

Discussion
In the territory of the Czech Republic, the highly pathogenic serotype 9 is a dominant serotype of A. pleuropneumoniae followed by frequently isolated serotype 2. This finding is in harmony with preceding studies performed in the Czech Republic (2). In case of H. parasuis serotypes the situation is more varied. Nine different serotypes and ten non-typable strains were recorded. This finding results in the need of careful laboratory diagnostics in pig production in case of vaccination against H. parasuis. Owing to the fact that the vaccination is effective against homologous strains, but ineffective against heterogenous strains, autogenous vaccines containing strains isolated in a given herd prevail. But autogenous vaccines must be updated frequently to cover the entire spectrum of strains occurring in a given herd.

Pericarditis by Mycoplasma hyorhinis

Lucas F. Santos; Kledna C. Reis; Joao Paulo S. Castro; Daniel L. Santos; Mayka R. Henriques; Walter V. Guimaraes; Jose L. Santos

Microvet, Vicoso, MG, Brazil

Introduction

Mycoplasma hyorhinis is a common agent found in the respiratory tract of pigs, and it can cause polyserositis when become systemic, especially in nursery and grower pigs (Rovira, 2009). Fibrinous pericarditis can be one of the clinical signs found at necropsy. (Buttenschøn et al. 1997). The fibrinous pericarditis has been linked to various agents such as Haemophilus parasuis, Pasteurella multocida, Actinobacillus pleuropneumoniae, Actinobacillus suis and Streptococcus suis (Mores, 2007). However, there are cases where you do not get the isolation of bacteria. Based on this aspect, we conducted a study to verify the presence of M. hyorhinis in pericarditis cases where the bacterial isolation was negative.

Materials and Methods

We evaluated 40 cases of pericarditis from pigs with age ranging from 20 to 106 days, negative for bacterial isolation performed by Microvet laboratory. The DNA genomic samples were extracted using the kit PureLink Genomic DNA Mini Kit (Invitrogen) and polymerase chain reaction (PCR) was performed according to Assunção et al. 2005.

Results

From the 40 samples studied, 67.5% were positive for M. hyorhinis, 7.5% for Mycoplasma hyopneumoniae, 7.5% for M. hyorhinis and M. hyopneumoniae, and 17.5% negative for both agents (Graphic 1).

Discussion

It has been observed in recent years a considerable increase in detection of Mycoplasma hyorhinis in polyserositis cases, however always associated with another bacterial agent or associated with PCV-2 causing a severe respiratory syndrome (Santos et al. 2008). Some authors consider this pathogen as the secondary agent of infection. This study showed that the M. hyorhinis can act as primary agent in some cases, mainly of fibrinous pericarditis. Another aspect to consider is in related to PCR technique, which proves to be very sensitive, rapid and less costly for diagnosis of this agent.

Prevalence of lesions of pleuritis at slaughterhouse

Jesus M. Bollo1 Rut Menjon1 Marta Jimenez1 Jesus V. Lopez1 Maria L. Perez-Brena1 Maria T. Tejedor2
1. Intervet Schering Plough. c/ Cantabria 2, Edificio Amura 28.108 Alcobendas, Madrid, Spain; 2. Dept. of Anatomy, Embryology and Genetics Unit of Genetics. Faculty of Veterinary Medicine, Zaragoza, Spain

Introduction

Pleuritis is a frequent finding in dead pigs whether they have died on farm or been killed in the slaughterhouse. The lesions are the result of infection by various respiratory pathogens, leading directly to economic losses, often price reduction or carcass condemnation. Thus it is important to investigate the prevalence of pleuritis.

Materials and Methods

The study was undertaken in Spanish slaughterhouses from 2000 to 2010, examining 145,456 lungs from 1,085 slaughterhouse batches, originating from 451 farms. Only the presence or absence of pleuritic lesions was recorded, without noting their position within the pulmonary lobes or whether in visceral or parietal pleura.

The aetiology of the lesions was not investigated, but it was suspected that the most probable pathogens were *A. pleuropneumoniae, P. multocida* and *H. parasuis*.

Statistical analyses were carried out by using the SPSS 15.0 software package. ANOVA was used for the comparison of means.

Results

The mean percentage of lungs with pleuritic lesions was 14.10% (± 0.34). Graph 1 is a histogram fitted to a normal curve to show the distribution of the percentage prevalence of pleuritic lesions in the different slaughterhouse batches assessed.

Graph 1: Distribution of percentage of pleuritis in the assessed slaughterhouse batches

For the 15% of batches with the lowest rate of pleuritis (≤ 3.84%; 162 batches), the mean percentage of lesions was 2.06% ±0.09. For the 15% of batches with the highest rate of lesions (≥ 25.00%; 163 batches), the mean value was 34.52% ±.81.

Table 1 shows % pleuritis over the 11 years of the study.

Significant differences (p<0.05) were found between the year 2004 and the years 2000, 03, 06, 07, 08 and 09, and also when comparing the year 2005 with the year 2009.

When the results were grouped for the 316 batches of pigs which had been fattened during the winter months (December 1 to March 31) for all the years, and compared with the results obtained during the rest of the year (769 batches), the mean prevalence of pleuritic lesions was 15.11% and 13.69% respectively. There were no statistically significant differences between these means, though the p value was close to the limit of significance (F=3.556 NS; p=0.06).

In the periods 2003-2005 and 2007-2009 there was an evident increase in the incidence of pleuritis during the coldest months, but this tendency was not repeated in any of the other years studied, which may explain the results obtained.

Discussion

Lesions of pleuritis are a common finding at the slaughterhouse. Important differences emerged between years in the extent of the lesions present, indicating a need to evaluate further the severity of the lesions found (1) and to diagnose the cause of the pleuritis when there is a high prevalence, in order to be able to implement effective control measures in herd and disease management.

In previous studies, the Slaughterhouse Pleurisy Evaluation System (SPES) and Actinobacillosis Pleuropneumonia-Index (APPI) have been shown to be valuable tools in assessing pleuritis (1,2).

Case report: Can a combination of PRRSv and Mycoplasma hyorhinis cause Enzootic Pneumonia-like lung lesions?

Mark Roozen; John B. Tasker; Oliver Duran
ECO Animal Health Ltd, London, UK

Introduction
Mycoplasma hyopneumoniae is the primary pathogen associated with Enzootic Pneumonia in pigs, and causes characteristic lesions. We report a case in which similar lesions were associated with respiratory disease during a PRRS virus outbreak. These observations were recorded during a trial comparing the use of a macrolide, tylvalosin (TVN), with a combination of tylosin and doxycycline for control of respiratory disease.

Material and Methods
A 3,500 finisher herd in the most densely populated pig area in The Netherlands had a history of PPE, PRRSv and multifactorial respiratory disease. PCR assay including multiplex PCR and Real time PCR for M. hyopneumoniae was carried out by the IVD Lab on endotracheal Bronchi-Alveolar Lavage Fluid (BALF). BALF samples were taken on arrival of the finishers at 10 weeks of age. ELISA (HerdChek Mycoplasma hyopneumoniae Antibody and PRRS 2XR-Antibody Testkit, IDEXX) was used when the pigs were 17 weeks of age. Lung scoring was carried out during two slaughterhouse examinations when the pigs were ~ 24 weeks of age.

Results
Diagnostic tests results
At 10 weeks of age all samples were positive for M. hyorhinis and PRRSv, but negative for PRCV, M. hyopneumoniae, SIV, PCMV and PCV-2. At 17 weeks of age there were no clear positives for M. hyopneumoniae (9 negative, 1 doubtful).

Macroscopic lesions at slaughterhouse
Lungs (177 pigs in the first batch, 131 pigs in the second batch) were scored as healthy, minor (10–50% of the lung tissue affected) or extensive (over 50% of lung tissue affected) with lesions of Enzootic Pneumonia (dark red/purple consolidation on the apical, cardiac and intermediate lobes). The number of lungs with lesions varied between the 2 batches, extensive lesions were present in 13/177 (7%) and 13/131 (10%). Minor lesions were present in 17/177 (10%) and 21/131 (16%). This resulted in 17% and 26% of the total number of animals with macroscopic lesions of catarrhal bronchopneumonia in the two batches. The incidence of pleuritis was very low (2-3%) whereas 10-15% is typical. The incidence of pericarditis was 2-3%, and for abscessation 0-2%.

Discussion and conclusions
These results suggest that M. hyopneumoniae did not play a part in the respiratory disease in this herd. M. hyopneumoniae was not found in BALF by PCR assay and the serum ELISA was also negative. M. hyorhinis has been shown in challenge studies to produce pneumonia with histological lesions similar to infection with M. hyopneumoniae. PRRSv infection has been shown to damage lung tissue, permitting colonisation of the serous membrane by M. hyorhinis.

These diagnostic tests are frequently used in the field. However, as the sensitivity of the ELISA for M. hyopneumoniae is relatively low and macroscopic lesions are non-specific a combination of diagnostic methods is advised. BALF is recognized as a valuable diagnostic method for porcine respiratory disease, but the isolation of pathogens is not sufficient to diagnose the cause of respiratory disease on the farm.

The diagnosis of M. hyopneumoniae, the pathogenesis of Enzootic Pneumonia and the role of M. hyorhinis in EP is not clear and further research is needed.

Swine respiratory diseases in Aragon (Spain): economic, pathology and microbiological study during the year 2008

Juan Grandía1 Ana Cristina Berges1 María Victoria Falceto2
1. Agrotest Control S.L., Zaragoza, Spain; 2. Faculty of Veterinary Medicine, Zaragoza, Spain

Objective
The objective was to evaluate the prevalence and economic impact of swine respiratory pathology in the region of Aragón (Spain).

The swine sector contributes greatly to the Spanish economy, since it has an annual production of more than 4,000 million euros/year. Spain is the second and fourth European and world swine producer respectively. Aragón contributes 18.60% to the Spanish pig census. Aragón has 411,861 sows and 1,884,649 feedlot hogs (1). An important part of the economic losses of the Spanish pig sector are due to respiratory disease, leading to worsening conversion rates, losses of daily average gain, prolonged stays in the pig farm and increased mortality. (2)

Materials and Methods
The development of this investigation has been based on three sections:

1) Study of 52 surveys answered by Aragón veterinarians responsible for 216,085 sows and 2,039,255 hogs. In the survey farm’s productive data were asked: % mortality due to respiratory problems, treatment costs and vaccination, % of delayed pigs following respiratory disease, seizures at slaughterhouse, conversion rates and veterinarian’s time dedicated to respiratory problems. The data was processed in a computer simulator of costs and sales (SIP Consultants Model).

2) Pulmonary post-mortem inspection of 7,014 lungs of pigs sacrificed throughout the year 2008 was reported. An evaluation of the lung was made to identify areas of pneumonia. A fast scale was used which allowed to obtain between 0 to 5 points per lung. The scores were assigned according to the following criteria:
   0: Absence of pulmonary injuries
   I: Injuries just in the apical pulmonary lobes
   II: Small injuries in other pulmonary lobes
   III: Injuries in three pulmonary lobes
   IV: Injuries in the intermediate lobe in addition to others.
   V: Presence of injuries in all the lobes.
   The presence of pleurisy and/or pericardial diseases and other injuries were also documented.

3) Microbiological culture in 616 samples and detection of viral antigens by indirect immunoperoxidase in 470 samples.

Results
After survey analysis, an economic estimate was obtained. A negative average of 13.72 € was found by each pig that goes to the slaughter house.

After pulmonary inspection at the slaughterhouse, it was verified that during summer and winter, 32% and 43.70% respectively, of the animals had healthy lungs (0). The pulmonary injuries were small (I) in 45.89% during summer and 62.54% during winter. The most serious pulmonary injuries (II) were 55% during summer and 14.75% during winter.

Discussion
The animals that have more pulmonary injuries are those coming from small capacity farms.

The low level of Aujeszky GE antigens indicates the effort made to eradicate this disease in Aragón.

Association between TTV genogroups 1 and 2 and PCV2 as well as various respiratory pathogens – a retrospective study

Christiane Lang1 Heidi Söllner1 Andrea Barz1 Andrea Ladinig1 Rebecca Langhoff1 Herbert Weissenböck2 Tuija Kekarainen3 Joaquim Segalés3 Mathias Ritzmann1

1. Clinic for Swine, Vienna, Austria; 2. Institute of Pathology and Forensic Veterinary Medicine, University of Veterinary Medicine Vienna, Vienna, Austria; 3. Centre de Recerca en Sanitat Animal (CReSA), UAB-IRTA, Campus de la Universitat Autònoma de Barcelona, Barcelona, Spain

Introduction

Torque teno viruses (TTV) are viruses discovered in humans and several domestic and wild animal species including swine (1). The virus belongs to the floating genus Anellovirus. Two TTV genogroups are identified in domestic pig as well as in wild boar (2, 3). Association between TTV and PMWS affected pigs has already been determined (4). In humans, also respiratory diseases linked to TTV have been described (5). In the present study a possible association between TTV and PCV-2 and respiratory pathogens was investigated.

Materials and Methods

A total of 253 sera collected in 2008 were tested by conventional PCR (6) for TTV genogroups 1 and 2. Retrospectively, results of former diagnostic findings of those samples were evaluated and possible association to TTV was investigated (Table 1). Furthermore, the association between the final diagnosis PRDC and TTV as well as PCV2 was evaluated. The diagnosis PRDC was based on patho-morphological findings (pneumonia, bronchitis, pleurisy). The percentage of corresponding results, the Pearson’s coefficient of correlation and the level of significance (p) were calculated. P-values less than or equal 0.05 were considered significant.

Results

Association between TTV and PCV2 is shown in Table 2. There was no correlation between TTVs and P. multocida or APP. A negative correlation between both TTVs and M. hyopneumoniae (p > 0.05) as well as H. parasuis (p = 0.041) was found. Significant correlation was found between TTV2 and the final diagnosis PRDC (p = 0.000), whereas there was no association between TTV1 or PCV2 (ISH) and PRDC.

Discussion

TTV in swine may have clinical relevance as a cofactor in multifactorial diseases. Association between TTV and PMWS affected pigs (caused by PCV2) has already been described. Also in the present study a significant correlation between PCV2 IgM-Ab and TTV1 as well as PCV2 virus and TTV2 was detected. IgG-Ab were not included into the evaluation because they could have originated from vaccination, whereas IgM-Ab only rarely appear in context with a vaccination. No correlation between other respiratory agents and TTVs could be found, but an association between PRDC and TTV could be determined. To what extent TTV has to be considered as a cofactor for the development of respiratory diseases in swine still needs to be investigated.

Pleurisy: characterisation of associated pneumonia and viral infections (PCV2, PRRSV, SIV)

Henrike J. Jager1 TJ McKinley1 James L. Wood1 Gareth P. Pearce1 Susanna M. Williamson2 Nicholas Woodger3 Benjamin Strugnell3 Stanley H. Done3 Henrike Habernoll4 Alexander W. Tucker1

Introduction
Pleurisy is recognized as an important aspect of respiratory disease. There are insufficient data on the extent of the relationship between pneumonia and pleurisy but it undoubtedly exacerbates the economic losses of respiratory disease due to consequent required carcase trimming at slaughter. A number of studies have identified risk factors associated with pleurisy (environmental (1), bacterial (2), and recently viral (3)). This study explored the relationships between histological types of pneumonia and active or resolved pleurisy and investigated the role of viral infections (PRRS, PCV2, and influenza) in pleurisy.

Materials and Methods
A total of 79 pigs were selected for necropsy across 12 UK finisher units that reported a consistent pleurisy prevalence of >10% at slaughter. Pigs were selected on the basis of clinical respiratory signs and included the youngest pigs showing respiratory signs (such as dyspnoea and/or coughing). Pigs on 3/12 units were vaccinated against PRRSV (18/79 pigs in study). On 10/12 units pigs were vaccinated against PCV2 (63/79 pigs) and PCV2-associated disease (PCVAD) was not reported as a clinical problem on any units. Each pig was allocated a pleurisy status based on a combination of gross and histopathological findings (no pleurisy (NP), active pleurisy (AP), resolved pleurisy (RP)). Histopathological evaluation permitted each pig to be categorised as having no pneumonia (NPn), bronchopneumonia (BPn), broncho-interstitial pneumonia (BIPn), or interstitial pneumonia (IPn). Virology investigations in each pig comprised PCR on blood for PRRSV, histopathology and immunohistochemistry on lung for PCV2-associated pneumonia, and on inguinal and ileocaecocolic lymph node for PCV2-associated lymphoid changes, and virus isolation on pooled tonsil, trachea and lung for swine influenza virus (SIV).

Results
Of the 79 pigs, 23 had no detectable pleurisy (age range 5-21wks), 25 showed active pleurisy (5-21wks) and 31 showed resolved pleurisy (10-21wks). AP and RP were found on all 12 units. Histopathology revealed the following findings: NPn – 8 cases, BPn – 21 cases, BIPn – 45 cases, IPn – 5 cases. Twenty four of the 79 pigs had a PRRSV viraemia, 11 had PCV2-associated pneumonia, and 13 had PCV2-associated pathology in lymph node. Analysis of the relationship between pleurisy and pneumonia revealed statistically significant associations (p=0.0006). For the no pleurisy group, pneumonia types were broadly distributed across NPn (30%), BPn (39%), BIPn (17%) and IPn (13%). However, for the AP group there was a marked increase in the proportion of cases with broncho-interstitial pneumonia (NPn – 0%, BPn – 28%, BIPn – 64%, IPn – 8%). This increased prevalence of BIPn was even more marked in the RP group (NPn – 3%, BPn – 16%, BIPn – 81%, IPn – 0%). Associations were found between pleurisy and infection by PRRSV and PCV2. For PRRSV viraemia, NP = 4 pos/23 (17%), AP = 9 pos/25 (36%), RP = 11 pos/31 (35%); p=0.03. For PCV2-associated pneumonia, NP= 0 pos/23 (0%), AP=7 pos/25 (28%), RP=6 pos/31 (19%); p=0.02. For PCV2 detection in lymph node, NP=0 pos/23 (0%), AP=7 pos/25 (28%), RP=6 pos/31 (19%); p=0.02. SIV was found in 1 pig.

Discussion
This study focused only on pigs from production units with consistently high pleurisy prevalence. Within these units we found that pigs affected by pleurisy were more likely to be affected by broncho-interstitial pneumonia than pigs on the same units without pleurisy. Furthermore, we found associations between pleurisy and PRRSV viraemia and pleurisy and PCV2-associated pneumonia or PCV2 pathology in lymph nodes. The majority of units undertook vaccination against PCV2-associated disease (PCVAD) and none reported clinically active PCVAD. These findings highlight the value of reviewing procedures to maximise PCV2 and PRRSV vaccine-induced protection as part of a strategy to control pleurisy.

Serum acute phase proteins as biomarkers of pleuritis and cranio-ventral pulmonary consolidation in slaughter-aged pigs

Lorenzo Fraile1 Yolanda Saco2 Merce Giménez2 Ana Alegre1 Rosa López-Jimenez1 Marti Cortey1 Joaquim Segalés1 Anna Bassols2
1. CReSA, Bellaterra, Spain; 2. Departament de Bioquimica i Biologia Molecular, Barcelona, Spain

Introduction

Pleuritis and cranio-ventral pulmonary consolidation (CVPC) are the most frequent pathological findings in pig lungs at slaughter (3). Several environmental factors and infectious agents have been associated with the occurrence of lung lesions in swine. Mycoplasma hyopneumoniae and Actinobacillus pleuropneumoniae are considered to be the most important primary bacterial respiratory pathogens (6). On the other hand, the acute phase protein (APP) response plays an important role in lung infection (5). Therefore, the purpose of this study was to investigate the relationship between the existence of lung lesions in pigs at slaughter and the concentration of three APPs, haptoglobin (Hp), pig-major acute protein (Pig-MAP) and C-reactive protein (CRP).

Material and Methods

Twenty-four farms were used for the present study. Pleuritis lesions were assessed based on the Slaughterhouse Pleurisy Evaluation System (SPES score). An A. pleuropneumoniae index (APPI) was defined to provide information on the prevalence and severity of pleuritis lesions as previously described (1). Farms were classified as "pleuritis negative (P-) or positive (P+)" if they had low or high APPI values, respectively. Moreover, farms were classified also as "CVPC negative (M-) or positive (M+)" if the percentage of lungs with these lesions at farm level were lower or higher than 60%, respectively. CVPC lesions were evaluated using a previously described method (2). Selected farms were divided into four combined groups (P-M-, P-M+, P+M-, P+M+), including 6 farms per category. Blood from 20 randomly selected pigs from each farm was collected and selected APPs determined in serum. Hp was quantified by a spectrophotometric method (haemoglobin binding assay). Pig-MAP levels were assessed with an ELISA kit (PigCHAMP ProEuropa, Segovia, Spain). Finally, CRP was determined using a commercial immunoturbidimetric method (Olympus System Reagent, OSR 6147).

A non-parametric test (Mann-Whitney) was used to evaluate the effect of pleuritis or CVPC lesions on the concentration of APPs. Finally, a Receiver Operating Characteristic (ROC) analysis was carried out to determine the capacity of discrimination of APPs in farms classified as P- or P+ or M- or M+ and when the four groups were taken into account (P-M-, P-M+, P+M-, P+M+).

Results

All APPs concentrations were significantly higher for M+ farms than for M- ones. However, only Hp and Pig-MAP showed significantly higher values for P+ farms than for P- ones (p<0.05). Pig-MAP was the most sensitive indicator since it was able to clearly discriminate between P-/P+ and M-/M+ groups (p< 0.001 in both cases). Hp was an excellent marker for pleuritis and good for CVPC lesions. CRP was able to discriminate for CVPC lesions but not for pleuritis. ROC analysis showed that Pig-MAP was the best biomarker, with 67.8% sensitivity and 78.8% specificity to discriminate between P-M- and P+M+ farms.

Discussion

There is little information in the literature about the relationship between serum APP and the degree of lung lesions of pigs at slaughter (4). The present study shows that both Pig-MAP and Hp can be used as unspecific markers for the presence of pleuritis and/or CVPC lesions at slaughter. None of the tested APPs was able to discriminate both types of lesions; such result is not surprising, taking into account to their unspecific role in the inflammatory response. It is very important, however, to note that pigs involved in the present study did not show any clinical sign of disease at slaughter, and lesions were identified in a retrospective evaluation by abattoir surveillance.

Potential use of long pentraxin 3 (PTX3) as a biomarker in pigs

Elisa Crisci, Lorenzo Fraile, Sonia Valentino, Meritxell Simon-Grifé, Gerard E. Martin-Valls, Tufária Mussá, Barbara Bottazzi, Alberto Mantovani, Maria Montoya

1. Institut de Recerca i Tecnologia Agroalimentàries (IRTA), Barcelona, Spain; 2. Centre de Recerca en Sanitat Animal (CReSA), UAB-IRTA, Campus de la Universitat Autònoma de Barcelona, Bellaterra, Spain; 3. Istituto Clinico Humanitas, Rozzano, Italy

Introduction

Long pentraxin 3 (PTX3) is a conserved pattern-recognition molecule and a host-defense-related component of the humoral innate immune system. PTX3 is produced in a variety of cell types and tissues, most notably dendritic cells (DC) and macrophages, in response to Toll-like receptor engagement and inflammatory cytokines. PTX3 regulates the complement cascade, facilitates the pathogen recognition via cellular receptors (opsonisation) and plays a regulatory role during inflammation. Moreover, PTX3 is related to female fertility in human and mice (1, 2, 4).

PTX3 has an antiviral role in early host defence against influenza infections (5) and it might be a useful biomarker of acute lung injury (4) in mice. No information on PTX3 role in pigs is available at the moment.

The aim of our study was to investigate the role of PTX3 as a biomarker in vivo and in vitro in pigs.

Material and Methods

For in vitro study, porcine bone marrow-derived DC were generated and infected with a H3N2 swine influenza virus (A/Swine/Spain/80598-LP1/2007).

For in vivo study, sixteen conventional pig farms with history of pleuritis lesions and cranio-ventral lung consolidation were used (3). Blood from 20 randomly selected pigs from each farm was collected and selected acute phase proteins were determined in serum. Hp was quantified by a spectrophotometric method (haemoglobin binding assay). Pig-MAP levels were assessed with an ELISA kit (PigCHAMP ProEuropa, Segovia, Spain). Finally, CRP was determined using a commercial immunoturbidimetric method (Olympus System Reagent, OSR 6147). Moreover, sera from 48 conventional sows from parity one to eight showing high swine influenza virus (SIV) antibody titres were also used.

PTX3 concentration in sera and culture supernatant was determined by sandwich ELISA (2C3 and 6B11 antibodies) as previously described (8).

Statistical analysis was performed using SPSS 15.0 software (SPSS Inc., Chicago, IL, USA).

A linear regression between different variables was carried out and a Kruskal-Wallis test was used to compare PTX3 serum levels between different sow parities. All this statistical analysis was performed using SPSS 15.0 software (SPSS Inc., Chicago, IL, USA).

Results

The in vitro study showed that porcine myeloid bone marrow-derived DC produced PTX3 after infection with porcine influenza virus H3N2.

The in vivo results have shown that PTX3 serum levels are correlated neither with Hp, CRP or Pig-MAP nor with lung lesions score in conventional swine farms. PTX3 concentration in SIV antibody positive sera of studied sows increased with the parity number showing statistical tendency between the youngest and the oldest sows (p=0.07). Moreover, there was no statistical correlation between SIV antibody titres and PTX3 amount in serum.

Discussion

PTX3 is produced by myeloid DC in human and mice and the present study confirmed in vitro production on porcine myeloid DC.

In vivo results have shown that PTX3 is not a good biomarker for chronic lung lesion status in swine farms when compared with Hp and Pig-MAP (7). However, PTX3 concentration in SIV antibody positive sera correlated with a greater exposure to infections, indicating that PTX3 might be used as a biomarker under certain conditions. Further studies should be performed to elucidate its possible practical application.

This is the first analysis of PTX3 role in pigs and future studies will determine its contribution in porcine innate immunity.

References

Introduction
Respiratory diseases are one of the main problems in human and animal health. Several models to study the respiratory immune system has been used, but humans and pigs share the unique feature of a non-constitutive bronchus-associated lymphoid tissue (BALT) (1-2). In spite of its importance, no studies on lung macrophage (Mf) development have been carried out. We examined the development of Mf in blood, bronchoalveolar lavage (BAL) and lung parenchyma (LP) of pigs after weaning by flow cytometry.

Material and Methods
Five 5 weeks-old weaned pigs (WP), five 3 months-old (3m) and four 5 years-old (adults) SPF potbellied mini pigs from the animal unit of CINVESTAV (UPEAL), compiling with local and federal regulations of animal care and with no vaccination protocols running, were used. PBMC were obtained by Ficoll/Isopaque gradient, BAL cells were obtained by tracheobroncheal lavage with PBS and lung parenchyma cells (LP) were obtained after enzymatic digestion of fresh tissue. Mouse monoclonal antibodies to pig CD172a (IgG1-MIL-2-), CD14 (IgG2b-74-22-15-) and MHC-II (IgG2a-MSA-3-) were used with fluorochrome conjugated goat anti-mouse secondary antibodies (IgG1-PE, IgG2b-APC, IgG2a-FITC). The cells were run in a FACScalibur (B-D) flow cytometer. Relative and absolute numbers of positive cells were calculated and the results were analyzed by ANOVA.

Results
The proportion (%) of CD14+MHC-II+ Mf was higher in all tissues of WP (WP>adults=3m) (Fig 1A). CD14+CD172a+cells were higher in 3m PBMC (3m>WP), and LP of adults (Adults>WP=3m) (Fig 1B). CD14+ double positive (DP) cells were higher in all tissues of 3m and adults (3m=adults>WP) (Fig 1C) and CD14+ double negative (DN) cells were higher in WP PBMC (WP>3m) and adult LP (Adults>3m) (Fig 1D). Absolute numbers of CD14+MHC-II+ were higher in PBMC (WP>3m), BAL and LP of WP (WP>3m=adults, Fig 1E). CD14+CD172a+ were higher in PBMC of 3m pigs (3m>WP, Fig 1F). CD14+DP cells were higher in 3m BAL (3m>WP) and LP (3m>WP=adults, Fig 1G) and CD14+DN cells were higher in WP PBMC (WP>3m=adults) and LP (WP>3m, Fig 1H).

Discussion
Mf subpopulations in the lung undergone important changes in proportion and number with age. At least four different CD14+subpopulations were identified. MHC-II+ and CD172a+ cells may have different roles since they tend to inversely change with age (Fig 1A, E & B, F). DP cells tend to increase with age (Fig 1C, G) in contrast with DN cells (Fig 1 D, H). MHC-II+ may correspond to activated Mf, CD172a+ is a SIRP molecule, related to activation control (3-5). DP cells may be related to fully differentiated Mf and DN to scavenger non-activated cells. Their role in lung protection remain to be elucidated. These data also show evidence of important differences among tissues.

Figure 1. Relative (A-D) and absolute (E-H) numbers of CD14+ macrophage subpopulations in PBMC, bronchoalveolar lavage (BAL) and lung parenchyma (LP) of weaned (WP), 3 months-old (3m) and 5 years-old (adults) SPF potbellied mini pigs (n=5/group). Bars show the mean plus SEM. ANOVA test. *P<0.05, **P<0.01, ***P<0.001.

**Interaction between Mycoplasma hyopneumoniae and fumonisin B1 toxin in the porcine respiratory tract**

Roland Pósa² Melinda Kovács² Judit Szabó-Fodor² József Mondok² Péter Bogner³ Imre Repa³ Tibor Magyar¹

¹. Veterinary Medical Research Institute, Budapest, Hungary; ². Kaposvár University, Faculty of Animal Science, Kaposvár, Hungary; ³. Institute of Diagnostic Imaging and Radiation Oncology, Kaposvár, Hungary

**Introduction**

Respiratory disease is one of the most important health concerns for swine production. The term porcine respiratory disease complex (PRDC) refers to a condition in which an interaction between various pathogens and inappropriate environmental conditions lead to severe respiratory disorders (1). In this study, we examined the possible synergy between M. hyopneumoniae (Mh) and fumonisin B1 (FB1) toxin in the lung of pigs. Computed tomography (CT) proved useful for imaging pneumonia (3). CT was applied to follow up the pathological events in the lung.

**Materials and Methods**

Twenty-eight 3-day-old pigs, obtained from a high health-status herd, were used in the study. The arrival of the pigs was day 0 of the study. After an early weaning, the piglets were artificially reared receiving milk-replacer until day 16 and then appropriate solid feed until the termination of the experiment (day 58). Four groups of 7 pigs were formed:

- **Group 1:** uninfected untreated controls
- **Group 2:** uninfected - treated with FB1-toxin
- **Group 3:** infected with Mh - untreated
- **Group 4:** infected with Mh - treated with FB1-toxin

Group 3 and 4 were infected with Mh (strain Mp 496) on day 30. The inoculum was prepared by suspending 1.5 g Mh containing lung tissue in 13.5 ml phosphate buffered saline (pH 7.2). Pigs were inoculated intra-tracheally with 0.5 ml of the suspension containing 10⁹ colour-changing units per ml. Groups 2 and 4 were fed with FB1-contaminated feed (10 mg/kg) from day 16 until termination. The toxin was produced as described (2). CT images of the whole lung were acquired at days 16, 30, 44 and 58 using a SIEMENS Somatom Emotion 6 multislice CT scanner. At termination, the pigs were humanly killed and lung lesions were evaluated post mortem (4). CT images were analysed by Medical Image Processing V1.0 software. Affected were compared with and non-affected areas.

**Results**

From day 37 the infected animals showed clinical signs (coughing, laboured breathing and huskiness). CT examination did not reveal lesions in the negative control pigs (group 1) and the FB1-treated group (group 2) suggesting that the toxin did not induce macroscopic lesion at this dose level. In the Mh infected groups (groups 3 and 4) lung lesions were found in all animals on day 44. The most pronounced lesions were observed in the cranial, middle, and the accessorius lung lobes and in the front of the caudal lobe. The lung lesions appeared first around the small respiratory airway passages, later whole lobules and lobes became affected. Necropsy did not reveal lung lesion in the negative control pigs (group 1). In group 2, mild interstitial oedema was observed in four animals. In the Mh infected groups (group 3 and 4) we found acute catarrhal pneumonia in all animals. The macroscopic lung lesions were more pronounced in group 4 than in group 3. Significant differences were detected between non-infected and infected groups by CT evaluation.

**Discussion**

The Mh infection produced lung lesions in young piglets that were increased by treatment with FB1 toxin. The only lethal case and the highest rate of lung lesions were found in group 4 that received FB1-toxin treatment beside the bacterial infection indicating that the FB1-toxin increased the severity of pneumonia caused by the bacterial pathogen. These findings confirm the idea of PRDC that various factors may act in harmony to produce pneumonia. Our results also indicate that CT can be applied for studying the pathological conditions in the lower respiratory tract of swine.

Virulence genes and PFGE types of Pasteurella multocida field isolates from pigs in South Korea

Aeran Kim; Ji Youn Lee; Chun Tae Lim; Kichan Lee; Suk Chan Jung
National Veterinary Research & Quarantine Service, Anyang, Korea

Introduction
Pasteurella multocida is widely recognized as the causative agent of progressive atrophic rhinitis and hemorrhagic septicemia in swine and is of considerable economic importance to the pig rearing industry throughout the world. The present study reports the frequency, features and molecular epidemiology of P. multocida isolates from diseased and finished pigs.

Materials and Methods
A total of 140 P. multocida isolates was collected from 751 cases of diseased and finished pigs during 2007-2009 in South Korea. The isolates were analyzed by PCR for the capsular type (A, B, D, E, F) and the presence of virulence genes. The 4 virulence-associated genes were detected with varying frequency. Genotyping of the isolates were performed by Pulsed field gel electrophoresis (PFGE)

Results
The most prevalent capsular type among P. multocida isolates was capA (54.1%), followed by capD (45.9%) from diseased pigs. However, from finished pigs, the prevalent of capA (97.5%) was higher than capD (2.5%). A higher percentage of toxA was detected among diseased pigs (12.5%) compared with strains isolated from finished pigs (3.8%). Among clinical isolates hgbB and tpbA was more frequently identified in strains isolated from diseased pig (95.8%, 54.2%) whereas 78.8% and 18.8% of the finished pig isolates harbour this gene. However, pfhA gene detected more frequently from finished pigs (50.0%) than diseased pigs (16.7%). The PFGE patterns of the isolates revealed five different genotypes.

Discussion
These data enforce further virulence and epidemiological studies, examining the properties of porcine P. multocida strains as well as factors of the porcine hosts themselves, which might be involved in disease susceptibility.

FUGATO RePoRl: Development of a powerful tool for the analysis of bacterial lung infections in pigs

Martin Selke3 Doris Hoeltig1 Gerald F. Gerlach2 Karl-Heinz Waldmann1 Fugato Consortium IRAS1 Fugato consortium RePoRI1
1. Clinic for Swine and Small Ruminants, Forensic Medicine and Ambulatory Service; 2. IVD GmbH, Hannover, Germany; 3. Institute of Microbiology, Department of Infectious Diseases, University of Veterinary Medicine Hanover, Foundation, Hannover, Germany

Introduction

Lung infections have a great impact on the pig breeding and fattening industries worldwide. Economical losses due to stunted growth of piglets or massive need of antibiotic treatment of infected herds along with the oftentimes missing alternative of vaccination strategies encouraged a change in strategy toward a breeding programme focusing on lung health. Therefore the FUGATO-IRAS project and the follow-up project RePoRl work on the identification of genetic markers responsible for an increased resistance towards bacterial lung infection by the use of the infection model *Actinobacillus pleuropneumoniae* (App).

Materials and Methods

Within IRAS 106 pigs of 4 breeding lines (German Landrace, Piétrain, Hampshire, Large White) were infected. The aerosol infection was performed using *App* serotype 7 strain AP76. Sampling (BALF, blood) and phenotyping were carried out twice (day 4 and day 20 post infection [p.inf.]). Pigs were euthanized immediately after the sampling, lung lesions were scored during necropsy by the Lung Lesions Score according to Hannan et al., and lung tissue was taken. For additional phenotyping a Respiratory Health Score (1) was used. Acute phase proteins were determined (blood, BALF), glycoproteins (BALF) were analyzed via differential two-dimensional gel electrophoresis (2D-DIGE) and RNA expression was investigated using the Affymetrix GeneChip® porcine Genome Array. In addition, a consumer study investigating the allele diversity within German pork was realized and SNPs for candidate genes, derived from known human genes, were detected and characterized.

As tool for the analyses of the host-pathogen-interaction a versatile, multi-species microarray based on the CustomArray™ platform of Affymetrix® was developed. Using extensive in silico analyses using BLAST and MUMMER (2) followed by hard and soft pruning, the resulting APP76PIG Chip contains the complete genome of 3 serotypes of *App*, the *Mycoplasma hyopneumoniae* strain 232 as well as the 1.500 most promising probes of the Affymetrix GeneChip® porcine Genome Array. Each gene is represented by 8 to 11 25mer probes as match and mismatch probe sets to subtract unspecific binding of labeled cDNA.

Results

Pair wise whole-genome comparisons of our infection model strain (*App* serovar 7) with *App* serovars 3 and 5 using the Maximal Unique Matching subsequence decomposition program MUMMER (Vers.3.0) delivered a number of serovar specific loci for each of the three genomes with 82 open reading frames (ORF) in serovar 3 and 68 ORF in serovar 5 which were not also present in serovar 7. Using BLAST and the Affymetrix® pruning software we condensed this list to 28 (serovar 3) and 49 ORF (serovar 5), respectively, which were unambiguous serovar specific and added these probes to the APP76PIG array. Now we are able to analyze the expression of three *App* serovars which differ in their clinical severity in pigs.

Next we added all OST of *Mycoplasma hyopneumoniae* strain 232, another important lung pathogen. This enables us to evaluate our App derived results with another bacterial infection model.

In a final step 1.500 probes of the porcine Genome Array representing the most promising potential genetic markers of FUGATO IRAS were added to the APP76PIG array.

Discussion

With this powerful tool for expression analyses we are able to not only get a detailed picture of the bacterial expression of *App* but also, simultaneously, of the direct response of the porcine host, based on our previous results from FUGATO IRAS. Moreover, using e.g. field samples of acute infections in pigs we should be able to compare these results with two additional serovars of *App*. Also, we can now get an impression detached from our chosen infection model by analyzing pigs infected with *Mycoplasma hyopneumoniae* and thereby ensure that our genetic markers are in fact lung specific and not *App* specific markers.

Herd based computerized analysis for swine respiratory diseases using ELISA

Kim Woo-Chang1 Joo Hoo-Don1 Kim Sung-Hee2 Lee Kyung-Kee2 Kim Baek-Sop3 Pak Sonil4 Park Choi-Kyu2

1. Biotechnology Laboratory, JENO Biotech Inc., Chuncheon, Korea; 2. National Veterinary Research Institute (NVROS), Anyang, Korea; 3. Hallym University, Chuncheon, Korea; 4. Vet College, Kangwon National University, Chuncheon, Korea

Introduction
The chronic respiratory diseases cause serious economic loss in the pig farms for a long time. Especially, PRRSV, PCV2, MH (Mycoplasma hyopneumoniae) were main causative pathogens in respiratory diseases. Moreover, PMA (Pasturella multocida), APP (Actinobacillus pleuropneumoniae), HP (Hemophilus parasuis) were also complex infective agents in chronic respiratory diseases in pig farms. It was difficult to diagnose infection or immune situation of herds. Most of diagnosis results were supplied as positive rates, individual antibody titers. These kinds of data mostly not useful in herd control for respiratory diseases. We need herd based overall statistical data to get information for profiling of farm including immune status and infection ages.

Materials and Methods
Antibody tests: The several commercial ELISA kits were used for testing antibody level of PRRSV, PCV2, MH, APP, PMA and HP (JENO Biotech Inc. Korea). For PRRSV, IDEXX 2XR was also used for testing.

Serum samples: 46 serum samples per herd according to age groups were collected from 200 or more farms in Korea. The age groups were divided with 7 groups by gilt, sow, suckling (20 days), weaner (40 days), early grower (70 days), late grower (100 days) and finisher (130 days). Serum samples were collected from 4, 10, 12, 5, 5, 5 and 5 heads by each age group respectively.

Statistical analysis: The several data including positive rate, mean SP value and CV% (Percentage Coefficient variation) were analyzed by age group of each herd. Mean SP value and CV% were used to determine the antibody level and variation of pig herds. We determine the sero-conversion age group by comparing SP value and CV% of each age group.

Software: Widows XP based standalone software was designed and used to analyze the ELISA results. It gets OD values from each ELISA and then transforms the data to report for herds.

Results
Total about 200 farms or above were tested and analyzed. Most of farm showed dramatic sero-conversion in specified age groups. Generally, high-level maternal antibody was detected in sucking group and drop down the level on weaner or early grower group. Then it showed increasing antibody again on early or late grower group regardless vaccinated or not.

We can determine simply sero-converted age, mean antibody level and variation as figure 1. Most pathogens were positive by PCR or RT-PCR on before 2-3 weeks of sero-converted age (Data not shown). It means sero-converted age determined by mean SP is important parameter in herd. Most infected herds showed higher SP value and CV% than maternal antibody and increased continuously after sero-conversion. It means cyclic infection and unstable immunity of herds was suspected. From the report based on seroconversion, mean SP value and CV% of each age group, disease and immunity information could be supplied to field veterinarian. It was consider as very effective to control respiratory diseases.

Discussion
The respiratory diseases have many differences from the other pig diseases. We didn't have ideal tool to evaluate immune and infection status. This novel model of computerized statistical approach can be applied to control swine respiratory diseases.

Identification of Mycoplasma flocculare by Multiplex PCR

Bogdan Faur¹, Virgilia Popa², Viorel Herman¹, Corina Pascu¹, Luminita Costinar¹, Ioana Vaduva¹

¹. Faculty of Veterinary Medicine Timișoara, Timișoara, Romania; ². National Society Pasteur Institut, București, Romania

Introduction
Enzootic pneumonia (EP) is a chronic respiratory disease that causes considerable economic losses in the pig industry worldwide. Mycoplasma hyopneumoniae (M. hyopneumoniae) is the aetiological agent of enzootic pneumonia in pigs (Assuncao and all). Mycoplasma flocculare (M. flocculare) was, and is still considered by majority of researchers a lack of pathogenicity species. Anyway, some researchers (Armstrong and Friis) isolated this Mycoplasma species from lungs with characteristic lesions, which could sustain the hypothesis in which M. flocculare has a pathogenic potential, generate symptoms and gross lesions like M. hyopneumoniae.

Materials and Methods
In September-October 2009 period, in more pig farms from the west side of Romania were reported serious respiratory disorders, a low rate of average daily weight gain and low feed conversion efficiency. Breeding farms were vaccinated against M. hyopneumoniae. The serological tests revealed that farms with respiratory problems were positive at PRRS virus. There were investigated a number of lungs with lesions. From younger pigs (10-12 week-old of age) from 8 lungs were made cultivations on PPLO broth and agar supplemented with horse serum. All cultures were incubated for 3-4 weeks at 37ºC. We can isolate only a strain which was subcultures in 3 tubes notes A, B, and C. Tube A contain the strain after 5 days of incubation, tube B contain the strain after 7 days of incubation, and tube C contain the strain incubated 7 days in PPLO broth supplemented with horse serum 5%.

This strain was identified by Multiplex PCR in Laboratory of Molecular Biology at Pasteur Institute Bucharest. DNA extraction was made with QiAamp DNA mini kit (Qiagen). Amplification was performed using illustraTMpReTaqTM Ready-To-GoTM PCR Beads (GE Healthcare 27-9557-01 UK).

Results
The isolated strain was identified as Mycoplasma spp. based on cultural and morphologic aspects.

All samples were generated unspecific amplicons for M. hyopneumoniae. It is recorded the amplicon by 754 pb specific for M. flocculare only in one tube, in which was PPLO broth supplemented with horse serum. For the other two we consider that in these tubes was insufficient DNA for testing.

Conclusions
Besides all unspecific amplicons for M. hyopneumoniae for all three samples, 754 pb specific amplicon for M. flocculare was record only in a sample, cultivated in PPLO broth supplemented with horse serum 5%.

Isolation of M. flocculare from specific enzootic pneumonia lesions could sustain the hypothesis of pathogenicity of this species, but more searching is demanding.

Visual-only evaluation of lung lesions as an alternative to palpation at necropsy

Angela Baysinger1 Dale Polson1 Reid Philips1 Micah Taylor2 Greg Hartsook1 Kelly Lechtenberg3
1. Boehringer Ingelheim Vetmedica, Inc., St Joseph, MO, USA; 2. Iowa State University, Ames, IA, USA; 3. Midwest Veterinary Services, Oakland, NE, USA

Introduction
As swine practitioners become increasingly involved in on-farm research trials, increase their practice geographic areas, and work around stringent biosecurity requirements, their ability to get to farms to perform hands-on necropsies becomes more difficult. We evaluated a potential alternative to hands-on evaluation of lung lesions in order to address these challenges. The objective of this study was to evaluate the inter-observer and inter-method reliability of visually scoring lungs for Mycoplasma hyopneumoniae lesions from digital images and from visual scoring of actual lungs with the benefit of palpation at necropsy.

Materials and Methods
This study evaluated lungs from 344 pigs in a M. hyopneumoniae challenge study.1 The lungs were from pigs in five treatment groups; one strict control, one non-vaccinated and challenged, and three M. hyopneumoniae vaccinated and challenged groups. The pigs were euthanized and necropsied 28 days post M. hyopneumoniae intra-tracheal challenge. Removed lungs were observed and palpated by two veterinarians who independently scored each lobe as a percentage of the area affected by M. hyopneumoniae (necropsy evaluation). M. hyopneumoniae-induced lesions were defined as dark-red-to-purple consolidated areas. Observations and digital images for each lung were completed within 15 minutes of being removed from the pig. The digital images were later presented to the same observers, who visually evaluated and scored the lungs as described above, without the benefit of palpation (image evaluation). Lung scores were weighted by the approximate volume each lobe contributes to total lung volume to derive a value for total percent lung affected, as previously described.2 A linear regression model was used to determine the correlation of necropsy versus image evaluation as well as inter-observer reliability for both methods.

Results
The mean score across both observers for image evaluation was 8.21%, while the mean score for necropsy evaluation was 6.21%. Means for image evaluation were 10.32% and 5.89% and for necropsy evaluation were 7.64% and 4.77% for observer 1 and 2, respectively. The linear regression showed a good fit of the data for all three parameters, including image versus necropsy (adjusted R2=0.76, p<0.001), image between observers (adjusted R2=0.67, p<0.001), and necropsy between observers (adjusted R2=0.84, p<0.001). The correlation coefficients were 0.873, 0.819, and 0.921, respectively, suggesting very good correlation.

Discussion
There was a high correlation between the image and necropsy evaluation and between the observers for both methods. There did appear to be a better correlation between observers when scoring at necropsy with the benefit of palpation, suggesting that palpation remains a more consistent method of evaluating lung lesions. However, image evaluation appears to be a potential alternative to necropsy evaluation. Practitioners that are unable to necropsy pigs because of biosecurity or time restrictions now have another tool to evaluate the respiratory health of their client’s pigs. Practitioners may also utilize this tool to send images to experienced lung scorers to assist in their on-farm research trials. Overall, visual evaluation with the benefit of palpation is still the preferred method.

Assessment of four sampling methods to detect Mycoplasma hyopneumoniae in live pigs

Christelle Fablet; Corinne Marois; Virginie Dorenlor; Florent Eono; Eric Eveno; Typhaine Poezevara; Marylène Kobisch; François Madec; Nicolas Rose
AFSSA-Site de Ploufragan, Ploufragan, France

Introduction
Mycoplasma hyopneumoniae (Mhp) is the primary aetiologial agent of enzootic pneumonia in pigs and in association with bacteria and viruses is also involved in the Porcine Respiratory Disease Complex (PRDC) (1). The availability of accurate, rapid and easy to perform diagnostic tools is necessary for epidemiological and control purposes. For practical reasons, under field conditions, the nasal cavities are the most frequently chosen sampling sites to assess Mhp contamination of live pigs. However, in experimental trials, tracheal and tracheo-bronchial washings are the most efficient samples for detecting Mhp (2; 3). The aim of the study was to assess the abilities of four sampling methods to detect Mhp by nested-PCR on live pigs in a field context.

Materials and Methods
The study was carried out on a herd chronically affected by respiratory disorders. A sample of 60 pigs was constituted by a random selection from a batch of finishing pigs. Each pig was restrained and submitted to 4 samplings: oral-pharyngeal brushing, tracheo-bronchial swabbing, tracheo-bronchial washing and nasal swabbing. Mhp DNA was identified by modified nested-PCR (4). The sensitivity and specificity of each sampling method were estimated using a Bayesian analysis framework (5). Parameters distributions were based on previous external data. Since samples taken from SPF pigs gave negative results, a deterministic constraint was used for the specificities of all sampling methods which was taken as equal to one. The sensitivity of the parameter estimation to the choice of priors was assessed by comparing 3 models incorporating different sets of prior distributions ranging from vague priors (M1) to more informative ones (M3). Model convergence was assessed using the Raftery and Lewis tests and the Gelman-Rubin diagnosis. The models were compared on the basis of the deviance information criterion, the number of parameters estimated in the model and of the Bayesian p-value. The models were run using the freeware program WinBUGS (6).

Results
Mhp was detected by nasal swabbing, oral-pharyngeal brushes, tracheo-bronchial washing and tracheo-bronchial swabbing in 13.3%, 40.0%, 53.3% and 60.0% of the pigs respectively. Whatever the model, nasal swabbing had the lowest sensitivity and tracheo-bronchial swabbing the highest with mean sensitivities of 19 % and 74 %, respectively (Table 1).

Discussion
Since the infection status of the pigs tested under these conditions was unknown, and no gold standard is available, the sensitivities of the sampling methods were analyzed using a Bayesian approach. To the best of our knowledge, this is the first field study to use such an approach to evaluate four sampling methods for assessing Mhp infection in live pigs. The results of the present study indicate that tracheo-bronchial swabbing and washing, in combination with nested-PCR assay, were the most sensitive sampling methods for Mhp detection in naturally infected live pigs. As far as practical aspects are concerned, swabbing the tracheo-bronchial area with a sterile catheter is almost as convenient as obtaining nasal swabs under field conditions and only requires adding a gag to the sampling equipment. Tracheo-bronchial swabbing ensures a gain in diagnostic accuracy, being 3.5 times more sensitive than the nasal swabs commonly used in pig farms.

Table 1: Mean and 95 % Credibility Interval of posterior distributions of the sensitivity of the four sampling methods of Mhp detection by nested-PCR, according to the 3 models with different prior distributions (60 pigs sampled, specificity=1 for all models and sampling methods)
Surveillance using oral fluid samples - PRRSV, SIV, PCV2, and TTV field data

Apisit Kittawornrat\textsuperscript{1} John R. Prickett\textsuperscript{1} Rodger Main\textsuperscript{1} John Johnson\textsuperscript{1} Roman Pogranichniy\textsuperscript{2} Amber Clark\textsuperscript{2} Jeffrey J. Zimmerman\textsuperscript{1}

\textsuperscript{1} Iowa State University, Ames, IA, USA; \textsuperscript{2} Purdue University, West Lafayette, IN, USA

\textbf{Introduction}

Oral fluid specimens have been used extensively in human diagnostic medicine, but only recently has the concept been investigated in production animals (Prickett and Zimmerman, 2010). The objective of this research was to evaluate the use of oral fluid samples for monitoring PRRSV, SIV, PCV2, and TTV in commercial pig populations.

\textbf{Materials and Methods}

Experimental design: Oral fluid samples were collected from one wean-to-finish barn on each of 10 sites across the Midwest, USA. At each site (i.e., barn), oral fluid samples were collected from the same 6 pens at 2-week intervals from placement (~ 3 weeks of age) to slaughter. Oral fluid samples were collected by farm personnel after a brief training session with the investigators. Thereafter, samples were assayed for PRRSV, SIV, PCV2, and TTV by PCR-based assays. Sample Collection: Standard operating procedures were developed to ensure the collection of uniform, clean, and clearly identified samples. Investigators demonstrated the first two collections and trained site personnel in the procedure. Once trained, site managers were responsible for the timely collection and submission of samples. Sample collection “kits” containing all of the required materials were assembled and delivered to each site prior to the commencement of the study. Each kit included a pre-cut length of cotton rope, scissors, poly-boots, screw cap tubes, permanent markers, diagnostic submission forms, ice packs, zip-lock bags, and postage-paid addressed shipping containers. Upon arrival to the Iowa State University Veterinary Diagnostic Laboratory, oral fluid samples were centrifuged at 9000 x g for 10 min. Prior to testing, all samples were completely randomized and re-labeled.

\textbf{Results}

Data indicated that oral fluid samples could be used to monitor the circulation of the targeted pathogens (Figure 1). Temporal patterns of pathogen detection suggest that oral fluid could be used to routinely surveil for pathogens of interest in swine populations.

\textbf{Discussion}

Oral fluid sampling offers a cost effective solution to infectious disease surveillance in populations of growing swine and offers a new tool for studying the disease causality, ecology, and economics of emerging (TTV) and endemic (SIV, PRRSV, PCV2) viruses in commercial swine populations.

Computertomographic investigation on porcine pleuropneumonia

Carsten Brauer¹ Doris Hoeltig¹ Gerald F. Gerlach² Karl-Heinz Waldmann¹
1. Clinic for Swine and Small Ruminants, Forensic Medicine and Ambulatory Service; University of Veterinary Medicine Hanover, Foundation, Hannover, Germany; 2. IVD GmbH, Hannover, Germany

Introduction

The aim of this study was to investigate the correlation between computertomographic (CT) and digital x-ray diagnosis, clinical as well as pathomorphological findings during necropsy in pigs experimentally infected with Actinobacillus (A.) pleuropneumoniae. This investigation should lead to the development of a CT scoring system which might allow an objective interpretation of CT images of the pig lung and therefore could be used as a tool for an early stage diagnosis of lung alterations in pigs.

Materials and Methods

29 German Landrace pigs (age: 7 weeks, averaged weight: 13,7kg) coming from an A. pleuropneumoniae free herd were infected. The pigs were randomized upon weight and sex and divided into four groups. For the infection A. pleuropneumoniae serotype 7 strain AP76 and two deletion mutants of different virulence were used in an established aerosol infection model (1). One group was mock infected and used as control.

Diagnostic imaging was done twice, on days 7 and 21 post infection (p.inf.); the clinical monitoring of the pigs was performed daily. All imaging procedures were carried out under anesthesia (2mg/kg Azaperon im., 20mg/kg Ketamine im.). The pigs were euthanized on day 21 p.inf., and a necropsy with pathomorphological examination of the lung was done.

For the radiographic examination 3 images were taken (2 laterolateral, 1 dorsoventral; film-focus distance: 150cm; 80kV and shutter priority [Precimat, Fa. Picker Int., München, Germany]). For the computertomographic examination a scanogram and transversal slices (7mm thickness) of the whole thorax using a single slice scanner of the 3rd generation (Tomoscan M, Fa. Philips, Hamburg, Germany) were performed. All acquired pictures were set in lung window (exposure settings: 120kV, 40mA). For interpretation of the CT images every single slice was related to its position (precardiac, cardiac, postcardiac) in the scanogram and divided into four quadrants.

For the quantification of results of the clinical, the radiographic and the pathomorphological examination three different established scoring systems were used (2,3).

Results

During evaluation of the lung alterations visible in the CT lung window mainly ground-glass opacities and consolidations could be found. The density of the consolidations was > -150 Hounsfield Units. The results of the CT examination are shown in Table 1. The results of the different examination methods used as established controls are shown in Table 2.

Discussion

Regarding the comparison of the computertomographic examination of the lung and the already established examination methods, the CT imaging is considered as a diagnostic tool of similar informative value. Therefore the development of a CT scoring system appears feasible and is the next step to be done. After finishing this development a second statistically approved assessment is necessary before application of the scoring system as a diagnostic tool.

Medical infrared imaging of the porcine thorax for diagnosis of lung pathologies

Carsten Siewert; Doris Hoeltig; Carsten Brauer; Hermann Seifert; Isabel Hennig-Pauka
University of Veterinary Medicine, Hannover, Germany

Introduction
Respiratory diseases in pigs affecting pork production worldwide have an impact on consumer protection, live stock trade and animal welfare. The early, non-invasive detection of lung disorders is a valuable tool for the maintenance of respiratory health in pig herds. A promising approach might be the quantification of the skin surface temperature of the thoracic cavity, which is mainly determined by the heat exchange between skin and environment, metabolic activity, blood circulation and anatomical structures beneath the skin. Zapoudrina, et al., (2008) demonstrated as part of a human medical study the good reproducibility of temperature distribution patterns in the central body area of 16 test subjects [1].

Materials and Methods
Thoracic imaging and examination of 17 pigs (German Landrace, age: 11 weeks) was performed before and after aerosol infection with Actinobacillus pleuropneumoniae (A.pp.) by passive infrared thermography for the recording of infrared (IR) images. After necropsy pathomorphological changes in the lung were evaluated according to a lung lesion score [2].

An infrared thermographic camera operating in the wavelength range from 8 to 12 μm was used (IR Flex Cam R2). The IR camera used a microbolometer array as the detector. The IR image matrix of the camera was 160 x 120 pixels, which are interpolated internally to 320 x 240 pixels. The thermal sensitivity is, according to the manufacturer’s specifications, 70 mK with reference to a temperature of the measured object of 30ºC. For the pigs’ skin an emissivity of 0.95 was assumed. Air temperature and humidity as well as body core temperature as well as heart and breathing frequencies were recorded.

Medical imaging (IR and X-ray)

a) The recorded thoracic IR images were evaluated by means of the image viewer software IRBIS3plus, (colour temperature coding: combined rainbow colour and black/white-scale, narrow temperature range over 13ºC).

b) Computed tomography (CT) images: CT images were scanned using the system Tomoscan M/EG Compact (Philips Medical Systems)- a single slice scanner of 3rd generation. Scans were performed at 7 mm slice thickness. All acquired pictures are set in lung window. Exposure settings: 120 kV, 40 mA.

Results
IR images were suitable to visualize the location of the diaphragm (Fig. 1a,c yellow line) and abnormal warm regions of the thorax which correlate to inflammatory alterations shown in CT images.

Discussion
The anatomical localization of inflammatory processes leading to reduced ventilation in the outer lung regions can be determined under certain conditions (IR-image Fig. 1a). Pathological findings (Fig. 1e) are visualized in the corresponding CT-images (Fig. 1d). The opposite region of the thorax is less warm (Fig. 1c, yellow circle) due to normal ventilation in the lung. The cool air breathed-in probably acts as a contrast agent, thus distinct anatomical structures become visible (diaphragm, Fig. 1a,c, yellow line). It can be assumed, that pathological changes in the peripheral (outer) lung regions characterized by reduced ventilation can be recognised non-invasively using passive IR thermography. A new generation of IR thermography and image processing might be a practical tool for the diagnostic of many cases of pneumonia in pigs.

Evaluation of DRAXXIN® Injectable Solution for the control of swine respiratory disease

Michael Senn; Robert Nutsch; Merlyn Lucas

Pfizer Animal Health, New York, NY, USA

Introduction
Swine respiratory disease (SRD) remains an important cause of disease and economic loss for swine producers worldwide. DRAXXIN® Injectable Solution (10% tulathromycin, Pfizer Animal Health) is one of the newest anti-infectives for treating SRD. It is rapidly released and absorbed from the injection site and extensively distributed, so the product acts quickly against respiratory disease, and provides an extended clinical duration of activity in pigs of at least nine days after a single dose. The clinical efficacy of DRAXXIN® as a single IM injection for the control of naturally occurring swine respiratory disease was evaluated in a multi-location study.

Materials and Methods
The study was conducted at 5 sites in North America. The animals at all locations were mixed sex commercial feeder pigs purchased from farms that had previously experienced swine respiratory disease. Pigs weighed between 9.3 and 44.8 kilograms at enrollment. All pigs were individually identified. SRD was defined as a pig that had a respiratory score of > 2, and a depression score of > 2 (both a scale of 0 to 3, where 0 is normal), and a rectal temperature of > 104 ° F. On study day 0, the day that a pen had at least 15% of the pigs meeting the case definition for SRD, all individual pigs in the pen were randomly enrolled in one of two treatment groups. Treatment 1 (T1), Saline, intramuscular, administered once, or Treatment 2 (T2) DRAXXIN® Injectable Solution (tulathromycin), 2.5 mg / kg, intramuscular, administered once. Each study location enrolled 2 pens with 30 to 40 pigs per pen. No concomitant medication of enrolled animals with systemic antimicrobial or anti-inflammatory agents was permitted during the study. Animals that exhibited clinical signs of disease other than SRD were removed from the study. Treatment groups were composited within each pen, with the individual pig being the experimental unit. General health observations were performed twice a day on enrolled animals from Study Day 0 through Study Day 6, and the morning of Study Day 7. All study animals remaining on Study Day 7 were clinically evaluated for respiratory scores, depression scores, and rectal temperatures. On Study Day 7, all remaining enrolled animals were euthanized and necropsied to aid in characterizing the swine respiratory disease. An animal was classified as a treatment success if on Study Day 7; it was alive, had both a respiratory score and a depression score < 1, and a rectal temperature of < 104 ° F. Failure to meet any one of these criteria classified the animal as a treatment failure. Secondary clinical endpoints assessed were mortality and lung lesion scores.

This protocol was reviewed by the Pfizer Animal Health Ethical Review Board and the Pfizer Animal Health IACUC committee and is in compliance with their recommendations.

Results
Four hundred fifty five (455) animals were enrolled in the study; 228 in T1 (Saline) and 227 in T2 (DRAXXIN®). The number of animals classified as a treatment success was significantly higher, p < 0.05, for the animals administered DRAXXIN® (59.2%) vs animals administered saline (41.2%). The number of mortalities found dead plus euthanized due to SRD was higher for the saline-treated animals (11/227, 4.8%) than the tulathromycin-treated animals (4/226, 1.8%), but not significantly different, p = 0.0676. The back-transformed least squares mean percentage of total lungs with lesions was significantly higher, p = 0.0096, for animals administered saline (13.1%) vs animals administered DRAXXIN®, (6.6%).

Discussion
The results confirm the value of using DRAXXIN® for the control of swine respiratory disease associated with Actinobacillus pleuropneumoniae, Pasteurella multocida and Mycoplasma hyopneumoniae. Treating groups when a percentage of the population is exhibiting signs of swine respiratory disease will help veterinarians to better manage respiratory disease outbreaks. Veterinarians often rely on water medication for its ease of administration. 3 Problems associated with water medication include variability in flow rates and inadequate consumption by ill pigs. 3 Variation in drinker flow rates and problems associated with dilution and delivery of antimicrobials create an important challenge for farm personnel. 4 DRAXXIN® provides high and long-lasting concentrations in the lung tissues providing for a complete treatment of individual pigs exhibiting swine respiratory disease, and excellent efficacy treating and controlling swine respiratory disease, ensuring instant compliance and fast long-lasting therapy, while reducing the need for extra labor and less handling of sick animals.

Health and performance improvements in pigs treated with Draxxin® Injectable Solution (tulathromycin) for swine respiratory disease (SRD)

John C. Johnson; Thayer C. Hoover
Outcomes Research Pfizer Animal Health, Spirit Lake, IA, USA

Introduction
Draxxin® Injectable Solution is approved in the USA for single-dose therapy of swine respiratory disease (SRD) caused by Actinobacillus pleuropneumoniae, Pasteurella multocida, Bordetella bronchiseptica, Haemophilus parasuis, and Mycoplasma hyopneumoniae, and for the control of SRD caused by A. pleuropneumoniae, P. multocida and M. hyopneumoniae. Two studies were conducted, with the first in a natural outbreak of SRD, comparing Draxxin to untreated pigs (saline), and pigs medicated using conventional therapy (penicillin G procaine). Variables included treatment response and weight gain. The second study compared Draxxin to untreated controls against induced SRD using a live M. hyopneumoniae challenge (MHYO). This study tracked performance (gain, feed efficiency) as well as clinical response. Study protocols were reviewed by the Pfizer Animal Health Ethical Review Board, Kalamazoo MI to ensure that animal use was consistent with sound scientific practices and ethical considerations.

Materials and Methods
Study 1.1 One hundred seventy pigs (170) from two farms positive for various bacterial and viral respiratory pathogens were commingled with 200 single-source Isowean pigs of similar age and weight. Pigs (N=370) were housed in a conventional finisher equipped with an AutoSort food court providing feed and electronically capturing individual pig weights. Pigs with SRD (n = 135; 36% morbidity) were randomly assigned in a 1:2:2 ratio to one of three treatments: saline (negative control), penicillin G procaine (IM; 5 mL/45 kg/day for two [2] consecutive days), or Draxxin (IM; 1 mL/41 kg, once). Pigs were observed daily, and clinically re-evaluated and weighed seven and 56-days after treatment.

Study 2.2 Two hundred (200) weaned pigs, sero-negative for M. hyopneumoniae were challenged intra-tracheally once daily for three consecutive days with a live culture of the organism. Ninety-six (96) pigs meeting SRD-criteria were enrolled and assigned to 24 pens according to a randomized block design. Each pen (the experimental unit) contained pigs treated with saline or Draxxin. Pig weights and feed consumption were measured at 10, 20, 30, 45, and 60 days post-treatment; response to therapy was evaluated 10-days post-treatment.

Results
Study 1. Compared to untreated pigs, Draxxin-treated pigs had a lower mortality rate the first week post-treatment and a significantly (P = 0.0360) lower mortality rate over the study. Further, pigs treated with Draxxin had a significantly (P = 0.0409) higher mean gain (3.7 kg [8.3 lb]) compared to controls (2.8 kg [6.2 lb]) one week post-treatment. Mean weight gain in pigs treated with Draxxin was 4.5 kg (10 lb) over pigs treated with penicillin (P = 0.0597) and 7.2 kg (16 lb) over controls (P = 0.0268), when adjusted to the 75th percentile of mean weight at enrollment. Draxxin-treated pigs were 1.6 times less likely to fail than pigs that were untreated. The risk of treatment failure was reduced in the Draxxin group 36% compared to conventional therapy, and reduced 46% compared to controls. In field settings similar to this study, six pigs (6) treated with Draxxin would be projected as the number needed to treat to reduce or prevent one treatment failure using conventional therapy (penicillin G procaine).

Study 2. Pigs with SRD, treated with Draxxin had a significantly (P = 0.0121) improved average daily gain ranging from 0.74 – 0.90 kg/hd/day (1.63 - 1.99 lb) over controls ranging from 0.61 – 0.80 kg/hd/day (1.35 - 1.77 lb). Feed consumption was higher in the Draxxin group with a corresponding improvement in Feed:Gain (1.26 kg feed/1.0 kg gain [2.78 lb/1.0 lb] compared to controls (1.62 kg [3.58 lb]; P = 0.1032). Treated pigs had a lower mortality rate (8.7% vs. 4.2%). Evaluated at 10-days, the proportion of Draxxin-treated pigs “normal” for attitude/depression and respiratory character was 11% and 24% higher compared to untreated cohorts, respectively.

Discussion
Pigs treated with Draxxin for SRD under field conditions, or in an experimentally induced M. hyopneumoniae challenge, responded with one treatment. This reduces antimicrobial use as well as animal stress and handling using multiple day therapy regimens. One-time Draxxin treatment improved both health and performance in both studies. These results support that Draxxin is an effective health management tool for reducing sickness and death loss due to SRD, a cost effective alternative to conventional treatment[s] requiring multiple day administration, and may be an important aid to improve performance and profitability in swine operations affected with respiratory disease.

**Evaluation of two in feed medication therapeutic programs for the control of swine respiratory disease in nursery**

Paolo Ferro¹ Claudio Mandelli²

¹. Elanco Animal Health, div. of Eli Lilly Italia, Sesto Fiorentino (FI), Italy; ². G.I.ma. S.p.A., Rubiera (RE), Italy

**Introduction**

Many studies showed that the initial prevalence of pathogens within the group plays a central role in the severity of the diseases and also that early interventions can reduce this prevalence(1). The objective of this study was to evaluate two different in feed medication therapeutic programs at weaning for the control of swine respiratory disease in nursery.

**Materials and Methods**

The study was performed on the nursery sector of a multisite farm in the north of Italy. After the confirmation of respiratory disease two groups of around 170 pigs / group were evaluated from weaning (age: 21 days) to the end of the nursery period (age: 67 days). Fifty pigs per group were individually ear tagged, numbered and weighed at weaning and at the end of the nursery period. The pigs were divided in the two groups according to the type of medication included in their prestarter feed:

- Pulmotil™ Group: Tilmicosin (Pulmotil™) 400 ppm,
- Control Group: Sulfadimetossin 1400 ppm + CTC 560 ppm (Polisulfan™).

The treatment period was the same (21 days after weaning) for both groups.

The parameters controlled and recorded were:

- Number of pigs / group,
- Average weight (kg) at weaning,
- Average weight (kg) at weaning of individually weighed pigs,
- Number of deaths + culls / group,
- Average weight (kg) at the exit from the nursery sector,
- Average weight (kg) at the exit from the nursery sector of individually weighed pigs.

Statistical analysis: means individual weights were compared between group by ANOVA one-way analysis when Bartlett’s test assess the homogeneity of variances and by Kruskal-Wallis test when homogeneity of variances was not demonstrate with Intercooled Stata 7.0 software. The significant level for this evaluation was p=0.01.

**Results and discussion:**

The general collected results are summarized in table 1. At the exit from nursery the means weight of individually weighed animals was significantly higher in the Pulmotil™ group (P) than in the Control group (C) (29.48 kg vs 25.92kg, Anova test F1,60 p<0.01, Table 1 and Graphic 1).

**Conclusions**

These results confirm that Pulmotil™ increases the animal health, with better growing performances from weaning to the end of the nursery period. As reported on other studies(2), the better weight at this age may improve the performances in the fattening and increase the number of Full Value Pigs™ that arrive at the slaughterhouse.

**Introduction**

Respiratory disease causes great economic losses in pig production (1) and usually involves several pathogens, causing a significant and quick increase in mortality and also affecting growth and feed efficiency of the animals (2). Soluble treatments are mostly used when an outbreak appears, especially during the fattening phase (3). The present study aimed to evaluate the effects of a soluble treatment with Pulmotil™AC during a respiratory outbreak in fattening pigs.

**Materials and Methods**

Two groups of pigs were included in the study (C, n=998 and P, n=876). When pigs showed respiratory signs (around 100d of age) and several pathogens were found (PRRSV, M.hyo and App), the pigs were treated either with Pulmotil AC at 17mg/kg BW (P) or Doxicicline at 10mg/kg (C) in water for 5 days. Before the treatments started, the mortality rates were 1.0% and 1.3% for the control and the Pulmotil group respectively. During the 5 days of treatment the mortality rates were 0.6% and 0.5% for the Control and Pulmotil group. The animals were monitored until the end of the fattening period. The variables collected and analyzed were mortality, average daily gain, feed conversion rate, and percentage of lightweight pigs at the end of the period. Also, a cost analysis calculation was done with the production results.

**Results and Discussion**

The treatment with PulmotilAC at the time of the disease outbreak decreased the mortality from 10.6% to 4.8%. Also, a difference in pigs sold as lightweights was detected (fig. 1), therefore the percentage of FVP™ was also impacted C=67.3%; P=88%.

**Discussion**

When a respiratory outbreak appears during the growing-finishing period, the animals treated with Pulmotil AC show an effective response. In this case the benefits were not only clinical but also in performance parameters and economic results. The pigs treated with Pulmotil in water improved the ADG, FCR and mortality rates. In addition, more Full Value Pigs™ were produced.

**References**

There was also a difference in average daily gain and a decrease of the FCR (table 1). This was highly affected because the weights of dead pigs (C=4456kg vs P=1801kg) were not used for the FCR calculation but the feed consumed was not excluded.
Early treatment with Pulmotil™ in piglets vaccinated against PCV-II. Effects on the performance of the piglets

Xavier de Paz¹ Albert Vidal² Jordi Bonet² Hernan Torrelles² Miguel Abad¹ Susana Lapuente¹
1. Elanco Animal Health, Madrid, Spain; 2. Vall-Companys, Lleida, Spain

Introduction
The presence of respiratory disease increases medication costs but also causes a loss of performance (ADG and FCR) since energy and protein is diverted towards fighting disease (1). The standard use of Pulmotil™ at weaning to prevent respiratory disease was evaluated to see the effects in piglets vaccinated against PCV-II.

Materials and Methods
A comparison study was performed with two different in-feed treatments for 3 weeks after weaning: a positive control, (C) with 300ppm of amoxicillin against 400ppm of Pulmotil (P). In total, 1440 21-day old piglets (C=721 and P=719) were individually tagged and weighed at weaning, at the end of the treatments (day 20), and at the end of the study (day 37). In addition, the feed also included 120ppm of colistin and 2500ppm of ZnO.

Results and Discussion
The mortality rate in the Pulmotil group was slightly higher than in the Control group (C=2.99% vs P=3.71%; p=0.4522). The number of injections was not different except for replica 1 the Pulmotil group received less treatments than the control (16.9% vs 12.5%; p<0.001). The initial liveweight (LW) of the piglets (figure 1) was not different between both treatments (p=0.4901)

Figure 1. Average LW (kg) at day 0.

As can be seen in figures 2 and 3, the Pulmotil piglets were heavier at day 20 and 37 for both replicas (p<0.05).

The ADG of the piglets was higher in the Pulmotil group for all the periods of the study.

Table 1: ADG and FCR for the different periods.

Different superscript letters are statistically significant (p<0.05)

Conclusions
The inclusion of Pulmotil during the first three weeks after weaning improves animal performance even in farms in which vaccination is being carried out against PCV-II:

- The pigs in the Pulmotil group grew more during the nursery and their final weight was greater (p<0.001) increasing the Full Value Pigs™ in the fattening unit.
- This has been consistently seen in other studies (2).

Early treatment with Pulmotil™ in piglets vaccinated against PCV-II. Effects on the weight distribution at the end of the nursery period

Xavier de Paz1 Albert Vidal2 Jordi Bonet2 Hernan Torrelles2 Miguel Abad1 Susana Lapuente1
1. Elanco Animal Health, Madrid, Spain; 2. Vall-Companys, Lleida, Spain

Introduction
The presence of respiratory disease increases mortality and medication costs but also causes a loss of performance (ADG and FCR) (1). In this study, the use of Pulmotil™ after weaning was evaluated to see the effects on weight distribution of the piglets and on the percentage of lightweights at the end of the nursery.

Materials and Methods
A comparison study was performed with two different in-feed treatments for 3 weeks after weaning: a positive control, (C) with 300ppm of amoxicillin against 400ppm of Pulmotil (P). In total, 1440 21-day old piglets (C=721 and P=719) were individually tagged and weighed at weaning, at the end of the treatments (day 20), and at the end of the study (day 37). The rest of the treatments were the same for both groups, including a vaccination against PCV-II with Ingelvac CircoFLEX™ (Boehringer Ingelheim). At each weighing time, four different quartiles were defined in order to have 25% of the total population was in each class (Light, Median1, Median2 and Heavy). The data came from 2 consecutive replicas and was analyzed with an F-test. The percentage of animals in each category depending on treatment was analysed by an association chi-square test.

Results and Discussion
At day0, the proportion of pigs in each weight class was the same for both treatments (p=0.9114); however, the treatment with Pulmotil reduced the proportion of “lightweights” at day 37 (C=27.86%, P=21.79%, p<0.01).

Table 1 represents the odds ratios of all the piglets for both groups. The main effects in the Pulmotil group were:
- The “Light” piglets at day 0 are more likely to be “Median 2” at the end of the study (p=0.05).
- The “Median 1” piglets at day 0 are more likely to be “Heavy” at the end of study (day 37) (p=0.02).
- The pigs classified as “Median 2” at day 0 are more likely to be “Heavy” at day 37 (p=0.05).

Conclusions
In piglets vaccinated PCV-II, the use of Pulmotil after weaning to prevent respiratory disease in early age still reduced the percentage of lightweights and provided more Full Value Pigs™. The opposite effect was seen for the PCV-II vaccinate piglets that received a control treatment. These effects are consistent with other studies (2).

Introduction
Swine respiratory disease (SRD) and polyserositis (PS) have substantial economic and welfare impacts on the European Swine industry. Disease control is generally achieved by environmental control, vaccination and antibiotic treatment. This GCPV compliant study compared two post-weaning metaphylaxis programmes: 1 - SRD metaphylaxis with tulathromycin (2.5 mg/kg Draxxin\textsuperscript{*}, Pfizer Ltd), followed by systemic treatment of SRD or PS clinical cases with ceftiofur injection (5 mg/kg Naxcel\textsuperscript{*}, Pfizer Ltd); 2 - SRD metaphylaxis with oral amoxycillin (400 ppm in-feed) followed by systemic treatment of SRD or PS clinical cases with long acting amoxycillin by injection (15 mg/kg); 3 - A sentinel group of animals (receiving no metaphylaxis treatment) included to confirm disease; clinical cases in this group were treated with long acting amoxycillin injection (15 mg/kg). The study was conducted to demonstrate the value of responsible, targeted antimicrobial use in disease control under field conditions.

Materials and Methods
Four-hundred piglets from two farms with a history of SRD \& PS in the nursery period entered the study on the day following weaning (the first day of metaphylaxis treatment). During the nursery period (approximately 41 days) piglets were group housed in 40 pens, each of 10 animals.

Animals were penned in four rooms and pens randomly assigned to one of the three groups in an 18:18:4 ratio ensuring a balance of treatments within each airspace.

Animals were observed daily for signs of abnormal health; veterinarians conducting clinical examinations were unaware of the treatment group attributed to each pig. Animals were assessed for SRD and PS using pre-defined criteria (a combination of clinical signs and pyrexia of >40°C). Animals were weighed at the beginning and end of the nursery phase, and feed intake measured on a pen basis.

Results
SRD and PS were observed and bacterial involvement confirmed by isolation from clinical cases (\textit{Pasteurella multocida} and \textit{Streptococcus suis}). The combined tulathromycin and ceftiofur programme significantly reduced the incidence of SRD, number of antimicrobial treatment days, number of SRD or PS relapses and significantly improved the feed conversion ratio when compared to the amoxycillin metaphylaxis/therapy group (1.66 vs. 1.83 respectively, \textit{P}=0.02). A tendency towards reduced mortality was observed in T1 compared to T2 (least squares mean of pen values 0.67% vs. 4.30% respectively, \textit{P}=0.071).

Discussion
In-feed antibiotics are widely used for metaphylaxis due to their ease of administration and low cost. Potential interactions with other ration components, difficulties insuring drug homogeneity in feed and the inappetence of sick animals can result in individual animals being underdosed, compromising efficacy. The use of injectable antimicrobial products for metaphylaxis \& therapy allow accurate, targeted dosing of the individual animal, particularly when the product chosen has a sufficiently long duration of activity to cover the period of expected disease and a suitable spectrum of activity. In the particular circumstances of this study, based on the drug and piglet (20-25kg live-weight) prices current in Spain at the time (making no allowance for labour costs), this disease management protocol provided a return of approximately €1.50 per pig compared to that used in group T02.

A treatment protocol designed to control Mycoplasma hyorhinis infection in a commercial herd points out to a potential association with Streptococcus suis

Charles Surprenant¹ Marcelo Gottschalk²
1. F. Ménard Inc., Ange-Gardien, QC, Canada; 2. Université de Montréal, Saint-Hyacinthe, QC, Canada

Introduction

Mycoplasma hyorhinis was named and characterized by Switzer et al. in 1955. Since then, this microorganism has been associated with different clinical conditions in pigs: pneumonia, arthritis, otitis, and eustachitis. Over the past 5 years, commercial swine nurseries, negative for Mycoplasma hyopneumoniae and belonging to the same pyramid, experienced clinical losses caused by M. hyorhinis and/or Streptococcus suis. A treatment protocol was designed to reduce respiratory problems associated with M. hyorhinis infection. Materials and Method

Herd description: Since 2002, a multisite commercial pig flow has experienced clinical signs of respiratory and S. suis disease at the nursery level. The 1800 crossbred sow unit is negative for PRRSV. Each week, 800 5-kg piglets averaging 18 days of age are transferred to a 3 barn nursery site. Each barn is filled up over a period of 10 days and completely emptied 40 days after the first pigs arrive. The sow herd is Mycoplasma hyopneumoniae positive, however sows have been vaccinated at 3 weeks prior to farrowing for over 10 years in order to stabilize the herd. Piglets are vaccinated against M. hyopneumoniae at 3 and 6 weeks of age.

Clinical Signs: Shortly after arrival, some piglets started to exhibit a dry cough and sneezing. These clinical signs became more severe and prevalent over time with some pigs developing pneumonia and/or a clinical syndrome associated with S. suis (meningitis, sudden death). Pig performance was adversely affected. Laboratory tests were always negative for M. hyopneumoniae (Table 1). However, M. hyorhinis and S. suis were found repeatedly in different samples.

Treatment protocol: After concluding that M. hyorhinis was the primary cause of the respiratory signs, a novel treatment protocol was implemented to control M. hyorhinis. All the piglets were injected once at weaning with 2.5 mg/kg of tulathromycin (Draxxin®) starting on February 3, 2009. No other changes were made.

Statistical analysis: Although the implementation of the new treatment protocol was not designed as a clinical trial, a Wilcoxon test was done using the median values of different parameters to compare results for 9 pre-treatment pig lots versus 10 post-treatment lots.

Results

Shortly after the implementation of this new procedure, coughing, sneezing and respiratory signs almost disappeared. Post-treatment results show an improvement in feed conversion and average daily gain. The overall viability of the post-treatment lots was significantly increased (P = 0.02). A reduction in the number of Penicillin V water treatments, the number of days on Penicillin V treatment and, surprisingly, in the frequency and severity of S. suis episodes was observed (Table 2).

Discussion

The injection of Draxxin® markedly improved the health status of these nurseries. M. hyorhinis was identified as the primary agent and because tulathromycin is effective against M. hyorhinis and not against S. suis, it is believed that the improvement observed in pig performance was associated with the action of tulathromycin on M. hyorhinis. A decrease in S. suis incidence was also observed. Can M. hyorhinis be a predisposing factor in the development of clinical S. suis infection like some irritants? Further work is needed to answer.

Elimination of PRCV and H3N2 swine influenza virus from a production network using a 4-week batch farrowing system

Manon St-Hilaire1 Desrosiers Robert2
1. Génétiporc Inc, St-Jean-Chrysostome, QC, Canada; 2. Boehringer Ingelheim, St-Hyacinthe, QC, Canada

Introduction
Porcine respiratory coronavirus (PRCV) is a pathogen of low economic impact. Swine influenza virus (SIV) can produce losses but is also often present on farms without significant clinical signs of the disease. Nevertheless, the presence of these two pathogens can, for certain farms with a high health status, constitute an obstacle to exportation of breeding animals. This paper describes a production network using a 4-week batch farrowing system where both viruses were eliminated.

Materials and Methods
Two high health sow herds (A and B) of 1200 sows each produced weaned piglets that went to a common nursery site, and from there to three different finishing sites. Replacement gilts and boars used in herds A and B came from the three finishing sites. In June 2006 herd A became infected with PRCV, and within a month pigs on all sites became infected as well. The biosecurity level on these sites is very high and to date the source of initial contamination has not been found. In January 2007, following the introduction of replacement animals in herd B, coughing was observed and determined to be caused by SI H3N2. Within a month, presence of the virus was detected in all sites. In January 2008 the owner elected to switch to a 4-week batch farrowing system for various reasons that included the possibility to more easily get rid of both viruses. An autogenous H3N2 vaccine was obtained for the vaccination of gilts (vaccinated twice in isolation and kept there for 8 weeks) and sows (vaccinated twice three weeks apart). Starting three to four weeks later sows were also vaccinated before farrowing in an attempt to maximize colostrum antibody content. Following that program, gilts were introduced in the two sow herds every four weeks. Circulation of the viruses within the herds was monitored using an IDEXX ELISA for PRCV and an IHA test, containing a H3N2 Quebec strain, for SI. Both pigs at the end of the finishing period and sentinels introduced in the two sow herds were tested.

Results
After infection of the sow herds, both PRCV and SIV circulated in finishing pigs. The first farrowings of the 4-week batch farrowing system occurred in June 2008 (batch 1). All 14 batches produced and tested so far, except batches 8 and 9, have remained negative to PRCV. The two infected batches are thought to have been infected at the finishing site from an indirect and undetermined cause. For SI the first two batches were infected, but all others have remained negative since then. Negative sentinels introduced in September 2008 in herd B, but not in herd A, seroconverted to PRCV.

Those introduced in June 2009 did not. In October 2008 sentinels introduced in Herd B seroconverted to SI H3N2, but those introduced in February 2009 have remained negative.

Discussion
Both PRCV and SIV are considered to be organisms that are usually shed for only short periods of time following infection. The 4-week batch farrowing system allows a sow herd to be without suckling piglets on site every four weeks. If the herd is temporarily closed to introduction of susceptible gilts and/or boars, this system should theoretically increase the chances of being able to get rid of pathogens, particularly those that are not shed for long periods of time following infection. This is because for a while there are no susceptible animals on the farm to maintain circulation of the organism.

In this study it was possible to get rid of both PRCV and SIV from two different sow herds, the nursery site and the three finishing sites and this occurred following the implementation of the 4-week batch farrowing system. It is not sure if elimination of these two viruses was due mainly, partially or not at all to the use of that production system. In fact in the case of SIV an autogenous vaccine was used and may have contributed to the results obtained. Furthermore there are situations where SIV was eliminated from swine farms without doing anything, or by delaying the introduction of gilts to every two months.1,2 This being said, the results obtained in this study as well as the theoretical advantages this system confers suggest, at the very least, that further studies should be conducted to determine to what extent it could improve the chances of eliminating some of the pathogens that have to be dealt with in swine production.

Palatability of Tilmovet® 250 mg/ml Concentrate for Oral Solution compared to a reference formulation containing tilmicosin

Alain Kanora; Henk Lecluyse; Koen De Gussem
Huvepharma NV, Antwerp, Belgium

Introduction
Tilmicosin is a semi-synthetic macrolide antibiotic obtained from tylosin which is affecting bacterial protein. Macrolides have a proven benefit as treatment for a wide range of infectious diseases, with an increased interest for respiratory infections. The objective of this study was to compare the palatability of Tilmovet® 250 mg/ml Concentrate for Oral Solution with that of a reference formulation containing tilmicosin and to evaluate the impact on pig water consumption.

Materials and methods
On a Belgian fattening unit containing two open compartments, 11 pens were selected, each containing 14 pigs with an average weight of + 60 kg. Two test groups of about 150 pigs each were identified. Compartments had own dosing equipment installed at 1%. The water uptake of each group was monitored during 5 days, split into 2 phases: 2 days of no medication (negative, control) and 3 days with medicated drinking water (Tilmovet® or a tilmicosin reference formulation). The inclusion rate of tilmicosin was calculated based on the registered dose of 16 mg/kg bodyweight and the actual water intake of the pigs. Each day, a fresh solution was prepared and administered.

Results
During the first phase of the trial period, temperatures ranged from 26° C to 30° C and for the animals receiving unmedicated drinking water in this phase, a daily water consumption was recorded ranging from 57 to 67 ml/kg bodyweight and both groups had very similar drinking water intake levels. In the second trial phase, in which the animals received medicated drinking water for 3 days, the registered temperatures ranged between 20° C and 23° C. During this phase, the Tilmovet® group had a somewhat higher daily water consumption intake level (53-68 ml/kg bodyweight, i.e. 3.18-3.81 liter/day/pig) than the group receiving the medicated drinking water with the tilmicosin reference formulation (49-60 ml/kg bodyweight, i.e. 2.47-3.05 liter/day/pig) (Figure 1). In terms of dosing, the pigs in the Tilmovet® group consistently reached higher dose levels than the tilmicosin reference group. The registered minimum dose of 16 mg/kg bodyweight was not reached in the tilmicosin reference group on any of the trial days, whereas in the Tilmovet® group, mostly higher dose levels were attained (Figure 2).

Discussion and conclusion
It can be concluded from this study that the overall daily drinking water consumption is not influenced by Tilmovet® 250 mg/ml Concentrate for Oral Solution and that the calculated concentration of tilmicosin is fully compliant with the registered dose of 16 mg/kg bodyweight.
Treating weaned piglets with tilmicosin oral solution to prevent circulation of viral infection in a closed sow herd

Jan Van Steelant¹ Lieven Tanghe² Henk Lecluyse² Alain Kanora²

Introduction
The PRRS virus is one of the most important pathogens in the pig breeding business. In the field, co-infections with multiple bacterial respiratory pathogens are commonly found, making effective treatment more difficult. The objective of this trial was to use tilmicosin drinking water medication as an effective tool next to vaccination with a life vaccine to prevent PRRSV replication. This was done in a previously vaccinated, yet positively diagnosed sow herd.

Materials and Methods
A Belgian closed sow herd (n= 350), suffering from early parturition (on average 2 days early) and having received multiple PRRSV vaccination (3 times in the previous year) after PRRSV was diagnosed with RT-PCR strain (in combination with influenza H3N2, H1N1 and H1N2) still had unusually high prevalence of abortions. Change in feed and feed supplier did not bring the expected result either. Blood samples were taken and through vertical serology the diagnoses of PRRSV circulating was re-confirmed (Figure 1).

Figure 1. S/P ratio

Results
Mortality rates dropped considerably in both the farrowing house and in the group of weaned piglets, respectively -2.30% and -1.40% (Figure 2).

Figure 2. Mortality rates (%), farrowing house and group of weaned piglets

Discussion
The 3-5 days treatment with tilmicosin oral medicated drinking water has successfully controlled the circulating viral infection of PRRSV in both farrowing house and within the group of weaned piglets. This was assessed by means of the piglet mortality rate which had dropped quite considerably.

**Economic benefits from the eradication of enzootic pneumonia and PRRS from a new 800-gilt herd**

**David G. Burch¹ Nigel J. Woolfenden²**

1. Octagon Services Ltd, Old Windsor, Berkshire, UK; 2. Bishopston Veterinary Group, Ripon, N. Yorkshire, HG42QR, UK

**Introduction**

In 2008, due to a period of high feed prices and poor meat prices, it was decided to kill out one of three approx. 800 sow herds (Herd 1), which was badly affected with chronic porcine circovirus type 2 (PCV2), porcine reproductive and respiratory syndrome virus (PRRSV), enzootic pneumonia (EP) and Actinobacillus pleuropneumoniae ST3. Herd 2, which was also positive for PRRS, EP & PCV2 but had a good reproductive performance and low post-weaning to slaughter mortality, was to be the source of gilts for Herd 1. It was decided to try to eliminate PRRS and EP through vaccination and medication prior to farrowing. Elimination of PRRS had been described (1) using gilt pool management and infection stabilization and Mycoplasma hyopneumoniae (Mhp) elimination by the use of tiamulin and chlorotetracycline in combination (2).

**Materials and Methods**

Approximately, 50 cross-bred (LRxLWXLW) gilts/week were weaned at 4 weeks of age into straw-based accommodation over a 21 week period from the start of 2008. The young pigs were vaccinated with a killed mycoplasma vaccine (Ingelvac® M Hyo) at 3 weeks of age and again at 8 weeks of age. A PCV2 vaccine (Ingelvac® Circoflex) was given also at 3 weeks of age. A live PRRS vaccine (Porcilis® PRRS) was given at 8 weeks of age. Following the closure of Herd 1 and the removal of all pigs at the beginning of June, the premises were thoroughly cleaned and disinfected. Three weeks later (21st June) the gilts were moved over in batches of 300 from Herd 2. Matings were started in the older gilts on the 11th of October and they were given Porcilis PRRS and a parvovirus and erysipelas vaccine (Porcilis® Ery + Parvo) 3 weeks before service. To ensure the required uniform immunity to PRRS, the whole gilt herd was vaccinated on 24th November with Porcilis PRRS (live), an inactivated PRRS vaccine (Progressis®) on the 15th of December and a final Porcilis PRRS (live) on the 5th of January, 2009. Medicated feed was also started on the 5th of January, 2009 for 6 weeks and containing sufficient tiamulin (Denagard 200 injectable) at 15mg/kg bodyweight respectively. The first farrowings commenced on the 3rd of February. The younger gilts (<300 days of age) and boars were also injected with tiamulin (Denagard 200 injectable) at 15mg/kg bodyweight, 3 weeks into the in-feed medication period.

Blood samples were taken from 60 pigs (8-22 weeks old) on July 14th and examined by ELISA tests for PRRSV (LSI Hipra) and Mhp (DAKO blocking). In December, an acute outbreak of coughing occurred in Herd 1 and a further 30 samples from 16-20 week old pigs were taken. A number of lungs at slaughter were also examined for EP lesions & pleurisy in July (240) and December (115).

**Results**

<td>-</td>
</tr>
</tbody>
</table>

All of the lungs examined were free from EP lesions. Pleurisy had fallen from >30% in 2007 to <6% in 2009.

**Discussion**

The EP part of the programme appears to have been very successful for over a year according to blood and lung lesion results. There appears to have been a breakdown in PRRSV in December, although the herd remained free clinically for over 10 months, suggesting the programme had been effective originally. Contaminated transport was the suspected cause. Number of pigs born alive/litter was increased by 1.5. Mortality was reduced in all stages of production by 5.1% but from post-weaning to slaughter by 3.8% or an extra 730 pigs sold resulting in a £25,500 margin over feed. FCE was reduced by 0.13, which equated to savings of £34,944, and a combined total of £60,444. PRRS and EP medication costs were £11,970, so the med cost/benefit ratio was 1:5.

**References**

Use of Tilmovet® 250 mg/ml Concentrate for Oral Solution in prefarrowing sows – a Danish field trial

Niels H. Rough1 Alain Kanora2 Koen De Gussem2
1. Samsvet, Tingvej 1, Samsoe, Denmark; 2. Huvepharma NV, Antwerp, Belgium

Introduction
Macrolides have been intensely studied in the past with regards to their effect on pig production parameters. A Danish sow farm suffered from an outbreak of *Mycoplasma hyopneumoniae* including pregnant sows. To minimize the infection pressure in the farrowing house, all pregnant sows were given tilmicosin (Tilmovet® - Huvepharma)1,2. The objective of this field trial was to control the Mycoplasma circulation in piglets by using tilmicosin in prefarrowing sows.

Materials and Methods
The Danish sow farm (n= 680, races LY and Zig Zag cross) is located on the island Samsø. Every week, there are 29 farrowings (average of 6 months prior to current trial) and all gilts are produced on farm. Historical data on the number of piglets being born, weaned, pig weight and piglet mortality were available. During an 8 week period (1 October- 23 November), all sows received an individual treatment of tilmicosin (Tilmovet®) of 12 ml per sow for 5 consecutive days prefarrowing. First pigs from treated sows were weaned around 28 days (28 October) and the last around 16 December. Weaning age was 28 days. Data on average piglet weight at time of weaning (data representing 2970 pigs weaned) were then compared to historical data relative to 6,186 pigs weaned (period of 17 weeks) and to data from 690 pigs weaned during the two weeks post treatment period. Secondly, piglet mortality data from the treated group were compared to the pre-trial historical data.

Results
In terms of average weight, the historical data showed an average weight per pig of 6.61 kg, whereas the piglets from the Tilmovet® treated group had an average weight of 6.81 kg, i.e. an increase of 2.92% (Table 1). During the post trial period of 2 weeks which was considered, the average weight per pig decreased again to 6.55 kg, being a decrease of 3.78% compared to the treated group.

Table 1. Avg. piglet weight, historical vs treatment

<table>
<thead>
<tr>
<th>Data relative to period</th>
<th>Number of pigs weaned</th>

<td>40,920</td>
<td>6.61</td>
</tr>
<tr>
<td>Tilmicosin treatment</td>
<td>2,970</td>
<td>20,220</td>
<td>6.81</td>
</tr>
<tr>
<td>Post trial (2 wk)</td>
<td>690</td>
<td>4,520</td>
<td>6.55</td>
</tr>
</tbody>
</table>

Secondly, the historical mortality data (over a period of 5 weeks) were compared to the mortality rate relative to the Tilmovet® treated groups. Taking into account the start and ending of the treatment, the first weaned pigs from these groups were in week 44 and the last ones in week 51. A clear tendency in mortality decrease in the treated groups can be noticed (Figure 1). The average mortality rate prior to this study was 16%, whereas the average mortality rate of the treated groups was 13.67%.

Discussion
Historical data showed that untreated sows had piglets of inferior weaning weight. This observation clearly confirmed the ability of tilmicosin to control the disease pressure. Secondly, it demonstrated the indirect effect on the average piglet weight of Tilmovet® treated sows when treated in the prefarrowing stage. Consequently, the average mortality rate of treated sows showed a tendency to be lower (in comparison to historical data).

Efficacy of florfenicol (Nuflor 40 mg/g Premix for swine) for the control of porcine respiratory disease complex in an Iberian pig farm

Pablo Arevalo1 Antonio Palomo2 Jesus M. Bollo3 Ruth Menjon3 Marta Jimenez3 Jesus V. Lopez3
1. Granja Iberica Alcudia, S. Lu., Ciudad Real, Spain; 2. SETNA NUTRICION-INIVIVO NSA, Madrid, Spain; 3. Intervet/Schering-Plough AH, Cantabria, Madrid, Spain

Objective

The object of the study was to compare safety and efficacy of florfenicol (Nuflor 40 mg/g Premix for Swine) with that of Tilmicosin for prevention of porcine respiratory disease complex (PRDC).

Materials and Methods.

Study was performed on a farm with 3,000 Iberian sows cross-bred with Duroc and Iberian boars in a closed production cycle. The farm had a history of PRDC with clinical and/or laboratory diagnosis of P. multocida, M. hyopneumoniae and S. suis.

A total of 604 piglets from two consecutive weanings were included in the study (302 per group). Animals from both groups were randomized according to their weaning group, age, weight and gender.

The treatments to be compared were mixed with pre-starter feed as follows:

- 80 ppm florfenicol (Nuflor 40 mg/g Premix for Swine, 2 kg/Tm) during 14 days.
- 200 ppm tilmicosin (1 kg/Tm) during 14 days.

The mean age at weaning was 27 days, and the study lasted 42 days, so piglets were 69 days old at end of study.

The pen was the experimental unit when weighing the animals (25, occasionally 26 pigs per pen). Pigs were weighed on day 0 (at weaning, the start of medicated feed intake), on day 14 (at end of medicated feed intake) and on day 42 (at end of starter feed intake and entry to pre-fattening barn) and average daily gain (ADG) calculated. Feed intake was recorded and feed conversion ratios (FCR) calculated.

The statistical study was performed using ANOVA, Pearson’s chi-square test and Fisher’s exact test.

Results

Both treatments proved safe; no adverse effects were observed. The average weights of both groups at start of the study were comparable (p=0.677).

Table 1: Mean weights (kg)

<td>21.7</td>
</tr>
</tbody>
</table>

The florfenicol group performed statistically significantly better for average weight on day 14 (p=0.001) and on day 42 (p<0.01) (Table 1).

Better growth rates and weights were found in the florfenicol group, both during pre-starter and starter periods, and these differences were statistically significant in all cases (Table 2).

Table 2: Weight gains and growths per study period

<td></td>
</tr>
</tbody>
</table>

ª b (p=0.001), c d (p=0.002) e f (p<0.01)

The florfenicol group had a lower mortality rate (1.7%) than the tilmicosin group (4%) though this was not statistically significant. However, significantly fewer pigs in the florfenicol group (9.6%) received injectable treatment than in the tilmicosin group (14.9%) (p= 0.031).

Table 3: Production data

<table>
<thead>
<tr>
<th></th>
<th>Florfenicol</th>

<td>Feed intake (g)</td>
<td>583</td>
<td>579</td>
</tr>
<tr>
<td>FCR</td>
<td>1.56</td>
<td>1.72</td>
</tr>
</tbody>
</table>

Table 3 indicates a 9% improvement in FCR of the florfenicol group over the tilmicosin group (160g less feed per kilogram gained). This represents an extra intake of 2.26 kilograms of feed in the tilmicosin group during this period.

Conclusions

It can be concluded that florfenicol (Nuflor 40mg/g Premix for Swine) in pre-starter feed for prevention of PRDC on an Iberian pig farm was safe.

Also, compared to treatment with tilmicosin at recommended inclusion rate, florfenicol led to better mortality rate and FCR, and statistically significantly better ADG, end weight, and %age animals receiving injectable treatment.

The in-feed use of florfenicol can be recommended as effective in reducing the effects of PRDC (1).

Draxxin® metaphylaxis against Swine Respiratory Disease (SRD) in suckling piglets: benefits on performance and morbidity

Ian A. Nanjiani1 Joaquin Morales2 Carlos Piñeiro2 Pascale Sierra3 Jens Christian E. Jensen4
1. Pfizer VMRD, Sandwich, UK; 2. PigCHAMP Pro Europa SA, Segovia, Spain; 3. TVIVERITAS France, Gerstheim, France; 4. Orion Pharma Animal Health, Nivå, Denmark

Introduction
Swine Respiratory Disease (SRD) is a complex multifactorial disease which has substantial economic and welfare impacts on the swine industry, particularly when present in young animals. Disease control is generally achieved by environmental control, vaccination and antibiotic treatment. This GCPV compliant study was conducted to investigate the effects of a metaphylactic treatment administered early to piglets at risk of SRD during their first week of life on the disease and their subsequent growth when compared to a conventional "intervention" approach.

Materials and Methods
One hundred and twenty litters containing 1170 Large White x Landrace piglets were included in fives batches on two commercial farms sites in Spain with history of respiratory disease in young piglets.

Litters were randomised within airspace to either: T01 - metaphylactically treated with tulathromycin (2.5 mg/kg Draxxin®, Pfizer Ltd), at 3 days of age on Day 0 (60 litters, 582 piglets); or T02 - control group (60 litters, 588 piglets) individuals treated therapeutically with amoxycillin injection when showing signs of SRD. Animals were observed daily for signs of abnormal health; veterinarians conducting clinical examinations were unaware of the treatment group attributed to each pig. All piglets were weighed on Day 0 prior to treatment and on the day of weaning (Day 24 or Day 25). Any piglet (T01 and T02) diagnosed with SRD during the observation period was treated with amoxycillin long acting injectable at the recommended dose rate of 15 mg/kg repeated at a 48-hours interval if necessary.

The primary variable for Draxxin® metaphylaxis effectiveness was the average daily weight gain between Day 0 and weaning (ADG). Secondary variables included the homogeneity of weaning bodyweight per litter, the percentage of pigs with SRD during the observation period, and the number of days and injections for treatment for SRD.

Results
Clinical signs of respiratory disease were observed in all study batches, though they were generally mild in character. Pasteurella multocida, Haemophilus parasuis and Streptococcus suis were isolated (nasal or lung swabs taken from pigs with SRD), and serological evidence of Actinobacillus pleuropneumoniae was present on both sites.

Discussion
The use of injectable antibiotics for metaphylaxis allows the effective treatment of an at-risk group by ensuring accurate, targeted dosing of the individual animal. This study is consistent with recent studies in showing respiratory problems early in current swine production systems. In this study, a tulathromycin metaphylaxis approach during a mild disease outbreak produced a tendency to better weight gain and higher bodyweight at weaning, more homogeneous litter weights at weaning and less need for subsequent antibiotic treatment in the metaphylactically treated group when compared to a conventional "intervention" approach.

On-farm comparison of the efficacy and profitability of Draxxin® vs. medicated-feed for the prevention of Swine Respiratory Diseases on weaners

Cyrille Malherbe2 Audrey Dedeurwaerdere1 Arlette Laval3
1. Pfizer Animal Health, Paris, France; 2. Cabinet Vétérinaire Gâtines, Valençay, France; 3. ONIRIS National Veterinary School, Nantes, France

Introduction

The possible transmission of most respiratory pathogens and the heavy consequences of early SRD clinic on pigs’ performances make the weaning period the most critical moment for controlling SRD. This can be achieved using in-feed medication, a practical and often satisfactory way of preventing SRD on weaners. An alternative way is the use of single-shot, long-acting injectable antibiotics. In Europe Draxxin® (tulathromycin 100mg/mL) is labeled for the treatment and prevention of SRD associated with Pasteurella multocida, Actinobacillus pleuropneumoniae Mycoplasma hyopneumoniae and Haemophilus parasuis.

This study compared on-farm results of a single shot of Draxxin® at weaning to the normal farm practice using a tilmicosine-medicated starter. Focus here was on clinical efficacy and profitability at batch level, while a second trial investigated further clinical results at individual level.

Materials and Methods

Herd history The farrow-to-finish herd, located in western France, showed a high SRD pressure: PRRS, PCV2 and Mhyo positive, plus history of App. Clinical outbreaks were under control via in-feed medication on weaners and occasional oral treatments on growers. Decreased performance and increased heterogeneity were reported in the post weaning units. Due to lack of palatability, the two-week administration of medicated starter (300ppm tilmicosine) was delayed one week from weaning (21 to 28 days of age).

Longitudinal study Five consecutive batches were included at 2-weeks interval of 21 days-old piglets between April and August 2009. The first two batches (n=666) followed the normal farm practice (NF group). The other batches (n=938) received a single IM injection of tulathromycin at 2.5mg/kg on weaning day instead of the in-feed medication (Draxxin group). No other parameter changed.

Data Mortality was registered at batch level during the 7.5 weeks of post-weaning period. Average daily weight gain (ADG) and feed consumption ratio (FCR) were recorded at pen level from 21 to 42 days of age. These data were analysed with a T-test for independent populations. The ROI was calculated based on the 2008 French National references for farrow-to-finish farms and translated with Osiris® software (Pfizer). Extra-labor and treatment costs were registered on-farm.

Results

Performance data The mortality rate over the weaning period significantly decreased by 1.2% in the Draxxin group. ADG and FCR showed no significant differences.

Discussion

Although not a randomised study, this investigation included multiple batches and management was consistent between batches, so reliable conclusions can be drawn on the efficacy of the products. During this observation period the use of Draxxin® at weaning proved better clinical and economical results than normal farm in-feed medication. ADG was less variable and the feed-conversion efficiency was numerically higher in the Draxxin-treated batches.

A possible explanation for these findings may reside in treatment compliance. Given the individual variations of feed intake (linked with observed lack of palatability), especially on young weaners of 21-days of age in case of high SRD pressure, a proportion of piglets may not receive the calculated dose of oral medication. Thus it would lead to a fraction of poor-performing and unhealthy piglets, diminishing the general performances of the batch. This bias disappears with single-shot injectables, guarantying full compliance and superior overall efficacy of the treatment.

On-farm comparison of the clinical efficacy of Draxxin® vs. oxytetracycline medicated-feed for the prevention of Swine Respiratory Diseases in at-risk weaners

Cyrille Malherbe2 Audrey Dedeuwaerdere1 Arlette Laval3
1. Pfizer Animal Health, Paris, France; 2. Cabinet Vétérinaire Gâtines, Valençay, France; 3. ONIRIS National Veterinary School, Nantes, France

Introduction
The possible transmission of most respiratory pathogens and the heavy consequences of early SRD disease on performance make the weaning period a critical time for controlling SRD. This is often achieved using in-feed medication, a practical and often satisfactory way of preventing SRD on weaners. An alternative way is the use of single-shot, long-acting injectable antibiotics. In Europe Draxxin® (tulathromycin 100mg/mL) is licensed for the treatment and prevention of SRD associated with Pasteurella multocida, Actinobacillus pleuropneumoniae Mycoplasma hyopneumoniae and Haemophilus parasuis.

This study compared the efficacy of a single shot of Draxxin® at weaning to the normal farm practice using a medicated starter, in two different herds in normal farm conditions. The first part of the trial (vs. tilmicosin, separate poster) addressed clinical efficacy and profitability at batch level. In this second herd clinical results were investigated further at individual level as well.

Materials and Methods
Herd history The farrow-to-finish herd was located in Normandy, France and was positive for SIV, Mhyo and (historically) App. The farm was reported to be PRRS and PCV2 negative. Regular outbreaks of clinical respiratory disease occurred in the post-weaning units, with high morbidity, individual weight loss and heterogeneity commonly reported. Normal farm practice scheduled preventive treatment for 3 weeks at weaning (medicated starter, oxytetracycline, 1000 ppm) then additional oral treatment (20mg OTC/kg BW x 4 to 5 days) for therapy when needed.

Longitudinal study Six consecutive batches of 21 days-old piglets were included at 1-week intervals between July and August 2009. Three batches (n=944) followed the normal farm practice (NF group). The other batches (n=1155) received a single IM injection of tulathromycine at 2.5mg/kg at weaning (Draxxin group) instead of the starter medication. No other parameter was changed. In one batch of each group 120 piglets from 10 litters were chosen at random by the dispenser and identified for individual observations.

Data Mortality & additional oral treatment were recorded at batch level during the 7.5 weeks of post-weaning. Clinical examinations and weighings were recorded once a week up to 21 days after weaning. Quantitative data were analysed with a T-test for independent populations, qualitative ones with Pearsonχ test.

Results
Mortality rate decreased from 1.68% to 0.65% (p=0.021) and therapeutic oral treatment from 3.71 to 1.42 days/pig (p=0.007) in favor of the Draxxin group. Mean pen ADG reflected the mean individual ADG recorded per 1-week period, significantly superior in the Draxxin group.

Discussion
Although not a randomised study, this investigation included multiple batches and management was consistent between batches, so reliable conclusions can be drawn on the clinical efficacy of the preventive treatments. Dramatic difference in individual weight gains in the first days after weaning while no visible clinical sign (at individual or group level) was observed, supports the hypothesis of an early viral challenge, then of secondary respiratory infections noticeable at piglet level 7 days after weaning, and at group level after 2 weeks.

The difference in clinical efficacy between the two preventive treatments may then reside in compliance. Indeed, early challenged piglets, even if not visibly sick, won’t eat their share. Added to the individual variations of feed intake, especially on newly weaned piglets of 21 days of age, one can assume that a proportion of piglets would not receive the calculated dose of oral medication. This would lead to a fraction of unhealthy and poor-performing piglets, diminishing the general performances of the batch – and increasing the risk of SRD transmission. This bias disappears with single-shot injectable antibiotics, guarantying full compliance and superior overall efficacy of the preventive treatment.

Pulmotil® (Tilmicosin) in feed reduces clinical disease associated with PRDC resulting in increased nursery performance

Chanunda Raphanaphraiwan2 Ampol Chayomchai2 Thitima Tripipat1 Dachrit Nilubol1
1. Faculty of Veterinary Science, Chulalongkorn University, Bangkok, Thailand; 2. Elanco Animal Health A Division of Eli Lilly Asia, Inc. Thailand Branch, Bangkok, Thailand

Introduction
Several reports suggest that the severity of PRDC associated clinical diseases reduced when Pulmotil® (Tilmicosin, Elanco Animal Health, Thailand) was used1, 2. The objectives of the study were to investigate the efficacy of Pulmotil® in feed as an early intervention regimen in the reduction of PRDC associated clinical disease and to observe the antibody response against PRRSV as measured by ELISA (Idexx, USA) in pigs administered Pulmotil® in feed.

Materials and Methods
PRRSV status of the experimental herd was considered stable/inactive in which clinical diseases associated with PRRSV infection and PRDC were observed in the nursery period. 266 barrows were randomly selected based on the stratification of weight and ear-tattooed. Pigs were allocated into 2 groups (Control and Pulmotil® groups. Pigs were weaned at 18-21 days of age into a wean-to-finish facility located few kilometers away from the sow herd. Upon arrival, each group was housed in 2 pens. Pigs in control group (n=140) were medicated in feed with Amoxycillin, Tiamulin and Colistin at the dosages of 200, 100 and 80 ppm, respectively. Pigs in Pulmotil® group (n=126) were medicated in feed for 3 consecutive weeks with Pulmotil® and Colistin at the dosages of 200 and 150 ppm, respectively. All pigs were weighed individually at weaning and 8 weeks of age. Feed consumption was monitored daily. Average daily gain (ADG) and feed conversion ratio (FCR) were calculated. Death and cull were recorded. Ten same pigs were followed serologically for antibody response against PRRSV as measured by ELISA (Idexx, USA) at weaning and 8 weeks of age. At 8 weeks of age, 5 pigs were randomly selected from each group and necropsied to assess the pneumatic lung lesion. Bacterial culture was performed in all lungs. Bronchial alveolar lavage fluid (BAL) samples were collected and assayed for the presence of PRRSV by PCR. The study was done in duplicate.

Results
Nursery performance including antibody response as measured by ELISA is displayed in Table 1. Pigs on Pulmotil® in feed had ADG and % CV of age at 8 weeks of age slightly better than pigs in the control group and the difference was not statistically significant.

</tbody>
</table>

Bacterial Secondary bacterial infection was found in the control pigs and none was detected in the Pulmotil group. PCR results indicated that all BAL samples of the control pigs were positive for PRRSV, while that of Pulmotil® pigs were negative. In addition, most of the control pigs increased in their antibody response against PRRSV. The S/P ratio of the Pulmotil® pigs, however, decreased and was below the cut-off level (0.4)

Discussion
The results of the study suggested that the administration of Pulmotil in feed reduced the severity of the clinical disease associated with PRRSV and PRDC resulting in increased nursery performance.

References
**Introduction**

The practitioner needs perseverance and critical self-appraisal. This is illustrated by this case report which starts with a complaint of a drop in carcass weight (CW) and mortality in spite of piglets PRRS vaccination.

**Materials and methods**

The case concerns a 350 sow breeding-finishing farm, 28 days weaning once a week, all in / all out post-weaning and finishing, dynamic depression ventilation, in a low pig density area. Piglets are weighed at weaning and at the end of post-weaning. The farm is known to be infected by the influenza virus, M. hyop, PRRSV, H. parasuis and P. multocida. It is free from APP. The respiratory disease control plan includes vaccinations of the breeding stock against rhinitis, influenza, and PRRS (live). This last is also used in piglets at 7 weeks of age. There is no Mh vaccination and no antibiotic prevention after the nursery feed.

June 05: PRDC, with the "18-week wall" and CW 6 kg less than before. Observations at the slaughterhouse and the absence of vaccination lead to the diagnosis of enzootic pneumonia. Mh vaccination was set up, and PRRS vaccination maintained. Situation did not improve. Flu-like episodes continued, and lab analysis indicated the presence of SI, PCV2, PRRS and Mh.

Dec. 06: Follow-up of 12 sentinel piglets showed a late circulation of Mh and an early circulation of PRRSV. Necropsy and histology confirmed Mh infection. Antibiotic prevention was set up during 22 weeks, while PRRS vaccination was suspended. In parallel, three further elements were examined (Jan.-Apr. 2007): (a) colostrum analysis showed an absence of antibodies against atrophic rhinitis despite sow vaccination, (b) an analysis of weight at the start of finishing showed a sudden drop of over 3 kg in 2005. In the same batches, a drop in carcass weight was observed, (c) PRRSV PCR in sentinel showed early circulation (6-10 wks).

April 2007. The following action plan was up:

(a) Continuation of vaccination against Mh (PORCILIS M HYO at 1 and 4 weeks of age),

(b) Earlier vaccination against PRRS (PORCILIS PRRS at 4 instead of 7 weeks of age).

**Results**

After adjusting the timing and quality of vaccination, a clear improvement was observed: improvement of mortality rates and lung scores (Figure 1), increase of body weight at the start and end of the finishing period (Figure 2). Taken over 6 years, data show that, after an important drop in performance between 04 and 06, all indicators of 08 and 09 were better than in 04 (Table 1).

**Conclusion**

- Consider the impact of postweaning on finishing.
- Check quality of vaccination
- Record technical and used them as a diagnostic tool.
- Use diag. lab and observations in the slaughterhouse.

**Acknowledgements**

The author would like to thank the farmer for his trust and Intervet Schering-Plough AH for its support.
Field observation of the effects on the performance of weaned piglets of Pulmotil™ in large farms in Spain

Xavier de Paz¹ Susana Lapuente¹ Miguel Abad¹ Joan Sanmartin² Gonzalo Cano²

¹ Elanco Animal Health, Madrid, Spain; ² Optimal Pork Production, Lleida, Spain

Introduction
The presence of respiratory disease increases medication costs but also causes a loss of performance (ADG and FCR) since energy and protein is diverted towards fighting disease (1).

The objective of the present field observations was to evaluate the effects of a standard medication with Pulmotil™ at weaning to prevent respiratory disease in two large farms in Spain.

Materials and Methods
Two different in-feed treatment programs were compared after weaning: a control group (C) received a prestarter feed with 120ppm of colistin and 3200ppm of ZnO and a pulmotil group (P) that received a prestarter feed which included 400ppm of Pulmotil besides 120ppm of colistin and 3200ppm of ZnO. Every piglet received 5kg of this prestarter feed. Also, all the piglets were vaccinated against M.hyo at one week of age. The data of these field observations came from 18015 weaned piglets coming from 2 different sow farms during 10 consecutive weeks.

Farm 1: 2480 sow-farm where piglets are weaned at 21 days and moved to nursery facilities in another location for approximately 6 weeks.

Farm 2: 4865 sow-farm where piglets are weaned at 21 days and moved to nursery facilities in another location for approximately 6 weeks. Data was analyzed using the GLM procedure of SAS System. The model includes the treatment effect and batch was the experimental unit. No statistical differences were found neither for weight or age at start of trial so no covariate was included.

Mortality was analysed using the logistic regression with treatment as fixed effect.

Results and Discussion
The global results are summarized in table 1.

</tbody>
</table>

The initial liveweight (LW) of the piglets was not different between both treatments (p=0.52) but at the end of the nursery period (60.2 days of life) the piglets in the Pulmotil group were heavier (18.01kg vs 19.06kg; p<0.0001).

The ADG of the piglets was higher in the Pulmotil group (304g/d vs 333g/d; p<0.001). The mortality rate in the Pulmotil group was slightly lower than in the Control group (C=1.12% vs P=0.75%).

The treatment with Pulmotil affect significantly (p=0.0098) the mortality of piglets. Also, the odds ratio for mortality was 1.505 (1.10-2.0 Confidence interval at 95%) so Pulmotil piglets had less probability to die.

Conclusions
The inclusion of Pulmotil in the prestarter feed of piglets improves animal performance even in farms with good health status (around 1% mortality rate). As seen in other studies (2), the piglets in the Pulmotil group were heavier at the end of the nursery (1.05kg more at 60.2 days of life). Therefore, the piglets in the Pulmotil group grew more which enables them to increase the Full Value Pigs™ in the fattening unit.

References
**Introduction**

During the first step of the immune defence, the concentrations of a group of plasmatic proteins called the Acute Phase Proteins (APPs) change. These APPs seem to be sensitive and accurate biomarkers of pig health. Therefore quantification of their concentrations in plasma or serum of pigs could provide valuable diagnostic information for prognosis and monitoring disease [1]. In intensive production systems, respiratory disorders are considered as the most serious problem affecting finishing pigs worldwide and represent one of the major health issues [2]. The aim of the study was to assess the relationship between macroscopic lung lesions and serum concentration of one APP: haptoglobin (Hp) in slaughter pigs.

**Materials and Methods**

A sub-sample of 70 pig farms was selected from a sample of 125 French farrow-to-finish herds included in an analytical survey designed to identify risk factors for Porcine Respiratory Disease Complex. The 70 farms were selected according to their pneumonia mean score, assessed on a sample of 30 slaughtered pigs:
- mean score ≤1.7, 37 herds (mild pneumonia)
- mean score ≥5.5, 33 herds (severe pneumonia)

For each herd, at the slaughterhouse, individual blood samples were obtained at exsanguination from a sample of 10 finishing pigs selected at random. For every pig the lungs were collected on the slaughter line and pneumonia, pleuritis and abscesses were recorded. As regard enzootic pneumonia, the lungs were scored [3]. In a second step, pigs were classified into 4 groups according to the extent of pneumonia (0:no lesion, 1≤score≤4; 5≤score≤8; score≥9). The serum level of Hp was measured by a spectrophotometric method using a commercial assay kit (Tridelta Development, Greystones, Ireland). Differences in serum Hp concentrations between healthy pigs vs those showing pleuritis or abscesses were assessed using Mann and Whitney test whereas Kruskal-Wallis test was used for pneumonia (p<0.05; SAS Inc.).

**Results**

Among the 700 selected pigs, the correspondence between blood and lung sampling was achieved for 517 animals. The levels of Hp were not significantly different between pigs showing or not either pleuritis or lung abscesses (p>0.05).

**Discussion**

The results of our study indicated that serum Hp concentration in slaughter pigs was higher in case of extended pneumonia whereas no relationships between Hp levels and pleuritis or lung abscesses were found. To the best of our knowledge, this is the first report on Hp levels measured in a large sample of commercial pig farms in France. These findings are partially consistent with those of Amory et al., [4] and Pallares et al., [5]. Nevertheless, infectious conditions other than respiratory ones or injury like lameness, diarrhoea, tail or ear biting may induce elevated levels of Hp [6]. As these conditions were not examined in the present study, it is likely that these kind of diseases have occurred in some pigs and may have induced an Acute Phase Response. This may be one explanation of the relative “high” mean value of Hp observed in the group of pneumonia free pigs when compared to values encountered in commercial healthy finishing pigs. This is in line with previous literature conclusions telling that Hp should be considered as a general biomarker rather than a specific respiratory infection indicator.

Impact of porcine respiratory disease complex on the efficacy of classical swine fever vaccination

Ming T. Chiou1 Cheng Y. Yang2 Tsung C. Chang1 Ming L. Hsieh1
1. National Pingtung University of Science and Technology, Pingtung, Taiwan;
2. Animal Technology Institute Taiwan, Chunan, Taiwan

Introduction
Porcine respiratory disease complex (PRDC), an endemic disease caused by co-infection with several respiratory pathogens, typically adversely affects pig weaning and growth, leading to considerable economic losses worldwide. Porcine circovirus type 2 (PCV2) and porcine reproductive and respiratory syndrome virus (PRRSV) are the most common pathogens causing PRDC; these pathogens cause severe respiratory disorders and interfere with pig immune function. Classical swine fever (CSF) is a highly contagious disease. In many countries vaccination is the main strategy for protection against CSF. Notably, CSF vaccine is generally administered after weaning. Therefore, determining whether the CSF vaccine efficacy is influenced by PRDC in pigs is warranted.

Materials and Methods
Based on routine pathogen screening and polymerase chain reaction (PCR) analysis results, this study selected 2 farrow-to-finish pig herds with a history of PRDC infection for more than 3 years. Thirty 4-week-old weaned piglets were selected randomly from each herd and ear tagged. Half of the pigs from each herd were housed in the same barn in independent pens with non-tested weaned pigs (group A). The remaining tested pigs were transferred into barrier-separated animal rooms after weaning (group B). All tested pigs were provided the same feed. Food and water were provided ad libitum. Both groups were vaccinated with 1 dose of Lapinized China (LPC) strain CSF virus at 6 and 9 weeks of age. Blood samples were collected from each pig at 4, 6, 9, 12, and 15 weeks. Clinical signs were recorded during regular visits. Competitive enzyme-linked immunosorbent assay (ELISA) tests were performed to identify CSF-specific antibodies. All study protocols were approved by the Animal Care and Use Committee of National Pingtung University of Science and Technology. Data were analyzed using the Student t-test. Values of P < 0.05 were considered statistically significant.

Results
Group A pigs from both herds presented marked clinical signs of respiratory disorder and had a high mortality rate (4/15; 26.7 %) during the test period. The cause of death for both herds was diagnosed as PRDC, except for the case of 1 pig in herd B. However, pigs from group B in both herds did not show remarkable clinical signs and only 1 pig died due to acute bacterial infection. The serologic profiles of pigs from both herds were extremely similar. Figure 1 shows the serological examination results of herd A pigs. The antibody titers of pigs in both groups were similar at different time points; the titer decreased gradually from weaning to 9 weeks of age, increased markedly after vaccination, and reached a maximum in 15-week-old pigs. The CSFV-specific antibody titer in group A and B pigs did not differ significantly at all tested time points.

Discussion
This study housed 2 groups of pigs at different levels in pathogens concentration. The pigs in group A had a higher mortality rate and clearer clinical signs of PRDC compared with pigs in group B. The CSFV-specific antibody titer in 4- to 15-week-old pigs did not differ between the two groups. Unlike previous reports suggesting that some pathogens may alter pig immune function, this study shows that pathogenic agents have no or little effect on the efficacy of CSF vaccination in PRDC-affected pigs.

Porcilis AR-T: uniformity of titers optimizing passive protection against Atrophic Rhinitis

Marc Martens¹ Alex Eggen²
1. Veterinarian, Nistelrode, Netherlands; 2. Veterinarian, Malden, Netherlands

**Introduction**

The infection in piglets that results in Progressive Atrophic Rhinitis (PAR) takes place in the first weeks of life. Sorensen (1990) reported the relationship between high titers against Pasteurella Multocida Toxin (PMT) and the absence of turbinate atrophy. In the swine industry, uniformity of batches is important at all stages of production. To ensure this level of consistency throughout the production system, all piglets need to obtain the same high level of protection.

**Materials and Methods**

Trial 1 Breeding stock was classified according to their titer against PMT. (Ridremont, B. et al IPVS 2006). Serological profiles were undertaken on 135 farms, selected by veterinarians, with a history of persistent minor or major PAR problems in spite of vaccination with Porcilis AR-T. Anti-PMT titers were assessed and the animals were grouped according to titer and age. Farms were classified according to the percentage of animals in the different qualitative groups. Advice on the correct vaccination scheme was given to farmers and some farms were checked again, 6 or 10 months later, to determine whether the quality of the serological profile had improved. The following classification was used on both occasions. Excellent: when 80% of both age groups had a high titer; Good: when 50% of both age groups had a high titer; Average-1: when 30-80% in the old sows, and up to 30% in the young sows had a high titer; Average-2: when 30-60% in the young sows and up to 20% in the old sows had high titers; Insufficient: when less than 20% in both age groups had a high titer.

Trial 2 Gilts were vaccinated with either Porcilis AR-T or a competitor vaccine (Supat Suwanna et al IPVS 2008) and the resulting titers were measured. Both vaccines contain PMT and inactivated *Bordetella bronchiseptica* cells. Gilts of 120 days of age were randomly allocated to one of two groups of 12 and vaccinated with one or other vaccine in accordance with the manufacturer's instructions and recommended vaccination program. The animals were grouped according to their titer measured on D42, 2 weeks after the second dose.

**Results**

Trial 1: In figure 1, there is clearly a wide variation amongst breeding stock in their titers against PMT, under field conditions, despite vaccination. Figure 2 shows that the situation can be improved by adopting better vaccination schemes.

Trial 2: Figure 3 shows the distribution of the gilts vaccinated with either Porcilis AR-T or the competitor product over the different log2 groups.

**Discussion**

The Trial 1 data show improvement after an updated vaccination schedule with more farms achieving uniformly high titers across the different age groups (See farms A and D). Trial 2 shows that vaccines differ in their ability to induce homogeneous titers in sows. The combination of Porcilis AR-T achieving optimal titers and the correct vaccination schedule led to the best results.

The prevalence of DNT and BfrZ genes in Bordetella bronchiseptica

Iwona Markowska-Daniel; Katarzyna Stepniewska; Kinga Urbaniak; Zygmunt Pejsak

National Veterinary Research Institute, Pulawy, Poland

Introduction

Bordetella bronchiseptica (Bbr) is worldwide spread pathogen of pigs’ respiratory tract. When infecting the pig alone it may cause mild form of atrophic rhinitis (AR) called NPAR, while invading the respiratory tract in cooperation with Pasteurella multocida (Pm) it may cause progressive changes characteristic for PAR. Among different factors influencing the pathogenic properties of Bbr dermonecrotoxin (DNT) possessing cytotoxic properties as well as the factor involved in iron acquisition and transport, necessary for Bbr replication and survival, are the most important (1, 2, 4).

The aim of the study was the detection of the exogenous ferric siderophore receptor gene - BfrZ gene and DNT gene in Bbr strains existing in nasal cavities of healthy and diseased pigs and estimation the correlation between the presence of both genes in Bbr.

Materials and Methods

Samples. The prevalence of BfrZ gene was checked in 280 DNA samples in total. From this number 150 DNA samples were obtained directly from nasal swabs of pigs, raised in 19 farms, located in 10 provinces. Because symptoms of PAR were observed in some of the farms all DNA samples extracted directly from the swabs were previously tested by PCR with the primers specific for DNT gene of both, Pm and Bbr. 99 DNA samples were obtained from Bbr cultures on G20G agar base in which the presence of DNT gene was previously confirmed. The remaining 31 samples were obtained from Bbr cultures negative in PCR specific for DNT.

PCRs. DNA was extracted using Genomic DNA Prep Plus Kit (A&A Biotechnology). Detection of DNT in Pm based on Register’s procedure with some ours modifications (5). Detection of DNT and BfrZ in Bbr based on PCR protocols elaborated by ourselves (3). The predicted sizes of amplified DNA were 501bp, 224 bp and 368bp, for DNT Pm, DNT Bbr and BfrZ, respectively. The PCRs were performed in 25μl mixture containing 10xPCR Gold Buffer, 25mM MgCl2 solution, polymerase AmpliTaq Gold 5U/mL, 10mM dNTPs, 20pM of each primer and water free from DNAse and RNase.

Results

One hundred fifty (100%) DNA samples extracted directly from nasal swabs were positive in PCR test for detection of DNT Bbr. From this number 59 samples (39.3%) possessed BfrZ gene. The presence of DNT Pm was evidenced in 23 out of 150 (15.3%) tested samples. 13 (8.6%) of them possessed also BfrZ gene. In 10 remaining samples lack of BrfZ gene was evidenced. Among 99 Bbr isolates possessing DNT gene BfrZ gene was found in 51 samples (51.5%). The lowest number of positive results was obtained in case of Bbr strains which did not possess DNT gene. From 31 tested strains only in 5 (16.2%) the BfrZ gene was detected.

Discussion

Bordetellaceae have wide range of ferric siderophore receptors genes but BfrZ gene, which was used in our study, is present only in Bbr genome so PCR test for its detection can be used as species specific assay.

The results obtained in our study demonstrate that over half of analysed strains (51.5%) have both, ferric siderophore receptor and dermonecrotoxin genes. Additionally we evidenced that BfrZ gene is present in both types of Bbr strains - those with, as well as those without DNT gene. However the highest number of positive results in PCR with primers specific to BfrZ gene was obtained in Bbr strains possessing DNT gene. Lower percentage of positive results in PCR test for BfrZ gene detection were obtained when PCR was performed with DNA extracted directly from nasal swabs. The lowest number of positive results was received in the group of Bbr strains, which don’t present DNT gene.

Moreover, the correlation between the presence of BfrZ and DNT genes, especially in the case of bacterial culture, was evidenced. There is no doubt that among Bbr strains which don’t possess BfrZ gene there is high probability of occurrence of DNT gene.

Ecology of *Lawsonia intracellularis* infection across rearing systems in Australia

Patricia K. Holyoake1 Peter Thomson2 David Hamilton3 Alison Collins4

1. Wagga Wagga Agricultural Institute, Wagga Wagga, NSW, Australia; 2. University of Sydney, Camden, NSW, Australia; 3. South Australian Research and Development Institute, Adelaide, SA, Australia; 4. Elizabeth Macarthur Agricultural Institute, Menangle, NSW, Australia

**Introduction**

In Australia, increasing numbers of pigs are housed on bedding (straw or rice hulls) in custom-built sheds (ecoshelters, hoops) instead of on concrete (partial or full slats) in ‘traditional’ sheds.1 A potential disadvantage compared with traditional sheds having under-floor effluent drains, is that the deep litter may only be cleaned out when the pigs are removed, giving the pigs ready access to their faeces for the entire period of their stay in the shed. Proliferative enteropathy (PE) is an enteric disease of pigs caused by the intracellular bacterium *Lawsonia intracellularis* (*L*. *intracellularis*). Its major effects include poor growth and diarrhoea or sudden death and dysentery.2 This project was designed to investigate the ecology of *L. intracellularis* herd infection of pigs raised in ecoshelters on deep litter bedding, compared with those raised in ‘traditional’ pig housing (concrete-based).

**Materials and Methods**

Pigs (Large White x Landrace) were reared on 6 different 2-site (weaner/grow-out) commercial farms. The study was repeated on 2 of the sites. Pigs were transferred at 8-10 weeks of age to grow-out farms (4 traditional, 4 ecoshelters). A group of 65 pigs per farm was identified and blood samples collected at transfer to the grow-out farm, and at 16 and 22-24 weeks of age. Sera were tested using an ELISA according to the manufacturer’s instructions (BioScreen ELISA, Synbiotics, France). Factors affecting a pig being test-positive were analysed using logistic regression (Generalised Linear Mixed Model, GenStat Release 12). Housing (traditional/ecoshelter) and age of pig (weaner, grower, finisher) were included in the model as fixed effects, and farm as a random effect. There was no interaction between housing and age of pig. The positive predictive value and negative predictive value of the ELISA were used to estimate seroprevalence and standard errors.

**Results**

There was no effect of housing type of test-positive status (F = 0.00; df = 1, 14; P = 1.00). Mean seroprevalence was identical in pigs housed in traditional (36.3%, SE 19.8%) and ecoshelter (36.3%, SE 26.6%). There was a strong effect of age, with test-positive status/seroprevalence increasing steadily with age (F = 16.3; df = 2, 14; P = < 0.001 (Table 1).

**Discussion**

There were substantial increases in the seroprevalence of *L. intracellularis*-specific antibodies with increasing age of pigs. This appeared to be unrelated to the use of bedding at the fattening stage i.e. under the conditions of this study, deep litter systems did not appear to pose a greater risk to pigs of infection compared with traditional concrete-based systems.

Pig-associated Lawsonia intracellularis in various stages of on-farm Dipteroid fly species

Steven McOrist1 Connie J. Gebhart2 Ruth Blunt1
1. University of Nottingham, Sutton Bonington, UK; 2. University of Minnesota, St Paul, MN, USA

Introduction
Insects on pig farms can cause loss in various ways, including a potential mechanical or biological vector ability to spread disease within and between farms. This may conceivably include re-infection of eradication or start-up project farms by insects travelling from adjacent farms when infected with the agent in question. Proliferative enteropathy (PE, or ileitis) is one of the most ubiquitous of pig infections worldwide, but there is little work on possible vectors, such as insects. Most infections in pigs are gained by pigs contacting infected faeces or faecal-contaminated materials. Other studies have indicated that flies and some floor-dwelling insects, such as cockroaches and beetles, may be capable of carrying other agents such as PRRS, pseudorabies (Aujesky’s disease), Salmonella and E coli for significant periods on commercial pig and chicken farms. Increases in farm bedding usage will presumably also increase potential infected vectors. This study aimed to address if insects on pig farms could be infected with Lawsonia intracellularis and whether this was associated with specific insect types.

Materials and Methods
On 15 farm study sites within England and Ireland, invertebrate communities were regularly trap-collected, counted and sorted into genus and species groups. The fly (Diptera) community was generally dominated by Musca domestica (house fly, n=14 farms), but also included Muscina stabulans (false stable fly, n=9), Ophyra spp (garbage fly, n=10), Drosophila (fruit flies, n=8), Stomoxys calcitrans (stable fly, n=2) and Syrphidae containing Eristalis species (hover flies, n=2); Blatta orientalis cockroaches were noted on 2 farms. Total DNA was extracted from at least ten 12-week-old pig faeces on each of the 15 farms and also from available adult, pupae and larvae samples of each Dipteroid group. Each DNA sample was tested for the presence of Lawsonia intracellularis DNA by specific PCR. A wide selection of Lawsonia-positive PCR products and controls, were tested by the variable number tandem repeat isolate typing (VNTR) method. This method distinguishes finely among isolates in intergenic Lawsonia DNA zones and so distinguishes between isolates from different farm systems. This VNTR testing was conducted by blinded technicians who did not know the origin of each DNA sample.

Results
Lawsonia-specific PCR products were routinely detected in weaner-grower pig faeces on 13/15 farms. On these farms, 12 were positive for numerous Musca domestica; total DNA extracted from the Musca collected on 5 farms where this was the dominant fly type, was also positive for Lawsonia DNA PCR reactions. All sets of adults, pupae and larvae of the Syrphidae hover fly Eristalis sp, collected from the only two farms positive for this fly, also had positive Lawsonia DNA reactions. Fruit flies were not found to be positive. Sub-typing of the Lawsonia DNA obtained from pigs and from insects by variable number tandem repeat analysis indicated that the same VNTR isolate type occurred within the positive farm pigs and the dominant pig-associated dipteroid fly stages on the same farm.

Discussion
This study indicates that the Dipteroid flies associated with pigs and pig bedding feed troughs and flooring, such as Musca domestica and Eristalis spp had the most likely potential to carry and transmit Lawsonia intracellularis. In contrast, Drosophila fruit flies, which do not have significant pig or pig faeces interactions on-farm were not found to be positive for Lawsonia. This suggests that a program aimed at reducing infection levels or re-infection with this agent should include not only Enterisol ileitis™ vaccination and appropriate pig medication, such as pleuromutilins or macrolides, but also anti-insect population control measures, targeted at those insects in association with pigs, particularly in summer months when fly populations peak. The infection of Dipteroid fly insects in different stages of growth also indicates that some transmission between farms may be possible, including to nearby farms in start-up situations, by infected adult flies. We are continuing these studies with experimental challenge exposure studies in Musca flies.
Increased variation in pig weight and reduced feed intake in pigs sub-clinically affected with proliferative enteropathy

Alison M. Collins¹ Shayne Fell¹ Jolien van Straaten² Nadine Bolsius² Lindsay Penrose³
1. Elizabeth Macarthur Agricultural Institute, Narellan, NSW, Australia; 2. University of Utrecht, Utrecht, Netherlands; 3. Orange Agricultural Institute, Orange, NSW, Australia

Introduction
Proliferative enteropathy (PE) varies in its clinical presentation, ranging from acute intestinal haemorrhage and sudden death of pigs, to diarrhoea and weight loss, or sub-clinical disease, where histological lesions of PE occur in the absence of diarrhoea¹. Clinical PE is a costly disease because it reduces weight gains and feed conversion efficiency (FCE) in pigs by as much as 50% and increases variation in growth². The impact of sub-clinical PE is difficult to estimate because many producers are unaware that sub-clinical PE is present in their herd. The aim of this study was to quantify the impact of sub-clinical PE on feed intake and live-weight gain.

Materials and Methods
Thirty six male hybrid weaner pigs (Large White x Landrace) were randomly allocated at 13.8 ± 1.0kg into 2 treatments: pigs infected with \textit{L.intracellularis}, and a cohort of uninfected pigs. Pigs were housed in individual pens, with strict quarantine between treatments (separate rooms). Serology and faecal PCR monitoring of pigs prior to challenge indicated that all pigs were naïve to \textit{L.intracellularis}. At 9 weeks of age, one group of 18 pigs was orally challenged with \(5.9 \times 10^9\) viable \textit{L.intracellularis} extracted from a PE-affected mucosa, and the control group was inoculated with phosphate buffered saline. The consistency of pig’s faeces was scored daily as either normal or diarrhoeic. Blood collected at 0, 28 and 38 days post inoculation (pi) was tested for \textit{L.intracellularis}-specific IgG using an indirect fluorescent antibody test (IFAT). Faeces collected twice per week from 0 to 35 days pi was tested for \textit{L.intracellularis} DNA by a conventional PCR. Feed intake and pig weights were measured weekly but changes were analysed over 3 periods: pre-infection (day -14 to day 0), early infection (0 to 21 days pi) and late infection (21-42 days pi).

Results
\textit{L.intracellularis} infection was demonstrated by faecal PCR and IFAT between 14 and 38 days pi in all pigs challenged with \textit{L.intracellularis}. The majority of infected pigs (>80%) were sub-clinically affected, but \textit{L.intracellularis} infected pigs had a significantly higher probability of diarrhoea than control pigs between day 22 and 26 pi. \textit{L.intracellularis} infection did not significantly reduce pig weights or weight gains, but did significantly increase variation in pig weight in the early infection period, as seen in the error variance of random effect models predicting pig weight as a function of infection period. When \textit{L.intracellularis} infected pigs started to recover, their rate of weight increase was significantly greater (\(P<0.05\)) in the late infection period than in the early infection period, unlike for the uninfected pigs. \textit{L.intracellularis} infection significantly decreased feed intake over the early infection period (\(P=0.017\)), but not in the pre-infection or late infection periods (\(P= 0.668\) and \(P=0.416\) respectively). Pig weight was a strong covariate for feed intake in each period (\(P<0.001\)).

Discussion
This study highlighted the reduced feed intake and the large variation in weight in a group of pigs sub-clinically affected with PE. While animal genetics plays a significant role in weight gain, it alone can not account for the observed variation in pig weights with sub-clinical PE. It is likely that differences in the host’s immune status or intestinal microflora may explain the variation in weight between infected pigs. Control of \textit{L.intracellularis} infections in herds with sub-clinical PE can minimize production losses and improve profitability for pig producers.

**Prevalence of Lawsonia intracellularis infection in grower-finisher pigs in Thailand during 2008-2009**

Chanunda Raphanaphraiwan; Yongyot Sriyong; Ampol Chayomchai

_Elanco Animal Health A Division of Eli Lilly Asia Inc. Thailand Branch, Nonthaburi, Thailand_

---

**Introduction**

Proliferative enteropathy (PE) or ileitis is an important enteric disease in swine industry worldwide. It is caused by an obligate intracellular bacterium, Lawsonia intracellularis (LI). In general, the specific immunoglobulin G (IgG) against LI infection is usually detectable 2-3 weeks after infection. This IgG response can be found in serum for up to 12 weeks after exposing to the bacteria, depending on the form of ileitis and the severity of the disease (1).

This IgG response can be used as a marker for screening on the status of LI infection in the herd. Several serological tests have been developed and available for use. Ileitest® is an indirect fluorescent antibody test that are commercially available. In Thailand, we have little information about the dynamic and the prevalence of LI infection in grower-finisher pigs. The objective of this study was to estimate the prevalence of LI infection in grower-finisher herds in Thailand using Ileitest®.

**Materials and Methods**

This study was conducted in 40 commercial grower-finisher swine herds located in Northern, Southern, Western, Eastern, Middle and Northeast part of Thailand during 2008-2009. Eight blood samples were randomly collected from each age of pigs as cross-sectional at 4, 8, 12, 16 and 20 weeks of age. A total of 1,600 blood samples were submitted to the diagnostic laboratory at Faculty of Veterinary Medicine, Kasetsart University, Kamphaengsaen campus. All serum samples were measured for serum IgG antibody against LI infection by using Ileitest®, which was provided by Elanco Animal Health.

**Results and Discussion**

The specific antibodies against LI infection were found in 36 of 40 (90%) grower-finisher herds in Thailand. In those positive herds, it shows that at least one-time point of pigs in the production system was exposed to the bacteria. Eighty percent of herd were positive with the Ileitest® at 4 weeks of ages (Figure 1). It is more likely that the positive results may be due to the passive antibody from sow to their piglets. Guedes et al (2002) found that passive immunity can be found in piglets up to 5 weeks of age (2). If this is the case, it indicated that most of the breeding herds in Thailand have the natural infection of LI.

The peak of herd prevalence was 85% when pigs were 12 weeks of age. Unfortunately, the prevalence of LI infection in grower-finisher herd decreased to 62.5% at 20 weeks of ages.

Overall, the dynamic of LI infection in grower-finisher herd in Thailand was summarized in Figure 2. The results from this investigation suggested that the prevalence of LI infection is more likely increasing during 8-12 weeks of age of pigs. Therefore, several strategies for treatment and control of LI infection might need to be developed and applied during that period.

**Introduction**

Lawsonia intracellularis (L. intracellularis) is an obligate intra-cellular bacterium causing porcine proliferative enteropathy (PPE), an enteric disease condition affecting growing and finishing pigs. The ileal mucosa is thickened due to proliferation of immature cryptal enterocytes (3). Porcine circovirus type 2 associated diseases (PCV-AD) include systemic or localized infection. The later recognized: PCV-associated pneumonia, enteritis, reproductive disorders and dermatitis nephropathy syndrome (4). Main histological lesions consist of lymphocyte depletion together with histiocytic and multinucleate giant cell infiltration in the lymphoid organs and, in a wide range of tissues with the presence in some cases of inclusion bodies (4). The aim of the present study was to report a case of granulomatous enteritis (GE) and regional granulomatous lymphadenitis associated with L. intracellularis infection in growing and marked pigs.

**Materials and Methods**

A total of 310 pigs (23.3 weeks-old) with an average of 113 kbw were examined in 2 slaughter inspections. Ileum samples, taken at 10 cm of the ileocecal junction and mesenteric lymph nodes were collected from 46 randomly selected pigs. Samples were fixed in 10% buffered formalin for histopathological (HP) and immunohistochemical (IHC) studies against PCV-2 and L. intracellularis. HP results of intestine were evaluated for statistical association by Chi square test.

**Results**

Characteristic histopathological lesions of PPE such as enterocyte hyperplasia with the absence of goblet cells were observed at the level of cryptal epithelia. In the lamina propria and Peyer’s patches lesions consisted of infiltration of histiocytes, multinucleate giant and epithelioid cells. In the regional mesenteric lymph-node lesions were similar to the above described with a diagnosis of granulomatous lymphadenitis. There was statistical significance association between PPE and granulomatous lesions (p = 0.0029). By IHC, strong immunolabeled of L. intracellularis antigen was detected in 34 samples of ileum (73.9%) and in 26 samples of mesenteric lymph-nodes (56.5%). Whereas, slight PCV-2 antigens was observed in 1 ileum (2.2%) and 3 lymph-nodes (6.5%) samples. These samples also showed a strong immunostaining against L. intracellularis. All samples were negative for Mycobacterium spp or fungi by PAS and Ziehl Neelsen stains.

**Discussion**

Previously studies reported the identification of L. intracellularis associated with granulomatous enteritis (2, 5). However, few samples were available and also PCV-2 antigen was identified (2, 5). In this study results showed statistical significant association between PPE and GE lesions. Further, immunostaining against L. intracellularis was strongly positive in multinucleated giant cells and histiocytes. In addition, PCV-2 antigens were not found in Peyer’s patches with granulomatous lesions and only a few positive cells were observed in the lamina propria. Lesions induced by L. intracellularis are restricted to enterocytes, but occasionally epithelial cells and bacterium were found in mesenteric lymph nodes (5, 6). In the study, granulomatous lesion in lymph nodes was also associated with strong immunostaining of L. intracellularis in macrophages, histiocytes and giant cells. According with the pathogenesis of the granulomatous inflammation (1), the above results might suggest that L. intracellularis may induce a granulomatous response, in absence of PCV-2 infection, when resolution of lesions and disappearance of the bacterium not take place. In this context, the granulomatous enteritis and lymphadenitis could be considered as a part of PPE complex.

This work was supported by grants from ANPCyT OC/AR PICT 2005-33987
Introduction

Lawsonia intracellularis (Li), curved bacillus Gram (-), intracellular, does not grow on conventional media in vitro in the absence of enterocytes, their presence in the body produces a humoral response variable and short-term (1). Therefore, the study of cellular response is truly meaningful to characterize and understand the pathogenesis, which has not yet been deepened. Affects several animal species, mainly in pigs, producing porcine proliferative enteritis (PPE) causing stunting and increased mortality. The objective of this study is to determine the response characteristics of cells involved in the lesions of the small intestine (ID) of pigs who were diagnosed by immunoperoxidase technique (IPX) and PCR mucosa, the presence of Li.

Materials and Methods

Se trabajó sobre 20 establecimientos confinados pertenecientes a 7 de las provincias con mayor producción de cerdos de la República Argentina. Fueron muestreados los ileon de un total de 60 cerdos con diarrea. Por cada animal se tomaron dos muestras, una a 50cm por delante de la válvula-ileocecal y otra a 10 cm por delante de la misma, las cuales se procesaron para histopatología con H/E. Work was confined about 20 stores belonging to 7 provinces with higher production of pigs in Argentina. The ileum were sampled a total of 60 pigs with diarrhea. For each animal were taken two samples, one at 50 cm anterior to the ileocecal valve, and another 10 cm in front of it, which were processed for histopathology with H / E. We searched for lesions compatible with EPP as villus atrophy, enlarged and branched crypts, hyperplasia of immature enterocytes in the crypts and absent or fewer goblet cells. The samples processed by IPX were considered positive when there was a brown color reaction in the luminal epithelium and criptal and special attention was paid to the mononuclear inflammatory response in lamina propria and submucosa. In addition, samples were processed to determine the Li Ag by PCR mucosa.

Results

Five of the 60 pigs sampled were positive for IPX. Three of them showed hyperplastic reaction in the epithelium of the crypts elongated and branched in macrophages, activated macrophages reticular appearance and giant cells in the lamina propria. The other two animals showed no reaction in the deep epithelium, as these despite being enlarged but showed goblet cell hyperplasia. Was observed in these ID staining in a few macrophages and giant cells of the lamina propria and in some macrophages in the submucosa. Furthermore, in all the samples had large numbers of immature lymphocytes and plasma cells. In the epithelia of villi and crypts increased the number of intraepithelial lymphocytes. These 5 pigs were also positive with PCR mucosa (PCR F).

Discussion

It is noteworthy that the pathogenic action of Li can be determined by the histopathological lesions and the technique of IPX. However, the cellular response that has deserved special attention because it is an infiltration and / or histiocytic proliferation and hyperplasia of intraepithelial lymphocytes that remain present even when the epithelial lesions have disappeared, as indicated in animals with hyperplasia goblet cells (2). It would be important to deepen the studies of the pathogenic mechanisms of Li mainly related to apoptosis, and cellular response it generates, through the marking of different cell types acting. Thus differentiating it from other agents such as circovirus and / or Yersinia that produce similar lesions and granulomatous responses (3). Moreover, these results related to the pathogenesis would allow us to begin to explore possible associations with Li circovirus in clinical presentation of PMWS as seen in the caseloads of our pathology and histopathology.

Detection of *L. intracellularis*, *B. hyodysenteriae* and *B. pilosicoli* in German wild boars

Gerald Reiner; Melina Winkelmann; Sonja Hillen; Hermann Willems

Department of Veterinary Clinical Sciences, Justus-Liebig-University, Giessen, Germany

Introduction

Wild boars are recognized as a potential reservoir of pathogenic microorganisms for domestic pigs. *Brachyspira hyodysenteriae* (*B. h.* ) and *B. pilosicoli* (*B. p.*) are important swine pathogens causing swine dysentery and porcine intestinal spirochetosis, respectively. Because of difficulties in culturing *Brachyspira* species and due to the obligate intracellular parasitism of *L. intracellularis* (*L. i.*) (Ileitis), diagnostics of these bacteria primarily relies on the detection of genomic sequences. Small amounts of these bacteria can often be isolated from subclinical cases. Few data exist about the occurrence of *Brachyspira* spp. in wild boar populations. Infections with *L. i.* have been demonstrated in single wild boars from Spain (Segalés et al. 2001), and Brasil (Zlotowski et al. 2008; commercial herd). Jacobson et al. (2005) did not find *Brachyspira* spp. or *L. i.* in Swedish wild boar samples. *L. i.* was detected in 29.6% and 9.1% of free ranging and enclosed wild boars from Czech Republic (Tomanova et al. 2002; Dezorzova-Tomanova et al. 2006). Nyree et al. (2009) found 18.9%, 8.1% and 0.45% of 222 Australian feral pigs infected with *L. i.*, *B. h.* and *B. p.* The aim of the present study was to determine the prevalence for the three species in German wild boars.

Materials and Methods

Samples from ileal mucosa of 165 wild boars were collected from 19 hunting grounds situated in fourteen of the 16 federal states of Germany between November 2005 and March 2006. The town states Hamburg and Bremen were not sampled. Wild boars were gathered after the hunting at central places. The wild boars were on average 12 months (1 to 84 months) old, with an average carcass weight of 34 kg (6 to 110 kg). Samples were taken half an hour to 2 hours after death with fresh, sterile disposable gloves and scalpels, and stored at -20 °C until further usage. DNA was extracted from 25-50 mg of tissue sample using the Qiagen Viral RNA Mini Kit (Qiagen, Hilden, Germany). Differentiating primers and probes for conventional and real-time PCR targeted the nox gene of *Brachyspira* spp. and the aspA gene of *L. i.* Real-time PCR was performed with 2.5μl of the isolated DNA on a 7300 Real Time PCR System (Applied Biosystems, Germany). The analytical sensitivity for the real-time PCR assay, expressed as limit of detection (LOD) was 14, 26, and below 10 DNA copies for *B. p.*, *B. h.*, and *L. i.*, respectively. The analytical sensitivity for the conventional PCR assay was below 10 DNA copies for all three species.

Results

None of the intestines sampled did show any gross pathological signs of enteritis. Pathological histology was not available. The overall prevalence for *L. i.*, *B. h.* and *B. p.* was 20.6%, 2.4% and 12.1%, respectively. None of the three agents was detected in 68.5% of the wild boars; 17.0%, 1.2% and 9.7% were monoinfected with *L. i.*, *B. h.*, and *B. p.*, respectively; 2.4% and 1.2% were mixed infections with *L. i./B. p.* and *L. i./B. h.*, respectively. 84.2% of the hunting grounds were found positive for at least one of the three agents; *L. i.*, *B. h.* and *B. p.* were detected in 15.8%, 0.0% and 10.5% of the hunting grounds as monoinfections; 36.8% and 21.1% of the hunting grounds were positive with *L. i./B. p.* and *L. i./B. h.*, respectively. Numbers of bacteria per sample were consistently low, and none of the positive samples was above the quantitation limit of 100 DNA copies per PCR reaction.

Discussion

This is the first time that *B. h.* was detected in genuine wild boars. Detection rates substantiate a wide distribution of the three agents in wild boar populations. Prevalence of *L. i.* corresponds well with those reported for the Czech Republic and for feral pigs in Australia. The occurrence of *B. h.* is rather low. Missing of gross pathological lesions and the low number of bacteria per sample argue for a commensal role. Further research is needed to get insight into the epidemiological impact of these results.

Mixed infections with *L. intracellularis*, *B. hyodysenteriae*, and *B. pilosicoli* in faecal field samples from German pig herds, simultaneously detected and quantified by realtime multiplex PCR

Gerald Reiner¹ Marion Kixmüller² Hermann Willems¹

¹. Department of Veterinary Clinical Sciences, Justus-Liebig-University, Giessen, Germany; ². Novartis Animal Health, München, Germany

Introduction

*Brachyspira (B.) hyodysenteriae* and *B. pilosicoli* are important swine pathogens causing swine dysentery and porcine intestinal spirochaetosis, respectively. Because of difficulties in culturing *Brachyspira* species and due to the obligate intracellular parasitism of *L. intracellularis* diagnosis of these bacteria primarily relies on the detection of genomic sequences. There is a close relation between the faecal load of *B. hyodysenteriae* and *L. intracellularis* and the clinical outcome of the infection (1, 2). Small amounts of these bacteria can often be isolated from subclinical cases and the positive result of a conventional PCR is often misinterpreted and does not lead to the causal diagnosis. Thus, to provide information from a clinical point of view, it is advisable to detect and quantify the putative agent of disease. We have developed a multiplex real-time PCR (mrtPCR) assay for the simultaneous detection and quantitation of *L. intracellularis, B. hyodysenteriae* and *B. pilosicoli* from faecal samples. The mrtPCR was applied to study qualitative and quantitative distribution of the three agents in commercial herds from Germany, in order to gain information on prevalences, bacterial loads, and the occurrence of mixed infections.

Materials and Methods

A total of 1176 individual faecal samples from 95 herds (including 33,000 sows, 64,000 piglets and 145,000 fattening pigs) were sent in by 48 practitioners in the course of a diagnostic study. All samples were accompanied by a detailed questionnaire. For DNA extraction 300 mg of faeces were thoroughly mixed and applied to a Quiagen extraction kit. Finally, DNA aliquots extracted from 12.5 mg faeces were used for mrtPCR. Primers and probes for real-time PCR were designed with the Primer Express software (Applied Biosystems) targeting the nox gene of *Brachyspira* and the aspA gene of *L. intracellularis*. Gene sequences were retrieved from the Genbank database. Real-time PCR was performed on a 7300 Real Time PCR System (Applied Biosystems, Germany). The limit of detection was below 1 x 103 cells/g of faeces for all three species.

Results

From the individual samples, 12.7, 8.3, and 3.2 percent were positive for *L. intracellularis, B. hyodysenteriae* and *B. pilosicoli*, respectively. The relation of mono- to mixed infections per sample was 70.2%/29.8%.

Regarding herds, 48.4, 24.2, and 31.6% were positive with *L. intracellularis, B. hyodysenteriae*, and *B. pilosicoli*, respectively. 68.4% of the herds were infected with at least two of the three organisms. 60.1%, 82.6%, and 73.3% of infections with *L. intracellularis, B. hyodysenteriae*, and *B. pilosicoli*, respectively, were mixed infections. Medians for the log number of cells/g of faeces (with 5% and 95% percentiles in brackets) were 3.3 (2.2-7.2), 5.9 (2.9-7.5), and 3.2 (2.1-5.8) for *L. intracellularis, B. hyodysenteriae*, and *B. pilosicoli*, respectively. Incidence and severity of diarrhea were correlated with the quantity of *B. hyodysenteriae* and *B. pilosicoli*, but not with that of *L. intracellularis*. Haemorrhagic diarrhea was associated with the presence of *B. hyodysenteriae* and was most severe with mixed infections of the two *Brachyspira* species. Of the positive faecal samples, 60%, 60%, and 80% did not correspond with the tentative clinical diagnosis of ileitis, dysentery, and both diseases, respectively.

Discussion

In conclusion, the three economically important pathogens have been shown to have a wide distribution among herds. The overlapping clinical signs, the relatively high incidence of mixed infections and the occurrence of *B. pilosicoli* in herds can lead to significant misinterpretations in the field, underlining the impact of a fast and reliable molecular diagnosis. The introduced mrtPCR can be a relevant tool in the diagnosis and prognosis of infections with *L. intracellularis, B. hyodysenteriae*, and *B. pilosicoli*.

Demonstration of *Lawsonia intracellularis* in necrotic ileitis cases by immunohistochemistry

Dinko Novosel¹ Zoran Lipej¹ Željko Grabarević²
1. Croatian Veterinary Institute, Zagreb, Croatia; 2. Veterinary Faculty, Zagreb, Croatia

**Introduction**

Proliferative enteropathy (PE) caused by *Lawsonia intracellularis* is well known common intestinal and one of most economically important disease. There are several different syndromes of PE - porcine intestinal adenomatosis, hemorrhagic enteropathy and necrotic enteritis [1]. Immunohistochemistry (IHC) continue to be golden standard as diagnostic tool [2]. Most typical histopathological lesions is absence of goblet cells and little evidence of infiltration of inflammatory cells, which is not common [3]. The aim of this study was to detect and describe morphological findings possible presence of PE syndromes in Croatian pig production units.

**Material and Methods**

From three different fattening farms was reported onset dying without clinical symptoms or with greyish diarrhoea shortly before death. Totally, 11 animals were necropsied and after completely post-mortem examination three samples of ileum, before ileocecal valve were collected in 10% buffered formalin. Tissue was routinely processed until paraffin blocks. Stained with H&E and for immunohistochemical detection *Lawsonia intracellularis* is used anti-*Lawsonia intracellularis* (Euroclone ®) monoclonal antibodies according previously described protocol [4].

**Results**

In ileum of 5 animals strong *Lawsonia intracellularis* signal in enterocytes were detected by IHC (Fig. 1.). Histopathological lesions in all 5 positive animals were uniform in distribution. The mucosa is thickened by necrosis of apex of villi. The strong inflammatory reaction with lymphocytes and globular leucocytes between villi was clearly seen (Fig. 2). In crypts were still vital immature epithelial cells. The most prominent findings were absence of goblet cells.

**Discussion**

The present study describes the ileum lesions associated with *Lawsonia intracellularis* infection in fattening pigs. In our cases most prominent histopathological findings were necrosis of apex of villi and absence of goblet cells. A strong inflammatory reaction with lymphocytes and globular leucocytes was seen which is in contrast with previous studies which reported very mild inflammatory infiltration [3].

According to histopathological findings and positive IHC signal in enterocytes of swine with necrotic ileitis are fulfilled key criteria which confirmed the first objective findings of *Lawsonia intracellularis* as PE causative agent in Croatia. As far as we know this is the first report about necrotic ileitis in pig population in Croatia. Nevertheless, infection with *Lawsonia intracellularis* caused considerable economic losses in pig production during many years ago.

Prevalence of faecal Lawsonia intracellularis shedding in piglets: A European field study using Lawsonia FIRSTtest®

Annick Sainves² Vincent Auvigne¹ Susana Lapuente¹
1. EKIPAJ, Madrid, Spain; 2. Elanco Europe, Brussels, Belgium

Introduction

Lawsonia intracellularis (LI) is a major bacterial pathogen in pigs, responsible for ileitis (Proliferative Enteropathy), a digestive disease that greatly reduces the animal’s performance in the growing and finishing stage. The pathogen is endemic worldwide. The level of its excretion is variable and is linked to the severity of clinical signs (1). It is therefore important to gain a better knowledge of the epidemiology of the excretion of Lawsonia, for a better, targeted preventive and therapeutic approach.

Materials and Methods

Lawsonia FIRSTtest® is a new ELISA diagnostic tool designed to detect LI in faeces (2). A qualitative result is obtained by comparison to a positive control by indication of a color change to blue. By validation testing comparing to PCR, it is determined that if more than 3 out of 10 samples are positives, the batch is considered as shedding LI with a prevalence of at least 40% (3). For most herds, a sample size of ten is adequate to determine if a farm is positive or negative.

The study was carried out in 2008 and 2009 in 12 European countries. 7362 growing pigs of 531 farms were included. On 138 farms, two or more age groups were sampled. The average number of fecal samples per age and per farm was 10.8. Age (weeks of life) was available for 624 out of the 684 sampled batches. When more than one age group was sampled, the effects of age and herd were studied, using the Wilcoxon Match-Pairs Signed Ranks Test and Spearman’s rank correlation, respectively.

Results

The overall individual and batch prevalence was 55% and 82%, respectively. The intra-batch prevalence (image. 1) shows a bimodal distribution with one subpopulation around the 50% prevalence mark and another subgroup with a prevalence of 90% or more.

The herd effect was confirmed in this study: if pigs of 16 weeks and older were positive, pigs from the same herd in age groups 11-13 weeks and 14-16 weeks tended to be positive as well. The age effect was also confirmed: pigs aged 11-13 weeks shed significantly less bacteria that those aged 14-16 weeks or 16 weeks and older (Tab 1).

Discussion

This study confirms the high prevalence of LI on pig farms (4). However, shedding is not homogeneous, as shown by the herd and age effect. Shedding should therefore be evaluated herd level by measuring shedding in 2 different ages in the same farm. Sampling should be sufficient to assess the intra-batch prevalence and to adjust the preventive and therapeutic approach. Sampling should be standardised to allow for a comparison of the results between farms.

A longitudinal study comparing four diagnostic tests for Lawsonia intracellularis

Annick Saives1 Vincent Auvigne2 Xavier De Paz Solanes1 Susana Lapuente1
1. Elanco Europe, Brussels, Belgium; 2. EKIPAJ, Madrid, Spain

Introduction
Lawsonia intracellularis (LI) is a major bacterial pathogen in pigs, and is endemic worldwide. An accurate diagnostic is necessary for a targeted preventive and therapeutic approach. Available tests either measure the immune response or the faecal shedding. The aim of the study was to compare the results of four of them.

Materials and Methods
The study was carried out between Dec. 2008 and Apr. 2009, on a 300-sow breeding farm, with an all-in-all-out management from weaning to slaughter. At weaning (21 days), 20 piglets were randomly selected and individually double-tagged. Samples (blood and faeces) were taken every two weeks between 3 and 21 weeks of age. The serological status was determined at the LDG lab (Barcelona, Spain), using an IFA test (Ileitest, Elanco) and ELISA test (Bioscreen) for LI. Faecal shedding was determined at the CReSA laboratory (Barcelona, Spain) using in-house PCR and at Labopat (Segovia, Spain) using FIRSTtest®. FIRSTtest® is a new antigen ELISA which uses magnetic beads technology. All results were qualitative. Doubtful ELISA results were considered positive.

Results
All piglets remained in good clinical condition and could be followed up during the entire study period. All methods confirmed that the farm was contaminated by LI, although there was a difference in the percentage of positive animals and the evolution of the infection depending to the tests. Faecal LI shedding was detected by the FIRSTtest® from 5 weeks of age. Between weeks 7 and 19, nearly all piglets were positive, although shedding seemed to decrease by 21 weeks of age. PCR detected the first excreting piglets by week 11, and shedding only became widespread (> 40% of positives) at 17 and 19 weeks of life. Four piglets were never found positive for PCR. ELISA only detected a few positive animals between 3 and 7 weeks of age, probably animals with remaining maternal antibodies. This was followed by a massive seroconversion from 13 weeks of age. Between 13 and 21 weeks of age, the ELISA negative piglets were not systematically the same for all time points. The percentage of animals positive for IFA evolved little during the study period (minimum 30%, maximum 50%). However, two periods can be distinguished: between 3 and 9 weeks of age, there is a large variation between IFA test results of individual animals, from one time point to another. In contrast, between 9 and 21 weeks, there is little evolution in the IFA status of the individuals: positive animals remain positive and negatives remain negative.

Discussion
In the absence of a gold standard, this study has not allowed to reach a direct estimation of the sensitivity and specificity of tests. Furthermore, different biological parameters were used for the tests (immune response vs. faecal shedding). Nevertheless, it can be concluded that, under the study conditions, ELISA allows better than IFA to determine the time of seroconversion. The results obtained by PCR is consistent with another longitudinal study where PCR+ faeces were observed before ELISA seroconversion (1). This inconsistency might be due to the presence of inhibiting factors in the faeces or to intermittent shedding. Finally, the FIRSTtest® seems a highly sensitive technique since shedding is detected as early as 5 weeks of age.

These results might aid the veterinary practitioner in the choice of test to be used in the field.

Sub-clinical Ileitis: use of a diagnostic tool, Lawsonia FIRSTtest, to understand the excretion of sows and piglets and the impact of Tylan treatments on sows

Annick Saives
Elanco Europe, Brussels, Belgium

Introduction
Lawsonia intracellularis (LI) is a major bacterial pathogen in pigs, responsible for ileitis (Proliferative Enteropathy), a digestive disease that greatly reduces the animal’s performance in the growing and finishing stage. The pathogen is endemic worldwide. The level of its excretion is variable and is linked to the severity of clinical signs (1). The aim of this study is to control the level of shedding of sows and their piglets in 5 farms presenting signs of subclinical ileitis and to understand if a Tylan treatment on sows could decrease the shedding.

Materials and Methods
Lawsonia FIRSTtest® is a new ELISA diagnostic tool designed to detect LI in faeces (2). A qualitative result is obtained by comparison to a positive control by indication of a color change to blue. By validation testing comparing to PCR, it is determined that if more than 3 out of 10 samples are positives, the batch is considered as shedding LI with a prevalence of at least 40% (3). For most herds, a sample size of ten is adequate to determine if a farm is positive or negative.

Five farrow-to-finish herds with same gilt source demonstrating sub-clinical ileitis at the beginning of the finishing period, were selected. Baseline level of LI shedding in production sows and piglets from these sows after weaning (aged between 5 and 7 weeks) was measured before treatment. Sample sizes were determined based on sow farm size and estimated prevalence. A Tylan premix treatment at 5mg/kg for 15 days was administered to the animals at the time of placing the sows before farrowing. Testing was repeated in sows and piglets to determine effect due to Tylan administration to sows.

Percentages of shedding per animal category, before and after treatment, were analyzed by using the Mantel Haenszel Chi-square test adjusted on farms (EPIINFO 3.5.1).

Results
The results of shedding levels for the 5 farms are presented in tables 1 and 2 by animal category, before and after treatment. Farms were pooled for analysis. Results are listed in Table 1, and shown graphically in Figure 1. The inclusion of Tylan in the sow ration for 15 days initiated prior to farrowing resulted in decreased prevalence of LI as indicated by fecal shedding in both sows and piglets.

Discussion and Conclusion
This study demonstrates that in herds with sub-clinical ileitis, the shedding of sows is an important factor and could contribute to the contamination of their young. The Tylan treatment of sows allowed a significant reduction of the shedding level from 71.2 to 39.2%. The study showed that the shedding level also decreases in the young of the treated sows, without using a treatment, from 76 to 43.3%.

Lawsonia FIRSTtest® is an interesting tool in the understanding of Lawsonia shedding in herds with sub clinical ileitis and may allow a better understanding of bacterium circulation and its impact on farming.

The importance of the choice of gold standard and target population in the evaluation of diagnostic methods, such as serology, for the detection of antibodies to *Lawsonia intracellularis* in pigs.

Magdalena Jacobson¹ Per Wallgren² Ann Nordengrahn³ Malik Merza³ Ulf Emanuelson¹

1. Dept. of Clinical Sciences, SLU, Uppsala, Sweden; 2. National Veterinary Institute, Uppsala, Sweden; 3. Svanova Biotech, Uppsala, Sweden

Introduction

Diagnosis of *Lawsonia intracellularis* in live animals is based on the demonstration of microbial DNA in fecal samples, or the demonstration of *L. intracellularis*-specific antibodies in sera. The diagnostic sensitivity (DSn) and specificity (DSP), used to assess the performance of a new method, are commonly evaluated by analysis of reference samples from animals with a known infectious status and compared to analysis by a gold standard. However, these reference samples may not reflect the actual population for which the methods are intended and a true gold standard is not always available. The aim of the present study was to compare the results obtained by a blocking ELISA to an IFAT in the detection of serum antibodies to *L. intracellularis*.

Materials and Methods

200 pigs from 25 herds were included. Sera obtained from three previous studies were stored at -80°C. The pigs in study (1) and (2) were 8-12 weeks old. Study (1) included 54 pigs from 9 herds with poor performance and diarrhoea in growers, and 12 pigs from 4 herds with good performance and no diarrhoea. In (2), 110 pigs from 11 herds with diarrhoea and poor performance were selected. In (3), 24 six-week-old pigs from an SPF herd free from *L. intracellularis*, were included.

Sera were analysed by two serological methods, an IFAT (4) and a blocking ELISA (5) using PI 35 as cutoff value. The two methods were compared using pigs from study (1) and (2). The DSn and DSP were determined by a 2 * 2 table using either the IFAT or the ELISA as gold standard. Further, samples from ten pigs confirmed to be infected with *L. intracellularis* by nested PCR on faeces, and the 24 pigs from herd (3), were used as reference samples and similarly compared.

Results

As analyzed by the blocking ELISA, 32 of 66 samples from population (1) and 30 of 110 samples from (2) were judged as positive. As analyzed by the IFAT, 47 samples from (1) and 28 samples from (2) were judged as positive. All samples from confirmed cases of *L. intracellularis* were serologically positive and all samples from population (3) were deemed as negative by both methods.

</tbody>
</table>

Analysing reference samples from known *L. intracellularis*-positive and -negative animals, the DSn and DSP was 100 % for both methods.

Discussion

Experimentally, *L. intracellularis*-specific antibodies are detected 2 weeks after challenge, but the time point of infection and the actual infectious status are usually unknown in clinical samples. Further, estimating the diagnostic sensitivity and specificity by a 2 * 2 table requires the use of a true gold standard with DSn and DSP close to 1.00. However, none of the tests applied in this study can be considered to be appropriate for that purpose. Hence, in the present study the diagnostic sensitivity and specificity varied depending on the gold standard and on the population. In the absence of a true gold standard, Bayesian modelling techniques may be used to validate samples obtained from the target population.

Susceptibility of different mouse strains to Lawsonia intracellularis infection using intestinal mucosa homogenate and pure culture

Aline M. Viott1 Fabio A. Vannucci1 Juliana S. Oliveira1 Mirella C. Costa1 Connie J. Gebhart2 Roberto M. Guedes1
1. Universidade Federal de Minas Gerais, Veterinary School, Belo Horizonte, MG, Brazil;
2. Department of Veterinary and Biomedical Sciences, University of Minnesota, Saint Paul, MN, USA

Introduction
The susceptibility of laboratory mice to Lawsonia intracellularis infection has been demonstrated by experimental infection1; however, the occurrence of proliferative enteropathy (PE) lesions varies among different mouse strains2. Moreover, Murakata et al.2 showed that there are differences with respect to the establishment of PE lesions in mice according to the type of inoculum used. The authors demonstrated that mice inoculated with intestinal mucosa homogenate extracted from PE-affected rabbits had more severe lesions than those inoculated with pig intestinal homogenate. The purposes of this study were to describe experimental infections of L. intracellularis in four different mouse strains using intestinal mucosa homogenate (MH) extracted from PE-affected pigs and pure culture (PC) of the bacteria as inoculum and to evaluate fecal shedding of L. intracellularis in these animals.

Materials and Methods
Forty 3-to-4-week-old male mice of four different strains (BALB/c, C57BL/6, DB/A2 and Swiss) were used. On D0, 16 animals of each strain were inoculated with 0.5 ml of L. intracellularis PC (7.75 x 107)3, 16 with 0.5 ml of MH (8.9 x 108)3 and eight with sham inocula using an intragastric gavage. Four and two mice from the infected and control groups, respectively, were euthanised on D7, D14, D21 and D28. Intestinal samples from the mice were analyzed by histology and immunohistochemistry (IHQ)4. A pool of fecal samples was collected from each cage weekly and tested using a nested PCR assay5 for L. intracellularis. Fisher exact test was used for the statistical analyses.

Results
No diarrhea or other clinical signs were observed in these mice. Macroscopically, DB-A mice inoculated with PC had thickening of the cecum and ileum wall at 14D. According to the exact Fisher test, the histological lesions and IHQ were more severe in mice inoculated with PC than in those inoculated with MH. Strains DB-A and Swiss had more intense lesions and IHQ label than the other strains. Results of fecal PCR were reflected the severity of the histologic lesions. Swiss mice inoculated with PC shed L. intracellularis on D7 and D14; those inoculated with MH shed on D14 only. BALB/C mice inoculated with either inoculum were positive by PCR only on D14. C57BL/6 mice inoculated with PC shed the bacteria on D7 and D14 while those inoculated with MH were negative throughout the experiment. PC and MH inoculated DB-A mice were positive by PCR on D7, D14 and D21. All control mice were negative in the analyses performed.

Discussion
Gross and microscopic lesions typical of L. intracellularis infection were successfully reproduced in the mice in this study. Our results demonstrate a significant variation of lesion severity and of L. intracellularis infection among the four mice strains studied. DB-A and Swiss strains were the most susceptible to PE lesions, while the lesions in BALB/c and C-57BL/6 mice were mild. These differences in susceptibility to infectious agents have been previously known, but the genetic basis for these differences remains to be determined2. Typical major lesions and bacterial shedding occurred in mice strains on D14, similar to what is described in pigs6. DB-A and Swiss developed more severe PE lesions and shed more bacteria, especially when inoculated with PC. This information can be useful for the establishment of an experimental model for L. intracellularis infection in mice.

Quantitative assessment of Lawsonia intracellularis in feces by real-time PCR

Ken S. Pedersen¹ Klaus Pedersen¹ Marie Ståhl² Øystein Angen² Charlotte Hjulsager² Lars E. Larsen² Helle Stege¹ Jens P. Nielsen¹
¹. University of Copenhagen, Frederiksberg, Denmark; ². National Veterinary Institute, Technical University of Denmark, Frederiksberg, Denmark

Introduction

Conventional PCR tests designed for detection of Lawsonia intracellularis (LI) in feces may detect infections with or without effect on clinical disease and production parameters. Quantification of fecal excretion may therefore serve as a method to distinguish between clinically and economically significant and insignificant infections. Recently a quantitative real-time PCR (q-PCR) for detection of LI has been developed (1). Repeatability is an important test characteristic for quantitative diagnostic tests. Q-PCR repeatability can be influenced by features inherent to the q-PCR assay, homogeneity of fecal samples and variation in level of excretion for the same pig within the same day. The objective of the current study was to investigate variation in fecal excretion of LI detected by q-PCR within one day. Variation in fecal dry matter was also determined for the same pigs and will be reported elsewhere in the proceedings.

Materials and Methods

A cross-sectional field study with follow-up was designed. A Danish farrow- to finish herd with a history of LI was selected at convenience. A batch of approximately 8 weeks old pigs having an outbreak of diarrhea was selected. The pigs had not received antibiotic treatment within the last 4 weeks and treatment of the current outbreak was not initiated before the fecal samples were collected. Thirty pigs were selected at convenience. Fecal samples were collected at 9am, 11am, 1pm, 3pm and 5pm from the rectum of each pig. The pigs were identified with two identical ear tags. At each time point the pigs were examined in the same chronological order. All fecal samples were transported to DTU-VET, stored at 4°C and further processed the following day. All fecal samples were subjected to q-PCR testing designed for detection of LI (1). Fecal dry matter content (DM%) was determined by the microwave method (2). DM% of the fecal samples from the first time point was used to stratify the pigs into non-diarrheic (DM%>18.8), semi-diarrheic (18.8≥DM%>13.1) or diarrheic (DM%≤13.1) in the statistical analysis (3). The data was analyzed in a linear regression model with a repeat measurement structure using the mixed procedure in SAS, version 9.1.

Results

A total of 29 pigs and 144 observations were included in the analysis. Twenty-eight pigs had detectable levels of LI in feces at all time points. One pig was negative at one time point. Decreasing DM% was significant associated with an increasing excretion of LI (p<0.001). A significant effect of time on mean fecal excretion of LI was observed for non-diarrheic (p < 0.02), semi-diarrheic (p < 0.01) and diarrheic (p < 0.01) pigs, table 1. In all three groups the mean fecal excretion of LI was lowest at 1pm. The maximum individual change in fecal LI excretion between any time points was below one log unit for 25 of the pigs. The most extreme change observed was 1.09 log units.

</tr>
</tbody>
</table>

Time points with different subscripts within rows are significantly different (p<0.05).

Discussion

The increasing excretion of LI in pigs with decreasing fecal DM% indicates that quantification of LI can be applied to distinguish between significant and insignificant infections. The mean fecal LI excretion changed significantly during the examination day. However, the change was small within each group of pigs and may not affect the potential of q-PCR as a group level test. At the individual level the change of more than one log unit in 14% of the pigs may indicate that within day variation is more important for application of q-PCR as a diagnostic test at the individual level. The lowest level of excretion was detected at time 1 pm for all 3 groups. This implies that the other 4 time points better represents the mean fecal excretion of LI. This should be taken into consideration during collection and interpretation of q-PCR test results for detection of LI.

Enteric diseases - Grower and finisher pigs – Lawsonia intracellularis
Introduction

Proliferative enteropathy, caused by Lawsonia intracellularis (L. intracellularis), is one of the major diseases contributing to economic losses in intensive swine production worldwide. The recommended methods for diagnosis of the disease are polymerase chain reaction (PCR) or immunohistochemistry (IHC) (1, 2). The aim of the study was to develop immunohistochemistry (IHC) for L. intracellularis detection and to compare this method with PCR.

Materials and Methods

Field samples used in the study comprised of intestines (ileum, caecum and colon) and feces from 21 pigs with clinical symptoms of proliferative enteropathy, originating from 11 medium and large swine units. They were analyzed by PCR (5) for the presence of L. intracellularis. Also, intestines were fixed in 10% buffered formalin, embedded in paraffin, cut and tested in (IHC), according to avidin-biotin complex method.

Sections of intestines positive for L. intracellularis, kindly provided by dr. T.K. Jensen (Danish Institute for Food and Veterinary Research, Copenhagen, Denmark) and dr. Dinko Novosel (Croatian Veterinary Institute, Zagreb) were used as positive controls. Sections of intestines from clinically healthy pigs, negative for L. intracellularis by PCR (5), served as negative controls. All the sections were additionally hematoxylin-eosin (HE) stained.

Results

DNA of L. intracellularis was found by PCR in samples of intestines and in the corresponding feces from 16 pigs from 9 farms. L. intracellularis antigen was detected by IHC in all positive controls and in sections from 9 diseased pigs, representing 7 farms.

In the HE-stained sections of positive controls and IHC-positive field samples enlarged and branched crypts with proliferating immature epithelial cells were found, which are characteristic lesions of proliferative enteropathy (4). The remaining 5 sections were negative in IHC and presented no lesions.

Discussion

The results of this study showed that L. intracellularis antigen could be detected in formalin-fixed, paraffin-embedded tissues of pigs using monoclonal antibodies. The IHC test showed high specificity but lower sensitivity than PCR. Most probably the samples with no obvious lesions characteristic for proliferative enteropathy, negative in IHC and positive in PCR most likely originated from chronic cases of disease or final stages of recovery, where bacteria were present in a small number or already absent in the tissue (3).

Introduction

Lawsonia intracellularis (LI) is an obligately intracellular organism and is the causative agent of proliferative enteropathy (PE) in pigs and other animals. In many studies, the estimation of bacterial quantity or level of LI infection in samples (pig feces, intestinal tissue, gut mucosal homogenate, and pure culture) is required. However, we lack the assays for accurate quantification of LI in those samples. Previously, estimates of LI loads were obtained using a cumbersome immunostaining procedure with specific antibody for LI (1). The objective of this study was to develop a quantitative PCR (qPCR) using SYBR green for quantification of LI in feces and bacterial pure culture.

Materials and Methods

The LI strain PHE/MN1-00 was used for all steps in the development and optimization of the qPCR. Specific primers were designed using the aspA gene as a target. The size of PCR product is 162 bp. Serial 10-fold dilutions of pure culture samples and several sets of spiked feces in the range of 108 to 101 LI/ml and LI/g of feces, respectively, were tested for qPCR accuracy and the limit of quantification. The specificity of the primers was tested against 16 swine enteric bacteria using qPCR and conventional PCR. DNA of LI from pure culture bacteria and from fecal samples was extracted using the DNeasy\textsuperscript{®} Blood and Tissue Kit and the QIAamp\textsuperscript{®} DNA Stool Mini kit, respectively. qPCR was conducted using the Brilliant\textsuperscript{®} II SYBR\textsuperscript{®} Green Master Mix and 5 μl of DNA template in a final reaction volume of 25 μl. The qPCR amplification and quantification were performed using an Mx3000P Real-Time PCR System. The standard curve was constructed using the DNA of LI pure culture in which the final bacterial concentration was determined using a direct count method (2) before DNA extraction. Several qPCR parameters were tested: the limits of detection and quantification, the linear range, and the inter- and intra-assay repeatability.

Results and Discussion

When detected from pure culture, the limit of detection and quantification of LI was 5.1x10\textsuperscript{1} LI/ml while the lower limit of the linear range of the assay was 5.1x10\textsuperscript{2} LI/ml. In spiked feces, the limit of detection of LI was 2.55x10\textsuperscript{2} LI/g while the limit of quantification was 2.55x10\textsuperscript{3} LI/g. A concentration between 2.55x10\textsuperscript{2} and 2.55x10\textsuperscript{3} LI/g was the lower limit of the linear range. No cross-reactivity of qPCR was found when the assay was tested using the DNA extracted from 16 species of swine enteric bacteria. Coefficients of variation of inter- and intra-assay repeatability was lower than 10%. The dissociation curve of the aspA amplicon (Figure 1) showed a single melting temperature (Tm) peak at 79oC. In one of five spiked fecal samples, a non-specific peak could be found (Figure 2, right peak) but only at low concentration of 104 to 101 LI/g. This peak of incorrect Tm appeared only after cycle 36.

The results obtained from this assay are sensitive, specific and precise for the detection and quantification of L. intracellularis in samples. This new qPCR assay will be helpful in future disease transmission and epidemiology studies. We will use this assay to determine the dynamics and quantity of LI excreted post-infection through feces after experimental and natural infections.

References

**Introduction**

Ileitis, caused by Lawsonia intracellularis (LI), is a widespread enteric disease in swine. It leads to reduced average daily gain (ADG), poor feed conversion in nursery and fattening and high variation of body weight at slaughter. McOrist (1) reported that 90% of pig farms in the world were LI infected. Most of the herds are only subclinically affected by ileitis meaning that the animals do not show any clinical signs but reduction and variability in growth. Wang et al. (2) tested 2,700 blood samples collected from 54 Chinese pig farms with a blocking ELISA for anti-LI-antibodies. In their survey 70% of the investigated farms were positive already at the end of nursery period. Adam (3) estimated that the economical impact of clinical and subclinical ileitis in Europe is in average 4.70 and 3.47 Euro respectively per pig.

**Materials and Methods**

The trial was carried out in a Chinese pig farm in Guangxi Zhuang Autonomous Region from 2nd of March to 25th of June 2008. Animals were assigned randomly into 2 treatment groups: the vaccinated group (Group V) and the non-vaccinated group (Group Nv). There were 489 pigs in Group V in replicating subgroups of 141, 142 and 206 pigs which were all vaccinated with Enterisol® Ileitis at 14 days of age. There were 489 pigs in Group Nv, which consisted of 3 replicating subgroups as well, with 140, 141, and 208 pigs, respectively. Both Group V & Group Nv were housed in the same barn, provided with the same feed and health management. An infection of the trial animals with LI was confirmed by clinical signs and serological testing.

**Results**

ADG of the vaccinated animals was 18.9 g higher and FCR was 0.09 lower compared to the non-vaccinated animals. Overall mortality was lower in the vaccinated animals by 0.82%.

An additional 46 Yuan/pig profit was generated by vaccination, including:

1. Feed consumption decreased by 2.16 kg (= 4 Yuan)/V pig;
2. Final weight increased by 2.14 kg (= 28 Yuan)/V pig;
3. Mortality and culling rates decreased, saving about 14.6 Yuan/V pig

**Discussion**

Throughout the trial, animals of Group V showed a better growth performance than those of Group Nv. Findings in the present trial demonstrate that Enterisol® Ileitis can effectively protect pigs from clinical ileitis in Chinese farms. Moreover, vaccination can improve the production performance, as indicated by ADG, FCR and mortality, leading to a higher profit margin. In conclusion, Enterisol® Ileitis is a powerful tool to control ileitis and boost profitability of pig farms.

**References**

Introduction
The vaccine Enterisol® Ileitis Vet. effectively controls ileitis caused by Lawsonia intracellularis (LI). In a pan-European survey, the gross margin (GM) increased 3-6 € per pig after vaccination, when benefits of increased average daily weight gain (ADWG), reduced feed conversion rate (FCR) and losses were valued (1). On top, the vaccine increases uniformity of pigs (2), and this parameter was not included in the calculations. As a rule of thumb for acceptable uniformity, the producers organisation in Denmark estimates, that every pig in a batch should have reached the minimal required weight (70 kg carcass weight), when half of the batch has been shipped for slaughter. Each kg a pig weighs below this minimal weight at this cut-off day, the GM per pig decreases by 0.53 € because of extra costs in production or depreciation of carcass value (3). Hence, a thorough calculation of economical benefits should not only include values of ADWG, FCR and losses, but also value arising from increased uniformity. In the present study, losses in GM caused by lack of uniformity were calculated for vaccinated and non-vaccinated pigs by calculation of their weight at the cut-off day, when 50% of the pigs had been slaughtered.

Materials and Methods
The study contained 9494 pigs from 3 Danish slaughter pig herds. From each herd, 16 batches of pigs were included, and pigs from every second batch (batch 1, 3, 5, 7, 9, 11, 13 and 15) were vaccinated against LI with Enterisol® Ileitis Vet. (Boehringer Ingelheim). Remaining batches were non-vaccinated controls. In herd 1 and 2, the vaccine was given in drinking water 1-5 days after weaning, and in herd 3, vaccine was administered orally by drench before weaning. Infection with LI was confirmed by laboratory diagnosis on intestines. The date of weaning was recorded, and individual data for slaughter date and carcass weight were obtained from the slaughterhouse. The number of days to slaughter and ADWG was calculated for each pig. The carcass weight of pigs at the cut-off day (when 50% of the pigs had been slaughtered) was calculated backwards from the cut-off day using actual carcass weight and assuming an ADWG of 850 g/day from the cut-off day until the actual day of slaughter. To put a value on (lack of) uniformity, the difference (Δ) between calculated carcass weight at the cut-off day and 70 kg was calculated for each pig. Lost uniformity GM was valued per pig as Δ kg x 0.53 €. Comparison of vaccinated pigs and controls was made with Students t-test for ADWG and with Kruskal-Wallis test for lost uniformity GM (significance level p≤0.05).

Results
In all 3 herds, vaccination gave a significant improvement in ADWG (table 1). The improvement varied from 27 to 46 g/day, comparable to results from other trials (1). The reduction in lost uniformity GM was between 0.52 and 0.89 €/pig. Fig. 1 shows the improved uniformity of the vaccinated pigs in herd 1, where only 8% of vaccinated pigs were below 70 kg carcass weight at the cut-off day, compared to 21% of non-vaccinated animals.

* = Statistically significant difference (p < 0.05).

Discussion and Conclusion
Vaccination with Enterisol® Ileitis Vet. significantly reduces losses in GM caused by low uniformity of pigs. To demonstrate full economical benefits of vaccination against LI, value of improved uniformity GM should be added to more traditional benefits, such as improved ADWG, FCR and mortality.

Vaccination against *Lawsonia intracellularis* in two Danish farms

Markku Johansen¹ Poul Baekbo¹ MaiBritt F. Nielsen²

1. Pig Research Centre; Danish Agricultural and Food Council, Kjellerup, Denmark;  
2. Pig Research Centre; Danish Agricultural and Food Council, Copenhagen, Denmark

**Introduction**

*Lawsonia intracellularis* (L.i.) is the causative agent of porcine proliferative enteropathy (PPE). PPE is an economically important enteric disease, causing diarrhea and reduced weight gain in weaners and grower-finishers (1). Lawsonia is present in most pig producing countries. In a Danish study, L.i was detected in 93.7% of the tested herds (2). Together with management, antibiotics have been used to control the disease. However, the use of antibiotics can cause an increased level of resistant bacteria, and this might cause public concern about the production method in the industry. Vaccination is a consumer-friendly alternative, and the objective of this study was to evaluate the impact of vaccination with Enterisol® Ileitis Vet. on the average daily weight gain in nurseries and finisher barns in two Danish pig farms.

**Materials and Methods**

This study was conducted as a randomized blinded clinical trial with parallel treatment and a placebo group in two pig farms with clinical PPE problems. The time of infection was established by serological profiles using an ELISA (3) to detect antibodies against L.i. From both herds, two to four unthrifty pigs were submitted to a diagnostic laboratory to confirm the PPE diagnosis by immunohistochemistry (4). The pigs were vaccinated orally by drench one to two weeks before weaning; half of the litters in each batch of pigs being vaccinated and the other half treated with placebo. In each of the two herds, approx. 250 vaccinated pigs and approx. 250 placebo pigs were ear tagged individually and weighed at vaccination, at the end of the nursery period and at the end of the fattening period. Statistical analysis was performed by linear regression in SAS Proc Mixed with average daily gain (ADG) as the dependent variable, start weight, herd and observation period as covariates and batch as the random effect. Light pigs were arbitrarily defined as pigs weighing less than 67.5 kg live weight at the end of the fattening period. The study was performed in cooperation with Boehringer Ingelheim and supported by grants from the EU and Danish Ministry for Food, Agriculture and Fisheries.

Attempt to eradicate Lawsonia intracellularis during establishment of a new breeding herd by combined strategic medication with tiamulin (Denagard®) and cleaning/disinfection

Marion Kixmoeller1 Magdalena Kmieć2 Josef Szancer3

Introduction

Lawsonia intracellularis (L.i.) is widely distributed among pigs in Germany and seems to play a dominant role in sows (1). The aim of this study was to eliminate L.i. from a breeding farm by medication with tiamulin (Denagard® 10 % oral powder) combined with cleaning and disinfection.

Materials and Methods

The eradication program was carried out in a breeding farm with 2500 sows with production of 30 kg pigs. Six weeks before the program started the farm was completely depopulated, cleaned and disinfected and routine rodent control was carried out. Barns were repopulated with 2500 gilts aged 20 – 24 weeks (60 – 120 kg) delivered in 5 consecutive batches (April to September 2008). The delivery multiplier herd was infected with L.i. Periodic outbreaks of PE (Proliferative Enteropathy) were observed and confirmed by post mortem investigations and L.i. was detected in faeces by polymerase chain reaction (PCR). Before arrival, 10 of 11 faeces samples from purchased gilts were positive for L.i. The medication program was carried out in a quarantine stable. After each batch received the medication, the gilts moved to a new facility 9 km away.

Medication

To reduce shedding of L.i. and to minimize the risk of contaminating the quarantine area, the gilts were given a dosage of 8mg/kg bodyweight/day (bw/d) of tiamulin (Denagard) orally three days before being transported from the farm of origin to the new facility. After arriving at the quarantine stable, the gilts were fed a dosage with 8mg/kg bw/day of tiamulin (Denagard 10% oral powder) for another 28 days. The dosage was calculated based on the heaviest gilt of approximately 120 kg. Tiamulin was given via wet feed twice a day. 4 mg/kg bw/d once in the morning and 4 mg/kg bw/d after 8-10 hours.

Cleaning/Disinfection

Faeces was removed from the pens twice daily after each feeding. Twice a week the whole pen was disinfected after cleaning with a disinfectant (Venno Vet 1 super).

Monitoring

Since the eradication program was conducted in October 2008 the herd has been clinically monitored twice a month for 15 months. 50 faecal samples from progeny weighing 20 - 60 kg were examined for L.i. by PCR and 56 blood samples from progeny (40-100 kg) were tested for specific antibodies for L.i. by ELISA test (2). Pigs showing the clinical symptoms of diarrhoea were submitted to gross pathology for further laboratory examination.

Results

There have been no clinical signs of PE since completing the eradication program. As shown in the Table, all 50 faeces samples tested negative for L.i., but 2 blood samples were positive at the cut-off point which could be considered positive.

<table>
<thead>
<tr>
<th>Date</th>
<th>Number of positive/negative faeces samples tested by PCR</th>

</tr>
<tr>
<td>Dec. 2009</td>
<td>——</td>
<td>1/26</td>
</tr>
</tbody>
</table>

Pigs with clinical symptoms which were submitted to laboratory examination were tested negative for L.i. Furthermore, there were no lesions characteristic for PE.

Discussion

This field trial indicates that L.i. may be successfully eradicated from a breeding herd by the presented procedure of medication with tiamulin combined with cleaning/disinfection. The two very low reactions for L.i. antibodies in blood are difficult to explain. It cannot be ruled out entirely that these two blood samples on the cut-off point could have been false positives since all data are against any signs of PE and in large parts blood samples as well all faeces samples tested negative for L.i.. Further investigation both in faeces by PCR and by serology for L.i. will be carried out in the near future to ascertain the herd is free from L.i.. The results will be presented.

**Denagard® (tiamulin) treatment in a *Lawsonia intracellularis* pure culture seeder pig challenge study**

Dana C. Beckler2 J. M. Hammer1 Connie Gebhart3 Linda Roycroft1

**Introduction**

Proliferative enteropathy (PE) causes considerable economic losses to the swine industry worldwide.1 Judicious use of Denagard® has been shown to be an effective means of reducing economic loss due to PE.2 A pure culture seeder pig model was designed to show transmission of *Lawsonia intracellularis* (*Li*) infection from *Li* challenged pigs in a population to susceptible pen mates. This model mimics the paradigm for natural transmission of the disease.3 The objectives of this study were to document the spread of *Li* infection from a seeder pig to multiple susceptible pen mates, document levels of shedding in seeder and susceptible pigs, and evaluate the effect of placing Denagard® at 38.5 ppm (35 g/ton) when a shedding threshold of 30% in susceptible pig was reached.

**Materials and Methods**

*Li* was isolated from a field case and cultured under conditions previously described4 and used as the challenge material for the seeder pigs. Sixty pigs were randomly placed into one of six pens. All pens were separated by an empty pen or a solid partition to prevent fecal oral contact between pens. The seeder pig to be challenged was designated as the pig closest to the median pig weight of each pen. Each seeder was challenged with $1.6 \times 10^{10}$ *Li* via esophageal tube. Pigs were weighed and blood samples were collected once a week. Weekly blood samples were analyzed by the immunoperoxidase monolayer assay (IPMA) for the detection of circulating *Li* antibodies. Fecal consistency, abdominal appearance, and demeanor scores were recorded three times a week. Fecal samples were analyzed by quantitative polymerase chain reaction (qPCR) to determine the amount of *Li* being shed per gram of feces. Denagard® at 38.5 ppm (35 g/ton) was placed in three (treatment T2) of the six pens when 30% of the sentinel pigs were shedding *Li* as detected by PCR. Three of the six pens remained untreated (treatment T1) throughout the trial. Pen was used as the experimental unit in all analyses.

**Results**

Fecal shedding of *Li* from 3 of the seeder pigs peaked on 21 days post-challenge, the other 3 seeder pigs peaked on day 11, 18, and 32. The highest amount of *Li* shed by a seeder pig was $8.62 \times 10^{9}$ bacteria/gram feces on day 11 post-challenge. The highest amount of *Li* shed by a susceptible pigs was $1.52 \times 10^{9}$ bacteria/gram feces on day 32 post-exposure to a seeder pig. There was a significant difference in the percent of IPMA and qPCR positive pigs between Denagard® treated (T2) and control (T1) pens (Fig.1). There was a significant difference in mean fecal consistency and mean abdominal appearance scores between T1 and T2 (Fig. 2). Numerically, T2 when compared to T1 had a lower percent of days with abnormal (score > 0) fecal consistency scores (3.91% vs. 8.44%, respectively) and abnormal (score > 0) abdominal appearance scores (17.08% vs 38.89%, respectively).

**Discussion**

Spread of *Li* and levels of fecal shedding were documented in this pure culture seeder pig model. Direct challenged seeder pigs shed lower quantity of *Li* than susceptible contact pigs when shedding was detected. Use of Denagard at 38.5 ppm (35 g/ton) in the model significantly decreased the clinical effects of PE in the susceptible pigs. Fewer Denagard® -treated pigs tested positive by PCR or serology.

Long term benefits of ileitis vaccination in a 5000 sow herd in Spain

Joan Sanmartin; Gonzalo Cano
Optimal Pork Production, S.L., Lleida, Spain

Introduction
Ileitis is an infectious endemic disease present in most of the Spanish farms (1) and all over the world. Multisite production systems have not been able to control the infection and the clinical signs of the disease or to eliminate its negative economical impact in the fattening period.

Enterisol® Ileitis is the unique oral ileitis vaccine for controlling the negative impact of the disease. The objective of this study was to evaluate the effect of ileitis vaccination in a 5000 sow system one year after introducing the vaccine.

Materials and Methods
The study took place in a three site production system with a 5000 sow farrowing site, 16,000 places in the nursery and 32,000 fattening places. The system produced weekly batches of 2000 piglets. Some of the batches went to external fattening sites.

At the beginning of the trial the performance of the sow herd and in the nursery were above the average level in Spain. Nevertheless the management was not satisfied with the performance achieved during fattening period especially concerning growth, mortality and cull rate. From 10-12 weeks of age onwards until end of fattening, animals had chronic diarrhoea and some animals showed clinical signs typical for Porcine hemorrhagic enteritis. Before ileitis vaccination was implemented Lawsonia intracellularis infection was confirmed and the time of infection was determined by serology and PCR of fecal samples.

In May 2007 ileitis vaccination with Enterisol® Ileitis was implemented and piglets were vaccinated via the drinking water in troughs between 3rd and 4th week of live, just after weaning. Later due to logistic reasons in farm, the animals were vaccinated by drench.

The study compares 6 batches of animals before implementation of ileitis vaccination (12,048 pigs) with 15 batches of vaccinated animals (29,221 pig as Enterisol® Ileitis group). All batches were kept under similar husbandry conditions. All data presented is from fattening period and dates in the SPC charts are starting dates of each batch in fattening.

Performance of both treatment groups was compared by SPC (Statistical Process Control), using Statistica® Version 8.0, Statsoft. Return of Investment was calculated using pork and feed average prices of the dates that animals were slaughtered.

Results
SPC analysis revealed a significant increase in ADG in favour of the vaccinated animals (+70g, fig. 1). The FCR was 0.4 kg/kg lower in the vaccinated animals compared to the non-vaccinated (fig. 2).

The mortality rate was 1.3 % lower after implementation of ileitis vaccination (6.55 % in the control group and 5.28 % in the vaccinated animals).

Finally, the cost of medication for enteric problems in the fattening period was dramatically reduced by 89% by cutting out two routine antibiotic treatments that were established in the farm before the start of the study. These improvements in performance resulted in a Return of investment 8.6 : 1 per pig (including the vaccination cost).

Discussion
In the present study Enterisol® Ileitis vaccination improved significantly the performance during fattening and was highly profitable. Fattening period is a critical point from an economical point of view and all the tools to improve its efficiency must be considered.

Laboratory of Microbiology and Infectious Diseases, Faculty of Veterinary Medicine, Aristotle University of Thessaloniki, Thessaloniki, Greece; 4. Deceased author, Thessaloniki, Greece; 5. Foundation of Biomedical Research, Academy of Athens, Athens, Greece

Introduction

Proliferative enteropathies (PE), also known as ileitis, are a group of acute and chronic conditions of widely differing clinical signs but with a common underlying pathological change visible at necropsy; a thickening of the mucosa of the small intestine and the colon. The primary causative agent is the obligate intracellular bacterium Lawsonia intracellularis. Ileitis is a common disease which affects pigs maintained under various management systems worldwide (1). The aim of this field study was the assessment of the possible antimicrobial activity of Larch sawdust based on the reduction of proliferative enteropathies prevalence in growing pigs. This trial was part of the SAFEWASTES specific targeted research project financed by the European Union (6th Framework Project).

Materials and Methods

This study was carried out on a commercial pig farm in northern Greece with a capacity of 250 sows under production. The farm was selected due to previous history of PE occurrence. 120 healthy of the same genetic background growing pigs at 8 weeks of age were used. A randomized block design was used with 3 treatments and 4 replicates (pens of 10 pigs each with equal sex ratio) per treatment. A day before allocation, all pigs were weighed and monitored for diarrhea. They were allocated to different groups, in order to achieve homogeneity in average weight, sex and diarrhea signs at the beginning of the trial.

The first group, designated as negative control group received feed formulated with 99% basic diet (grower ratio of wheat/barley/soya mix with no antimicrobial agents or performance enhancers) and 1% corn starch from trial day 0 until the end of the trial (6 weeks later). The piglets of the second group received feed formulated with 99% basic diet and 1% larch sawdust, while the third group was offered feed formulated with 97.5% basic diet and 2.5% larch sawdust. Productivity parameters and diarrhea score (DS) were recorded daily, while blood samples from 10 pigs/group at days 0, 14, 28 and 42 were collected for the detection of L. intracellularis antibodies.

Results and Discussion

The in-feed use of larch did not show a clear positive antimicrobial effect against L. intracellularis infection in growing pigs, although the 3rd group (larch 2.5%) had less positive blood samples at 14th week relatively to the other 2 groups (p=0.114) (graph 1). However, for the overall trial period, productivity parameters and DS of larch-fed pigs were improved relatively to the negative controls (tables 1 and 2).

Longitudinal field case study on the impact of ileitis vaccination on performance

Kerstin Klien2 Bernd Grosse Liesner3 Ricarda Deitmer1
1. Boehringer Ingelheim Vetmedica GmbH, Ingelheim am Rhein, Germany; 2. Practitioner, Gribow, Germany; 3. Boehringer Ingelheim Animal Health GmbH, Ingelheim am Rhein, Germany

Introduction

It is widely demonstrated that vaccination controls the effects of Lawsonia intracellularis (Li) infections allowing improved performance (growth, feed efficiency, uniformity etc.) and generating higher profitability 1, 2. However any established practice is challenged from time to time to save costs. This longitudinal case study describes changes in production parameters and therefore the economic impact of the implementation and termination of ileitis vaccination.

Materials and Methods

The study took place in a farrow-to-finish farm of 1,600 sows and 10,000 fattening places in Germany. All pigs were housed under identical conditions. Parameters monitored were recorded per batch. ADG (average daily gain), FCR (feed conversion rate), mortality, and amount of antibiotics used against enteric diseases (AB use) in the finishing unit were monitored by SPC methodology (Statistical Process Control) since 2004 3. ADG, FCR and antibiotic use were evaluated by one-way ANOVA, pairwise comparison and adjusted by Bonferroni approach. Mortality is evaluated using a Chi-square test. All tests were performed with the software Statistica® v8.0, Statsoft®. Two time periods were considered for evaluation of the ileitis vaccination impacts. During these two periods no other changes than implementation and withdrawal of ileitis vaccination were undertaken.

Implementation: August 2004 to March 2005 and March 2005 to November 2007 representing 95,134 animals. Sows were mass vaccinated against PRRSV every 4 month. Pigs were vaccinated against PRRSV (14 days of age) as well as against Mycoplasma hyopneumoniae (21 days of age). The producer added a third piglet vaccine, Enterisol® Ileitis in March 2005 (vaccination by drench, 14 days of age).

The batches between these two periods were not taken into account since other changes were implemented in the vaccination protocol: vaccination with Ingelvac CircoFLEX® against PCV2 (21 days of age) was started by December 2007, and by end of February 2008 vaccination against PRRSV was terminated as the flow became PRRSV negative. The overall performance improved by 10 % during this time.

Results

The improvement in performance following implementation of ileitis vaccination was similar to the decrease following withdrawal (table 1).

Discussion

The decline in performance after withdrawal of ileitis vaccination mirrors the gain observed three years earlier. Also the antibiotic use was reduced after implementation and increased again after withdrawal of ileitis vaccination. This indicates the consistent effect of the ileitis vaccination on performance parameters. The results indicate as well that losses in performance due to Lawsonia infections in non-vaccinated animals could not be prevented by treatment with antibiotics. Furthermore the decline in the second period indicates the potential additive eff ect of ileitis vaccination on top of PCV2 vaccination.

Reduction of growth rate variation for finishing pigs vaccinated with Enterisol® ileitis oral vaccine in a sub-clinically infected Australian pig farm

Geoffrey P. Pollock1 Greg V. Marr2

1. Boehringer-Ingelheim Animal Health, North Ryde, NSW, Australia; 2. IAS Management Services, Kingaroy, QLD, Australia

Introduction
Porcine Proliferative Enteropathy (PPE or Ileitis) is due to the infection of Lawsonia intracellularis. It is a major factor affecting intestinal health of growing pigs. The economic impact of ileitis has been reported in Australia to be AUD$15.00 /sow/year and AUD$141.00 /sow/year with the non-haemorrhagic and hemorrhagic PPE respectively. Sub-clinical ileitis was observed as uneven growth rates and longer time taken to reach market weights. Enterisol® Ileitis is a modified live oral vaccine that offers lifelong immunity to grower pigs. The objective of this study was to document the efficacy of Enterisol® Ileitis in a herd with subclinical ileitis.

Materials and Methods
A field evaluation was conducted in a 700 sow commercial pig-gery in Queensland. The presence of Lawsonia was confirmed by ELISA test. Seroconversion was found to be in late finisher at around 17 to 18 weeks of age. Clinical signs were not observed. However some variation in growth rate was observed regularly by the management. Two batches of vaccinated animals (Vx) were compared to two batches of non-vaccinated animals (CX). Pigs were vaccinated with Enterisol Ileitis at 14 days of age. Pigs were identified by batch with ear tags. Pigs were housed by batch in separate rooms. Growth rates from weaning until 21 weeks of age for 477 animals (2 batches) were calculated and compared to 544 non-vaccinated animals (2 batches). An average weaning weight was collected for each batch of the control groups (6.46Kg, 6.30Kg) and vaccinated groups (6.54 and 6.51 kg). Pigs were weighed at 21 weeks of age in groups.

The farm used in-feed antibiotics against Lawsonia intracellularis infections in both treatment groups; OTC at 200ppm from 3 to 8 weeks of age, Olaquindox at 50ppm from 12 to 14 weeks of age, and Tylosin at 100ppm from 18 to 20 weeks of age. No changes to in-feed medication or farm management were made during the trial. Data was analysed with Statistica® V 8.0.

Results
Mean Growth rate of vaccinated animals from weaning until 21 weeks of age was 726 g per day versus Non-vaccinates 678 g per day an improvement of 48 g per day. A frequency analysis of the data indicates that 61.5 percent of non-vaccinated animals grew at growth rates under 700 grams per day. In comparison, only 22% of vaccinated animals grew under 700 grams per day (p<0.000001).

Discussion
Vaccination with a live oral vaccine improved growth rate in finishing pigs and variation significantly. The implications of this are that pigs will be turned off more quickly, reducing feed costs and improving profitability. A reduction of in-feed medications specifically targeting would also offer further cost savings.

Despite the use of in feed antibiotics, the long lasting protection though vaccination against Lawsonia intracellularis significantly improved performance. Vaccination improved growth rates and variation which resulted in cost savings through reduced to days to market.

Tylvalosin (Aivlosin®) water medication for control of porcine proliferative enteropathy (PPE): a field trial carried out in Denmark

Jens Sørensen² Klaus Hellmann³ Isabel Radeloff³ John B. Tasker¹
1. ECO Animal Health Ltd, London, UK; 2. Odder Veterinary Clinic, Odder, Denmark; 3. Klifovet AG, Munich, Germany

Introduction
Porcine proliferative enteropathy (PPE) is a ubiquitous and commercially important enteric disease of pigs, caused by the obligate intracellular bacterium Lawsonia intracellularis¹ ². This is the first report of water medication with tylvalosin to control PPE on a commercial pig farm.

Material and Methods
This GCP-compliant trial was conducted in Denmark. Tylvalosin (TVN, Aivlosin® 625 mg/g Granules) was administered in drinking water at 5 mg TVN/kg bodyweight for 5 days and compared to water-soluble tylosin (Tylan™, Elanco). Tylosin is approved in Denmark at a dose rate of 5-10 mg/kg bodyweight for 5 days. In this study the highest approved dose of tylosin was used namely 10 mg/kg.

309 pigs, mean weight 11.5 kg, were allocated to two groups (TVN 155, tylosin 154 pigs).

Within each group response to treatment was assessed (treatment claim). The ability of each product to prevent PPE developing in clinically normal pen-mates was also assessed (prevention, or metaphylaxis claim).

A diagnosis of PPE was made before the trial using clinical history, necropsy and faecal PCR. On the final day of treatment (D5 of the study) 54/78 (69%) faecal samples taken from pigs with positive faecal scores were PCR-positive for L. intracellularis.

Medication started when 27% of all the pigs (85/309) had a faecal score of ≥2 (diarrhoea). These pigs were included in the treatment claim (TVN 46, tylosin 39 pigs). At this point 155 pigs had faecal scores of zero and were assessed for PPE metaphylaxis (TVN 72, tylosin 83 pigs). 69 pigs failed to meet the inclusion criteria for efficacy assessment but were treated and observed for adverse reactions.

The primary efficacy variable for the treatment claim was faecal score, and for the metaphylaxis claim, the % of pigs that developed a faecal score of ≥2 during the study. L. intracellularis shedding, average daily liveweight gain, condition, demeanour, abdominal appearance and mortality were measured in both groups.

Results
A clear clinical response was observed in the treatment groups. Mean faecal score was reduced from 2.13 to 0.24 in the TVN group, and from 2.08 to 0.25 in the tylosin group (89% and 88% reduction respectively). The clinical scores of the pigs in the TVN group were equivalent to those in the tylosin-treated group throughout the study.

Treatment was followed by a significant reduction in the proportion of PCR-positive results in samples taken from pigs in the treatment groups (Table 1).

</tr>
</tbody>
</table>

In the metaphylaxis group, pre-treatment clinical scores suggested that pigs had sub-clinical disease. Both products were very effective in preventing the development of diarrhoea during the trial, with only one animal in each group developing a faecal score of ≥1.

No pigs died during the study and no adverse reactions were observed.

Discussion
In this trial 5 mg tylvalosin/kg bodyweight given in drinking water for 5 days was effective for treatment of PPE. This dose also prevented development of disease in pigs exposed to challenge from infected pen-mates. Medication was followed by significantly reduced shedding of L. intracellularis.

In conclusion, tylvalosin given at half the dose of tylosin but for the same treatment period produced the same clinical effect. Such a reduction in antimicrobial use is an important objective in many European countries.

### Introduction

Porcine Proliferative Enteropathy (PPE or Ileitis) is due to the infection of *Lawsonia intracellularis*. It is a major factor affecting intestinal health of growing pigs. The economic impact of ileitis has been reported in Australia to be AUD$15.00 /sow/year and AUD$141.00 /sow/year with the non-haemorrhagic and hemorrhagic PPE respectively. The aim of this study was to compare the growth performance of vaccinated animals with non-vaccinated animals in a commercial environment.

### Materials and Methods

ELISA testing for serum antibodies prior to the experiment confirmed infection with *Lawsonia intracellularis* at about 11 to 12 weeks of age. Pigs were showing clinical signs of diarrhea and poor growth at 14 to 15 weeks of age. All animals were weaned to a separate site and data was collected from all male animals. The farm used in-feed antibiotics against *Lawsonia intracellularis* infections in both treatment groups. Olaquindox at 25ppm from 12 to 14 weeks of age, OTC at 200ppm from 15 to 17 weeks of age and Tylosin at 50ppm from 18 to 19 weeks of age. No changes to in-feed medication or farm management were made during the trial.

Females were not weighed as they were sent to other grow-out units for the grower-finisher stage. Pigs were housed in conventional housing until 7 weeks of age, straw based shelters from 7 to 15 weeks of age. At 15 weeks pigs were moved into conventional grower accommodation until slaughter. All pigs had liveweight measured at 15 and 19 weeks of age in groups of 4 – 6 animals per weight group. Pigs were housed by batch in separate sheds. Growth rates of 900 animals (2 batches) vaccinated at 14 days of age were calculated and compared to 1,425 non-vaccinated animals (3 batches). Growth rates presented are calculated from mean liveweight of the group at weaning until the 19 week liveweight. An average weaning weight was collected for each batch of the control groups (6.45, 6.42 and 7.16 kg) and vaccinated groups (6.41 and 6.71 kg). Data was analysed with Statistica® V 8.0.

### Results

Vaccinated pigs were significantly heavier at both 15 weeks and 19 weeks of age (Table 1: P<0.001) with liveweight improvements of 3.19 kg and 3.33 kg respectively. Liveweight variability as measured by standard deviation was also lower for the vaccinated animals at both ages. Wean to 19 week growth rate was significantly improved by 30 g/day in vaccinated pigs (Table 1: p<0.0005).

### Discussion

The study indicates that despite the use of in feed antibiotics, the lifelong protection though vaccination against *Lawsonia intracellularis* significantly improved performance. Vaccination improved growth rates and variation which resulted in cost savings through reduced to days to market.

### References

Introduction

Prophylactic measures e.g. vaccination programs are of high importance in order to control disease. In the present case the effect of ileitis and PCV2 vaccination on finisher performance was examined in a pig flow that was already vaccinated against PRRSV and Mycoplasma hyopneumoniae (M. hyo).

Materials and Methods

The study took place in a farrow-to-finish farm of 1,600 sows and 10,000 fattening places in Germany. All pigs were housed under similar conditions. During the entire evaluation period neither the genetics of the pigs nor the management were changed. Since 2004 ADG (average daily gain), FCR (feed conversion rate), mortality, and amount of antibiotics used against enteric diseases (AB use) were monitored batchwise by SPC methodology (Statistical Process Control) for the finishing unit. ADG, FCR and antibiotic use were evaluated by one-way ANOVA, pairwise comparison and adjusted by Bonferroni approach. Mortality was evaluated using a Chi-square test. All tests were performed with the software Statistica® v8.0, Statsoft®. During period I of the study (August 2004 – March 2005, 32 batches, 16,032 pigs included) sows were mass vaccinated against PRRSV (Ingelvac® PRRS MLV) every 4 month. Pigs were vaccinated against PRRSV (Ingelvac® PRRS MLV, 14 days of age) as well as against M. hyo (21 days of age, M+Pac®). At the beginning of period II (March 2005 – November 2007, 152 batches, 7,773 piglets) a third piglet vaccine, Enterisol® Ileitis (vaccination by drench, 14 days of age) was added. At the beginning of period III (10 batches, 4,932 pigs included) PCV2 vaccination (Ingelvac CircoFLEX®, same time but different injection sites as M. hyo vaccination) was implemented as a fourth vaccine.

Results

Following introduction of ileitis vaccination in 2005 significant improvements were observed in ADG (by 33 g/day), FCR (by 0.1 kg/kg) and mortality rate (by 1.08 %). At the same time, the amount of oral antibiotics used decreased by 59 % to 0.9 kg per fattening group. In 2007 vaccination against PCV2 was implemented in addition to the three other vaccines generating further significant improvements: ADG (+42 g/day) and FCR (-0.25 kg/kg).

The mortality rate in the observation period III was numerically higher than in period II. The breakdown of causes of losses in the herd in suspected PCV2-related as well as non-PCV2 related cases confirmed however that the increased losses were not attributed to PCV2. In period II (no PCV2 vaccination) every 4th loss was considered to be caused by PCV2. In the case of the PCV2 vaccinated animals only one pig from a total of 4932 pigs in period III could be attributed to a PCV2 infection.

Discussion

The present work provides an example how additional significant improvements in performance are made possible after implementation of a third and fourth piglet vaccination into an already established vaccination scheme. The two additional vaccines Enterisol® Ileitis and Ingelvac CircoFLEX® also increased profitability by generating an overall additional revenue of €11.48/pig.

Field Evaluation of the effect of Aivlosin® (Tylvalosin) for the control of Porcine Proliferative Enteropathy using two dosing regimens

Vladan Miljkovic¹ Andrea Ladinig¹ Oliver Duran² Mathias Ritzmann¹

1. Clinic for Swine, University of Veterinary Medicine Vienna, Vienna, Austria; 2. Eco Animal Health, London, UK

Introduction
Porcine proliferative enteropathy (PPE) caused by Lawsonia intracellularis (Li) is one of the most important diseases economically in the swine industry worldwide (1). Control of the disease can be achieved by the use of antibiotics given either parenterally, in feed or in water. The aim of this field trial was to evaluate the efficacy of an in feed formulation of tylvalosin (TVN, Aivlosin® 42.5 mg/g Premix, Eco Animal Health) in two different dosage regimens at reducing the production losses associated with infection with Li.

Materials and Methods
The field trial was conducted on a 1000 sow commercial gilt producing farm in Austria. Piglets became naturally infected with Li from 5 weeks of age as confirmed by clinical signs (diarrhea, uneven growth), serology and fecal PCR for Li. In total, 782 piglets, about 5 weeks old, were randomly assigned to three groups. The pigs of each group were housed in 8 different pens in the same room. Group 1 (n = 262) served as the untreated control group. Pigs in group 2 (n = 252) were given feed containing 42.5ppm TVN daily for 14 days. Group 3 (n = 268) pigs were given feed containing 85ppm TVN daily for 10 days. These inclusion rates were equivalent to dose rates of 2.125 and 4.25 mg TVN/kg bodyweight for group 2 and group 3 pigs respectively. TVN treatment was started at 5 weeks of age. All pigs were ear tagged and individually weighed 3 times: at the beginning of the trial (at 5 weeks of age), at 13 weeks of age (end of nursery period) and at 24 weeks of age (before slaughter). Data on feed intake by pen was available during the nursery phase only. For statistical analysis the pen and the pig were used as the experimental unit. Pig uniformity was assessed from the coefficients of variation of individual bodyweight by using F test.

Results
Diarrhea was not detected in the treated pigs.

The body weight (BW) at 13 weeks of age and the average daily gain (ADG) over the nursery period (G1 vs G3 p = 0.0023; G1 vs G2 p = 0.044) were significantly higher in both TVN treated groups compared to the control when analyzing the data by pen. As the BW at 5 weeks of age was higher in group 3 the initial body weight was included as a covariate in the analysis. For statistical analysis the pen and the pig were used as the experimental unit. Pig uniformity was assessed from the coefficients of variation of individual bodyweight by using F test.

Discussion
Tylvalosin has previously been proven to be effective against infection with Li using two different dosage regimens (2, 3). In this trial the comparison of TVN at 2.125 mg/kg body weight for 14 days and 4.25 mg/kg for 10 days with a negative control confirmed the effective reduction of production losses caused by Li. Pigs that received the higher dose were more uniform in weight at the time of slaughter. Analysis of the individual pig data between treatments confirms that bodyweight at slaughter and the ADG during the whole trial period was better with both dosage regimens when compared to the control and not significantly different from each other. It appears that one well timed treatment with Aivlosin® can result in a reduction of productivity losses due to PPE.

Denagard® (tiamulin) liquid concentrate dose titration in a Lawsonia intracellularis Mucosal Homogenate Ileitis challenge study - performance response

Nathan Winkelman1 Mark Hammer2 Linda Roycroft2 Ulrich Klein3 Connie Gebhart4

Introduction
Clinical and subclinical ileitis (PPE) is ubiquitous in the global swine industry. Both forms have an economical impact on a swine unit’s profitability. A Lawsonia intracellularis (Li) disease challenge model can reproduce both forms of the disease1. Denagard® administered in the water at 60 ppm is very effective in minimizing the negative impact of PPE on growth performance2. There is no information on the efficacy of higher doses of tiamulin (LC) to possibly eliminate PPE carriers during the course of treatment or after the treatment is withdrawn. The objective was to compare three treatment dose levels of tiamulin LC in pigs given a high dose Li mucosal homogenate challenge.

Materials and Methods
One hundred and fifty-five week-old PPE naïve crossbred pigs were randomized by weight and gender into five treatment groups of 30 pigs per group (6 pens with 5 pigs/pen): T1 was a strict negative control group (unchallenged, no medication), T2 was a positive control group (Li challenged, no medication), T3, T4, and T5 were all Li challenged groups receiving 60, 120, and 180ppm Denagard respectively. All pigs were individually infected by intraoesophageal gavage with 2.0 x 109 Li organisms per pig on Day 0. Treatment with tiamulin water medication was initiated on Day 7 (DM = first day of medication) when 20% of pigs and 60% of the pens had a minimum fecal score of 1 (semi-solid feces). Treatment continued to Day 12 (DM+5) when all pigs returned to non-medicated water for the remainder of the study. All surviving pigs were euthanized on Day 27 (DM+20) post Li challenge. Gross pathological PPE lesion scores were recorded for each pig on Day 27. Pigs were individually weighed and feed consumption per pen was recorded on Day -1 (acclimation start), DM, DM+5, DM+10, DM+15 and DM+20 for individual average daily gain (ADG), pen Feed Conversion Ratio (FCR – feed/gain) and Average Daily Feed Intake (ADFI) calculations. Pen was the experimental unit in all analyses.

Results – Performance Variables
Body weights were significantly higher in all treatment groups compared to the positive control from DM+10 to DM+20. Overall Average Daily Gain: (ADG from DM to DM+20) was significantly lower for the positive control group compared to all other groups and significantly higher for the negative control compared to all groups. There were significantly higher ADGI and improved FCR in all three treatment groups compared to the positive Li challenged control groups. Gross Pathology: Significantly lower PPE gross lesion scores in the ileum, jejunum, and colon in all treatments compared to the T2 challenged controls were found. There were also significantly lower ileal PPE scores in the Denagard 120 ppm and Denagard 180 ppm compared to the Denagard 60 ppm treatment groups. The lesion length was significantly longer in the T2 challenged controls compared to all other treatment groups. The T1 non-challenged control group remained negative throughout the study as evidenced by no fecal PCR positives and lack of Li IPMA titers (not shown).

Discussion
There were no differences between the three tiamulin LC treatments in performance variables. The results show excellent efficacy at the 60 ppm dose even when pigs were challenged with a high (10⁹) Li mucosal homogenate in which PPE mortality occurred in the challenged controls. Ileum PPE scores were significantly better in the 120 ppm and 180ppm groups compared to the 60 ppm group. No other group differences in pathological scores were identified.

Denagard® (tiamulin) liquid concentrate dose titration in a *Lawsonia intracellularis* Mucosal Homogenate Ileitis challenge study – clinical response

Nathan Winkelman¹ Mark Hammer² Linda Roycroft² Ulrich Klein³ Connie Gebhart⁴

Introduction

Clinical and subclinical ileitis (PPE) is ubiquitous in the global swine industry. Both forms have a negative economical impact on a swine unit’s profitability. A *Lawsonia intracellularis* (Li) disease challenge model can reproduce both forms of the disease¹. Denagard® administered in the water at 60 ppm is very effective in minimizing the negative impact of PPE on growth performance². There is no information on the efficacy of higher doses of tiamulin (LC) to possibly eliminate PPE carriers during the course of treatment or after the treatment is withdrawn. The objective of this trial was to compare three treatment dose levels of tiamulin LC and control pigs given a high dose Li mucosal homogenate challenge. The clinical data is shown in this abstract.

Materials and Methods

One hundred and fifty five-week-old PPE naïve cross-bred pigs were randomized by weight and gender into five treatment groups of 30 pigs per group (6 pens with 5 pig/pen): T1 was a strict negative control group (unchallenged, no medications), T2 was a positive control group (Li challenged, no medication), T3, T4, and T5 were all Li challenged groups receiving 60, 120, and 180 ppm Denagard respectively. All pigs were individually infected by intraoesophageal gavage with 2.0 x 10⁹ per pig Li organisms on Day 0. Treatment with tiamulin water medication was initiated on Day 7 (DM = first day of medication) when 20% of pigs and 60% of the pens had a minimum fecal score of 1 (semi-solid feces). Treatment continued to Day 12 (DM+5) when all pigs returned to non-medicated water for the remainder of the study. All surviving pigs were euthanized on Day 27 (DM+20) post Li challenge. Parameters recorded daily were mortality, abdominal appearance score (AAS), pig demeanor score (DS), and fecal score (FS). Gross PPE lesion scores were recorded for each pig on Day 27. Pigs were individually weighed and feed consumption per pen was recorded on Day -1 (acclimation start), DM, DM+5, DM+10, DM+15 and DM+20 for individual average daily gain (ADG), pen Feed Conversion Ratio (FCR) and Average Daily Feed Intake (ADFI) calculations. In addition, fecal samples were collected on all pigs on days DM, DM+5, DM+10, DM+15, and DM+20 for Li polymerase chain reaction (PCR) analysis. Li immunoperoxidase monolayer assay (IPMA) serum samples were collected from two pigs/pen on Day -1 and DM+20. Pen was experimental unit for all analysis.

Results – PPE Mortality and Clinical Observations

Mortality: There were three pigs which died due to PPE, all in the T2 challenge control group. Fecal Score: There was a significantly higher average pen fecal score for the positive control group when compared to all other groups on all days after day DM+1. Abdominal Appearance Score: There was significantly higher average AAS for the positive control group when compared to all other groups starting on DM+7 and continuing each day through DM+20. Demeanor Score: There was a significantly higher average pen demeanor score for the positive control group compared to all other treatments from DM+10 through DM+20.

Discussion

There were no differences between the three tiamulin LC treatments in clinical measures. The results show excellent efficacy even at the 60 ppm dose when pigs were challenged with a high (10⁹) Li mucosal homogenate in which mortality occurred in the challenged controls.

Efficacy of Aivlosin® Water Soluble Granules for the control of porcine proliferative enteropathy in pigs challenged with Lawsonia intracellularis

Elizabeth M. Abbott1 Mark J. Gnozzio2 Rickie J. Domangue3 Nate Winkelman5 Chris D. Eliopoulos3 Sharon A. Bauer6 Jeff B. Wilson1

Introduction

Porcine proliferative enteropathy (PPE), or ileitis, caused by the obligate intracellular bacterium Lawsonia intracellularis (Li), is an important enteric disease of swine1. In vitro studies have demonstrated that tylvalosin accumulates rapidly in high concentrations inside intestinal epithelial cells2, and has proven efficacy in the control of PPE when administered in-feed3-5. The objective of this study was to evaluate the efficacy of tylvalosin administered in drinking water for the treatment of PPE in weaner pigs.

Materials and Methods

In this multi-centre study with three separate sites, 144 five week-old weaned pigs at each site (Rice, Minnesota; Harrisonburg, Virginia; Burford, Ontario) were randomly assigned to one of three treatment groups: Challenged – Untreated, Challenged – Treated (50 ppm Aivlosin in drinking water) and Challenged – Treated (75 ppm Aivlosin in drinking water). Pigs were orally challenged with Li from a field case of PPE on Day 0. Drinking water was medicated with Aivlosin® Water Soluble Granules (ECO Animal Health, London, UK) for five consecutive days and treatment began when ~15% of pigs had semi-solid feces. Body weights and feed consumption were measured throughout the study. Twenty-two days after the start of treatment fecal samples were collected for PCR analysis and all surviving animals were euthanized. At necropsy, the intestinal tract was scored for gross lesions consistent with PPE and ileal samples were obtained for immunohistochemistry (IHC) analysis. Statistical analyses were conducted using analysis of variance and contingency table methods.

Results and Discussion

During the study, 14.9% of the untreated pigs died due to PPE infection. There was no mortality due to PPE in either of the treated groups, and this difference was significant (P<0.01) when compared with the untreated group. Pigs in both treated groups had significantly improved mean pen gross lesion scores (P<0.03), and pen production parameters (Table 1), compared to the non-medicated group. Significantly decreased frequencies of Li positive fecal PCR and ileal IHC samples were found in the treated groups compared to the untreated group (Table 1).

The decreased frequency of positive fecal PCR samples collected at the end of study indicates that fecal shedding of Li was reduced due to treatment when compared to the untreated pigs. Appetite may be depressed as a result of Li infection. Therefore administration of Aivlosin® in drinking water can be advantageous as pigs can receive adequate uptake of the drug. Water medication also allows treatment to be initiated promptly once a diagnosis has been confirmed and the relatively low dose and short treatment duration is consistent with prudent use of antibiotics6. This study demonstrates that tylvalosin administered in drinking water is effective in reducing mortality, intestinal lesions, fecal shedding of Li and growth suppression that are associated with PPE in pigs orally challenged with Li.

Table 1. Mean pen average daily gain (ADG) and feed efficiency (gain/intake) and proportion of pigs testing positive for Li by fecal PCR and IHC at study termination.

**Introduction**

Porcine proliferative enteropathy (PPE), or ileitis, is a significant enteric disease in swine. The obligate intracellular bacterium *Lawsonia intracellularis* (Li) is the etiologic agent, and the disease is characterized by a thickening on the mucosa of the small intestine and colon, evident at necropsy¹. Tylvalosin, a macrolide antimicrobial, has demonstrated efficacy in the control of PPE²-⁴. The objective of this multi-site study was to evaluate the efficacy of tylvalosin administered in feed for the control of PPE in weaner pigs challenged with Li.

**Materials and Methods**

Two studies were conducted at separate sites in North America. 144 four-week-old weaned pigs in each study were randomly assigned to one of two groups: treated (42.5 ppm tylvalosin in feed) or untreated (0 ppm). Pigs were orally challenged with Li on Day 0. Treatment began when ~15% of pigs had semi-solid feces and continued for 14 days. Pigs were scored daily for abdominal appearance, demeanor and fecal consistency. Body weights and feed consumption were measured throughout the study. Animals were euthanized 21 days after the start of treatment. At necropsy, the intestinal tract was scored for gross lesions consistent with PPE and ileal samples were collected for immunohistochemistry analysis. Data from the two study sites were analyzed separately using analysis of variance and contingency table methods.

**Results and Discussion**

Cumulative mortality due to PPE was lower in the treated pigs across the study sites, with statistically significant (P<0.03, Table 1) differences observed at one of the two sites.

Table 1. Proportion of pigs that died due to PPE, mean proportion of pens with abnormal fecal scores and mean pen lesion scores for the treatment groups across both sites.

Pigs in the treated groups at both sites had significantly improved mean pen gross lesion scores (P<0.03) and mean pen fecal scores (P<0.001) compared with the untreated pigs (Table 1). Pen feed efficiency was significantly increased (P<0.05) in the treated pigs compared with the untreated (Table 2). Mean pen average daily gain was numerically greater in treated pigs and this difference was significant (P<0.001, Table 2) at one study site.

⁴Rows at each site with different letters are significantly different at p<0.05

Treatment with Aivlosin® Premix for 14 consecutive days in Li challenged pigs was associated with significantly lower gross PPE lesion scores in the treated groups when compared with untreated animals. Mortality due to PPE was decreased in the treated pigs compared with the untreated group. The treated groups showed improved performance in production parameters such as ADG and feed efficiency.

Consistent with previous studies²-⁴, this multi-site study demonstrates that Aivlosin® Premix is effective in reducing mortality, clinical signs, intestinal lesions, and growth suppression that are associated with PPE in weaner pigs orally challenged with Li.

The prevalence of swine enteropathogens in Brazilian grow/finisher

Aline M. Viott1 Andrey P. Lage1 Eduardo C. Cruz Jr.1 Daiane D. Spessatto2 Roberto M. Guedes1
1. Universidade Federal de Minas Gerais, Veterinary School, Belo Horizonte, MG, Brazil; 2. Universidade Federal do Paraná, Palotina, PR, Brazil

Introduction

Brazil is the fourth largest pig producer in the World, behind China, the European Union and United States. The state of Minas Gerais is the fourth largest producer of pork in Brazil, and the growth of pig production in the state has been increasing year after year. As a result, it is necessary to accurately detect and identify porcine pathogens in order to devise proper treatments and prevention programs. Enteric infections are among the most frequent problems in pig production, being responsible for significant losses. The purpose of this study was to determine the prevalence of the enteric pathogens and the occurrence of mixed infections in Brazilian growing/finishing pigs in herds with diarrhea or a history of diarrhea in the state of Minas Gerais, Brazil.

Materials and Methods

Forty-six farrow-to-finish herds; 31 with 101-500 sows and 15 with >500 sows; with diarrhea or a history of diarrhea were randomly selected from four different geographical regions of the state of Minas Gerais, Brazil (south and southwest (SSW), metropolitan area of “Belo Horizonte” (MBH), “zona da mata” (ZM) and Triangle mining and high “Paranaiba” (TMHP)). Randomly were collected feces from rectum for approximately 10 animals of each property between 60 and 140 days old. Multiplex PCR was used for the diagnosis of L. intracellularis, B. hyodysenteriae and B. pilosicoli and for enterotoxigenic E. coli. For the detection of Trichuris suis eggs in the swine faeces, the faecal samples were individually examined by flotation technique (Willis-Mollay). Salmonella was isolated according Waltman, 2000. For statistical analyses Fischer’s exact test was used.

Results

A total of 512 faecal samples were examined. The analysis by the Fisher exact test showed no significant association between the pathogen and the size of the farm. The only subspecies of Salmonella spp. found, potentially pathogenic for pigs, was Salmonella enterica subspecies Typhimurium. The results are demonstrated in Table 1. The mainly mixed infection observed was Salmonella Typhimurium associated with L. intracellularis present in 5 herds (10,8%). T. suis eggs and B. hyodysenteriae were not diagnosed. The B pilosicoli was observed in two farms with mixing infection cases. The most prevalent enterotoxigenic E. coli virotype was StaP-Stb-F18.

<td>21.7</td>
<td>4</td>
<td>8.7</td>
</tr>
</tbody>
</table>

Discussion

The prevalence of herds only infected by L. intracellularis was 19.5%. This result is in agreement with previously reports from other countries, where the prevalence of L. intracellularis varied between 15% and 93.7%. The differences among prevalence indexes observed may be due to regional variations, different swine breeding systems, antibiotics use and population sampled. The prevalence of mixing infections was high in our work when compared with European data. The overall prevalence for Salmonella Typhimurium alone (6.5%) was elevated mainly when we associate this bacterium to the cases of mixing infection. The presence of enterotoxigenic E. coli in grow/finishing pigs it is not clear. It seems that this pathogen may alter the ecological gut flora, which would favor some pathogenic bacteria.

Rodent dispersal between piggeries following total pig depopulation as part of a swine dysentery eradication program

Alison M. Collins1 Anil Manavalan2 Jocelyn Gonsalves1 Shayne Fell1
1. Elizabeth Macarthur Agricultural Institute, Narellan, NSW, Australia; 2. University of Wollongong, Wollongong, NSW, Australia

Introduction
Rodents have been identified as potential vectors for a number of bacterial pathogens of pigs, including *Lawsonia intracellularis*1, *Brachyspira pilosicoli*, and *B. hyodysenteriae*2. Monitoring the dispersal of rodents between piggeries in relatively close proximity may be important in assessing the risk of transmission of these pathogens to naïve pigs, especially following disease eradication programs. The aim of this study was to use microsatellite markers to demonstrate the genetic diversity between rats trapped at two separate pig farms and therefore rodent dispersal.

Materials and Methods
Twenty-eight black rats (*Rattus rattus*) were caught in snap traps over a three month period in two pig units separated by one kilometre (sites A and B). During this period, pigs had been removed from site A as part of a swine dysentery eradication program. Both pig farms were surrounded by natural boundaries to rodent dispersal (roads and rivers) but alternate food sources were available at neighbouring pig farms (4 and 9km away). Genomic rat DNA was extracted from the rat’s ears using a QIAGEN tissue kit (DNeasy). Microsatellite markers were amplified from the rat DNA as previously described3-4 using 8 sets of PCR primers (D5Rat83, D8Rat28, D11Rat56, D16Rat81, D18Rat75, Rr54, Rr107 and Rr114). PCR products were typed with an ABI genetic analyzer using the GeneMapper v3.7 software (Applied Biosystem). The genetic relatedness of rats was analyzed with STRUCTURE software5 trialing the number of populations (k=1-5).

Faecal samples were collected from pigs at site B at the completion of rat trapping. DNA extracted from pig faeces and rat intestines were tested for the presence of *L. intracellularis*, *B. hyodysenteriae* and *B. pilosicoli* by conventional PCR.

Results
All of the microsatellite loci except D8Rat28 were polymorphic in our rat populations. A total of 27 alleles were detected across the 8 microsatellite loci in population A versus 26 alleles in population B. However, 66% of alleles were common in both populations and 44% were different between populations A and B. The genotypes of the 28 rats analyzed was best explained by one population (maximum log likelihood reached a plateau at k=1). *L. intracellularis* DNA was detected in the faeces of the majority of the pigs sampled, but was not detected in the small intestine of any rats. *B. hyodysenteriae* and *B. pilosicoli* DNA were not detected in any of the porcine faecal samples or rat intestinal samples.

Discussion
The genotype of rats trapped at the two units was similar, suggesting that rats were able to interbreed, and could travel more than 1km. This was significantly further than previously thought6, and may have been due to the scarcity of food at site A during the swine dysentery eradication program. While rats are unlikely to travel far from pig farms where food and shelter are provided, pig depopulation as part of a disease eradication program may provide the stimulus for dispersal. Although we didn’t find porcine enteric pathogens in rats trapped at these pig farms, previous reports have found *L. intracellularis* and *B. hyodysenteriae* in rats trapped on pig farms1,2. If rodents can travel more than 1km between pig farms, disease eradication programs may be more effective if performed on a regional basis.

References
**Introduction and Objectives**

The research group at León University (Spain) is working on different topics associated with swine dysentery (SD), a severe mucohaemorrhagic diarrhoeal disease that primarily affects pigs during the growing-finishing period caused by *B. hyodysenteriae*. We have found that more than 30% of Spanish farms and 12% of faecal specimens testing positive for *B. hyodysenteriae* (1). However, it is necessary to obtain information about the population structure of *B. hyodysenteriae* in Spain. A multilocus sequence typing (MLST) scheme was used as a tool for investigating the diversity of Spanish isolates of *B. hyodysenteriae* (2).

**Material and Methods**

In total, 50 Spanish and 1 Portuguese isolates of *B. hyodysenteriae* from 47 farms spread all around the country were included in the analysis. All isolates were recovered from pigs affected with SD between 2001-2007 and came from the collection held at the University of León. Isolates were obtained from the most important pig production regions of our country. Data from strain reference B204 were obtained from PubMLST (http://pubmlst.org) and included in the study. Seven MLST loci (2) were used and the MLST results were visualised by constructing a dendrogram using the unweighted pair-group method for arithmetic means (UPGMA) in START2 (3).

**Results**

Spanish isolates were allocated to 9 sequence types (STs), of which 7 were new with an allele frequency ranging from 2 to 8 per locus. The predominant ST1 included 21 Spanish isolates from 18 farms located in 8 different autonomous regions distributed from the North to the South of the country. STs 2, 8 and 10 each also included several isolates from different regions. ST8 is widespread as well whilst ST2 appeared in the northern regions of the country. 4 singletons were identified (4, 5, 6 and 9), one of them represented by the Portuguese isolate (H32). We confirmed that *B. hyodysenteriae* got a moderate heterogeneity as previously described for Australian isolates (2). Based on the number of isolates the population had an Index of Association value of 0.786 and 0.990 based on the number of STs. Significant linkage disequilibrium was found in both analysis (P=0.000; P=0.001). For 5 Spanish farms where multiple isolates were available, 2 of the isolates belonged to different STs (1 and 8). The eBURST analysis (data not shown) indicated ST1 and ST8 do not belong to the same clonal complex pointing out that 2 isolates might be present in the same farm at the same time. When we combined our 51 isolates to the population as a whole (2) we found 3 monophyletic clusters each including 3 STs.

**Discussion**

This study has gained an insight into the population structure of *B. hyodysenteriae* using a reliable method which provides useful molecular epidemiological data to investigate the diversity of *B. hyodysenteriae* isolates, and allows the easy comparison of results between laboratories. The bacterial population was found to be clonal with evidence of likely transmission of strains between farms all around the country. Three major lineages of descent have been detected in Spain.

ELISA using meat juice to detect herds with swine dysentery

Yong Song¹ Barbara Frey² David J. Hampson¹

1. School of Veterinary and Biomedical Science, Murdoch University, Perth, WA, Australia; 2. Consistent Pork, Perth, WA, Australia

Introduction

Swine dysentery (SD) is a mucoid hemorrhagic colitis resulting from infection of the large intestine with the anaerobic spirochaete Brachyspira hyodysenteriae. Successful disease control programmes rely on accurate, cost-effective and timely detection of infected animals and herds. Recently an enzyme-linked immunosorbent assay (ELISA) using recombinant Bhlp29.7, an outer membrane protein of the spirochaete, has been shown to have potential to be used at the herd level as a routine serological surveillance test (1). The aim of the current study was to determine whether the ELISA could be used with muscle fluid from pigs at slaughter to detect evidence of B. hyodysenteriae infection in herds with SD.

Materials and Methods

Pigs from two healthy herds, and three with a recent history of SD, were sampled. Disease in the infected herds was routinely controlled using in-feed medication. Diaphragm muscle from 50 finisher pigs in each herd was collected at slaughter. A piece of muscle was excised and placed into the mouth of a sterile plastic funnel set over a sterile bottle. This was covered with plastic film, held at -20°C overnight, and after thawing the passively-released muscle fluid (“meat juice”) was collected. The samples were diluted 1:20 in PBS and were tested in two ELISAs for specific IgG and IgM against recombinant Bhlp29.7, as previously described (1). The optical density (OD) was measured at 450 nm on a microplate reader. For across-plate standardization, a positive control consisting of a meat juice sample collected from a pig that previously had recovered from SD, was added in triplicate to each plate. Calibrated ODS were calculated according to the following formula: (OD value of test sample - OD value of blank control)/average of (OD value of control sample - OD value of blank control). Cut-off values were calculated as the mean plus three standard deviations of the readings from the samples from the two negative herds. Herds with any pigs with readings over that value were considered to be infected.

Results

The diagnostic threshold values for the assays were set at ODs of 0.68 ± 0.13 for IgG and 0.64 ± 0.12 for IgM. Using these criteria, the two negative herds were recorded as negative in both assays. Single serum samples from each of the three infected herds exceeded these cut-off values in the two ELISAs. In each of these herds, different serum samples were positive in the IgG and IgM ELISAs.

Discussion

Meat-juice ELISAs have been used in a number of sero-epidemiological studies and in surveillance for specific microbial diseases of pigs (eg 2). Taking muscle samples at the abattoir avoids on-farm biosecurity risks, and generally muscle samples are easier to collect at the abattoir than are blood samples. Although serological ELISAs previously have been developed for detecting SD at the herd level, this is the first report where meat juice samples have been used as a source of antibodies. Under the test conditions, both the IgG and IgM ELISAs were specific and sensitive as herd tests. The IgM ELISA may detect more recent infection than the IgG ELISA.

Although Bhlp29.7 worked well as a plate-coating antigen in the current study, a recent report that the gene encoding Bhlp29.7 could not be detected by PCR in 33 (45%) recent German isolates of B. hyodysenteriae is of concern (3). Consequently, further work is required to identify additional specific B. hyodysenteriae antigens that can be used in meat juice (and serum) ELISAs. In conclusion, meat juice samples from pigs in herds with SD contain IgG and IgM antibodies that react with B. hyodysenteriae antigens. As such, testing meat juice samples is a convenient way for screening herds for SD. Such testing could be integrated into other meat juice ELISA screening, for example for Salmonella infections.

This study was supported by a grant from the Australian Cooperative Research Centre for an Internationally Competitive Pork Industry (“the Pork CRC”).

N-terminal amino acid sequencing of 22kDa protein in *Brachyspira hyodysenteriae* reacting strongly with convalescent antibody of pig affected with swine dysentery

Yoshikazu Adachi; Susumu Ochiai

School of Agriculture, Ibaraki University, Ami-machi, Japan

**Objectives**

Presence of 22kDa has been discovered by using convalescent antibodies after recovering from swine dysentery. The antigen has been confirmed among 11 serogroups and 17kDa antigen as well. However, we have never been studying on amino acid sequencing of the 22kDa protein and gene cloning. In this paper, we attempted amino acid sequencing of the protein.

**Materials and Methods**

ATCC27164, ATCC31212, B169, A1, WA6, Q16, NSW1, ATCC49887, and ATCC29796 were used in this test. SDS-PAGE was carried out according to Ochiai et al.(2000). 2D-PAGE were carried out as previously described(2000). Amino acid sequencing was carried out for the comparison of the amino acid sequence among serogroups.

**Results and Discussion**

The 22 and 17kDa proteins of *Brachyspira hyodysenteriae* which reacted with convalescent antibody have been analyzed by a peptide sequencer after 2 dimension polyacrylamide electrophoresis. The results demonstrated the N-terminal amino acid arrangement was consistent among ATCC27164, ATCC31212, and B169 but it did not get any results by western blotting technique after SDS-PAGE. The amino acid arrangement was Met-Thr Val-Thr-Phe-Gln-Gly-Ala-The-Gln. These results indicated that 22kDa protein was species specific antigen of *Brachyspira hyodysenteriae*. Furthermore, the 22kDa protein has been found in every isolate of 11 serogroups of *Brachyspira hyodysenteriae*, they also reacted strongly with the infected piglet sera and they was also digested with proteinase K. Therefore, 22kDa protein was real protein and it also may play a role of the protection against swine dysentry. It may be like 16kDa antigen as described by Sellwood(1995)(1).

A retrospective comparison of the specificity of culture and PCR technique for the detection of *Brachyspira hyodysenteriae* and *Brachyspira pilosicoli*

Christina L. Planz1,2, Judith Rohde3 Elisabeth Grosse Beilage1 Heiko Nathues1
1. Field Station for Epidemiology, University of Veterinary Medicine Hannover, Bakum, Germany; 2. IBEI - University of Veterinary Medicine Hannover, Hannover, Germany; 3. Institute for Microbiology, University of Veterinary Medicine Hannover, Hannover, Germany

**Introduction**

*Brachyspira hyodysenteriae*, the etiological agent of swine dysentery, and less commonly *Brachyspira pilosicoli*, the infectious agent of spirochaetal diarrhoea, are frequent causes of colitis and diarrhoea in grower and finisher pigs. Especially swine dysentery causes considerable economic loss for pig farmers due to reduced weight gain, mortality and cost-intensive treatment, eradication and preventive measures. To get the disease under control, a quick and reliable laboratory diagnosis is a prerequisite. Up to date, culture is a very common since highly sensitive method, with the disadvantage of being extraordinarily time-consuming and therefore leading to delayed diagnosis with all its negative consequences. The use of PCR as a very rapid method could solve the problem, given a similar sensitivity and specificity to culture. However, veterinarians and farmers fear false positive results from PCR including all consequences of *B. pilosicoli* from culture and PCR.

**Material and Methods**

Data obtained from routine diagnostics between Jan 2006 and Dec 2009 in North-Western Germany was analysed retrospectively: Results from faecal samples or anal swabs from pigs that were submitted to the Field Station for Epidemiology for the purpose of detecting enteric pathogens were extracted from a SQL database. Datasets were further filtered for those where samples had been examined for the presence of *Brachyspira* species by both methods PCR and culture. The multiplex PCR assay applied to the samples detects specific genome fragments of *Brachyspira hyodysenteriae* and *Brachyspira pilosicoli* and additionally fragments of *Lawsonia intracellularis* (Nathues et al. 2007). For cultural testing, identical samples were examined on *Brachyspira* selective- and Columbia Blood Agar incubated anaerobically at 42 degree Celsius for at least 6 days. Differentiation of *Brachyspira* species was based on biochemical reactions and nox-RFLP. For statistical analysis of the data SAS®, version 9.1., was used to calculate the κ-value as measure of concordance.

**Results**

During four consecutive years (2006-2009), 6,228 samples were tested for the presence of specific genome fragments of *B. hyodysenteriae* and *B. pilosicoli* by PCR. Overall, 184 samples were tested by both PCR and culture since the veterinarians and/or farmers did not rely on PCR alone. In 61 samples, unidentifiable *Brachyspira* spp. or others than *B. hyodysenteriae* / *B. pilosicoli* were detected culturally. These cases were excluded from further analysis to maintain exact comparability. Of the remaining 123 samples, 44 were positive for *B. hyodysenteriae* in PCR compared to 55 in culture, resulting in detection rates of 35.8% (PCR) versus 44.7 % (culture). Twelve samples identified as positive culturally were negative in PCR whereas one sample negative in culture resulted positive in PCR. The level of agreement is 80.1 %. Only in one sample *B. pilosicoli* was found (detection rate of 0.8 %), this being positive in PCR and culture, resulting in an agreement of 100%. The unweighted κ-value is 0.78, which is 96 % of the maximum possible κ-value of 0.82.

**Table 1: Results for Brachyspira hyodysenteriae and Brachyspira pilosicoli from culture and PCR**

</tr>
</tbody>
</table>

**Discussion**

This retrospective analysis on a subset of data obtained by routine diagnostic indicates a substantial to almost perfect agreement between results from PCR and culture to detect *B. hyodysenteriae* and *B. pilosicoli*. As mentioned, culture was preferred in terms of suspicion of better specificity than PCR in 58 submissions comprising 123 samples. However, results show that specificity of both methods were equal. Contrary, the PCR is lacking sensitivity when compared to culture, which might be caused by low concentration of the target in some samples or by inhibition of the PCR. Nonetheless, the PCR is a suitable alternative to cultural methods with comparable specificity for the diagnosis of *B. hyodysenteriae* and *B. pilosicoli*, with the added advantage of more rapid results.

Antimicrobial susceptibility of Brachyspira hyodysenteriae isolates from cases of swine dysentery in Italy recovered by different sampling procedures

Chiara F. Magistrali; Lucilla Cucco; Nicoletta D’Avino; Michele Tentellini; Giovanni Pezzotti
Istituto Zooprofilattico Sperimentale Umbria e Marche, Perugia (PG), Italy

Introduction
Swine dysentery (SD) by Brachyspira hyodysenteriae is still a common disease and a major cause of production losses in Italian pig industry. Control of SD is based upon the use of antimicrobials, but few antibiotics are licensed for treatment; moreover, multi-resistant strains were recorded in Europe, Italy included. The aim of this work was to assess antimicrobial susceptibility of B. hyodysenteriae isolates from pigs in Italy. For this purpose, B. hyodysenteriae isolates were collected from culture collections of diagnostic laboratories (passive sampling) and from pigs affected by SD (active sampling). All the isolates collected were tested for antimicrobial susceptibility using the broth dilution method.

Materials and Methods
Isolates for antimicrobial testing were recovered using two different procedures: passive and active sampling.
Passive sampling: B. hyodysenteriae isolates (n=27) were taken from bacterial collections in diagnostic laboratories. Active sampling: samples were collected from clinical cases of SD, following a standard sampling procedure, and a questionnaire was filled in. Thirty-nine herds were sampled, 28% of them were farrow to weaning, 33% finishing and 39% farrow to finish herds. The average number of sows/herd was 600, while in finishing herds the number of finishers was 2550/year on average. Regarding treatment, 54% of the herds used pleuromutilins either for medication purposes in the groups of pigs sampled. On each farm, animals showing symptoms suggestive of SD, or living in the same box of symptomatic pigs, were sampled. At least 9 fecal samples were taken from each herd, cultured anaerobically on TSA-BJ medium at 41.5 °C for five days. Suspected colonies were isolated on Blood agar and typed by PCR. Thirty isolates of B. hyodysenteriae from active sampling and 27 from passive sampling were tested as described below.

Broth Dilution Method: was performed according to Rohde, 2004, using a standardized MIC panel for Brachyspira spp. (Vet-MIC TM Brachy ver 2, SVA, Uppsala, Sweden). The concentrations ranged from 8 μg/ml to 0.063 μg/ml (tiamulin), 4 μg/ml - 0.031 μg/ml (valnemulin), 64 μg/ml – 0.5 μg/ml (lincomycin), 128 μg/ml – 2 μg/ml (tylosin). The interpretation of MIC values for both strain collections was based upon MIC-breakpoint values reported by Ronne & Szancer, as follows (1990).Tiamulin: ≤1μg/ml : sensitive (S); >1-≤4μg/ml : intermediate (I); >4μg/ml : resistant (R). Valnemulin: ≤1μg/ml : S; >1-2μg/ml : I; >2μg/ml : R. Lincomycin: ≤4μg/ml : S; >4-≤32μg/ml : I; ≥32μg/ml : R. Tylosin: ≤1μg/ml : S; >1-4μg/ml : I; >4μg/ml : R.

Results
MIC values of tested antimicrobial agents for B. hyodysenteriae isolates from active and passive samplings are shown in Table 1 and 2.

Table 1: AB MIC values for B. hyodysenteriae isolates from active sampling (n=30).

Discussion
B. hyodysenteriae isolates from both active and passive samplings were resistant to tylosin, confirming results of previous studies reported, while most of them resulted in intermediate results to lincomycin. Regarding pleuro-mutilins, a different picture was found by active and passive samplings: no tiamulin or valnemulin resistant isolate from active sampling was found. The presence of multi-resistant strains in Italy was confirmed by passive sampling. Identified MIC differences recorded for passive vs. active sampling may be due to a selection of isolates originating from farms with recurrent SD problems. Those samples are sent to diagnostic laboratories. The sensitivity to pleuro-mutilins of B. hyodysenteriae strains is good in the majority of farms in Italy. Emergence and spreading of multi-resistant strains must be kept under control by implementation of appropriate dosing regimes, biosecurity measures and continuous monitoring of the isolates.

Introduction

Swine dysentery is a serious hazard on swine health in affected farms1. The increasing resistance of the bacterium *Brachyspira hyodysenteriae* against pleuromutilins complicates treatment options on several farms2. Since elimination protocols are mainly based on the use of tiamulin or valnemulin, eliminating the disease on farms with a resistant strain becomes problematic. One option could be a higher efficiency of tiamulin. In literature, a synergistic effect of tiamulin and tetracyclines is reported, more specifically on respiratory pathogens in poultry and swine3,4. Therefore, the aim of the present study was to examine whether a combination of tiamulin and doxycycline resulted in in vitro susceptibility of *B. hyodysenteriae* at lower tiamulin concentrations.

Materials and Methods

Susceptibility of 26 *Brachyspira hyodysenteriae* isolates was determined using the agar dilution technique2. Minimal inhibitory concentrations (MIC) were determined against tiamulin (range 0.03 – 16 μg/ml), doxycycline (range 0.06 – 16 μg/ml) and against tiamulin (range 0.03 – 16 μg/ml) supplemented with respectively 16, 2, 1 and 0.5 μg/ml doxycycline. MIC was determined as the lowest concentration where growth was inhibited.

Results

Table 1 represents the MIC values for the 26 isolates tested. Nine strains showed decreased susceptibility to tiamulin (MIC > 1 μg/ml), eleven isolates had decreased susceptibility to doxycycline (> 4 μg/ml) and six to both antibiotics.

</tbody>
</table>

Considering the combination of both antibiotics, growth was inhibited in all isolates when the concentration of doxycycline in the agar exceeded the MIC of the isolate, independent of the MIC for tiamulin. In case the MIC for doxycycline was higher than the agar concentration, a lower MIC for tiamulin when combined with doxycycline was noted in 33 to 68% of the isolates (Table 2). When considering the strains with decreased susceptibility to tiamulin, two strains (22%) had a decreased MIC for tiamulin in combination with doxycycline. A difference of at least two dilutions was considered valid when comparing MICs for tiamulin with or without doxycycline.

Discussion

In the present study the in vitro susceptibility of *B. hyodysenteriae* isolates to tiamulin was compared with and without doxycycline. There was no difference in MIC50 or MIC90 when all isolates were considered. When looking at the isolates with higher MIC than the concentration in the agar, these in vitro data demonstrate a higher susceptibility to tiamulin in the presence of 0.5 to 2 μg/ml doxycycline for one third of the isolates. From the strains with decreased susceptibility to tiamulin, two were in vitro susceptible when tiamulin was combined with doxycycline.

Further examination is necessary to confirm this combined effect of tiamulin and doxycycline on *Brachyspira hyodysenteriae*. Based on these limited in vitro data, a positive effect of combining both antimicrobials in the treatment of swine dysentery may be expected for some strains which can be helpful in treatment protocols.

Efficacy of Econor® (Valnemulin) for the treatment of swine dysentery under field conditions in Japan

Nobuo Nakanishi1 Koji Ishii1 Hiroshi Otaki1 Ulrich Klein3

Introduction
Swine dysentery (SD) caused by Brachyspira hyodysenteriae (Bh) is one of the common and important enteric diseases worldwide. The objective of this study was to evaluate the clinical efficacy of Econor® 1% premix in-feed medication against SD under field conditions in Japan as part of routine post-approval regulatory requirements.

Materials and Methods
Sixty six SD-infected crossbreed pigs were enrolled from three geographically different farms in Japan (Aichi, Kyoto and Ehime) from April, 2008 to April, 2009 (62 fattening pigs at age of 90 to 160 days and 4 sows). SD was confirmed by fecal microscopy and isolation of Bh. Other infections including parasites, Salmonella spp, Campylobacter spp, Clostridium perfringens and rotavirus were excluded based on additional tests. MICs of valnemulin (VAL), tylosin (TS), lincomycin (LCN) and tiamulin (TML) were evaluated using 46 Bh strains. The pigs were treated in-feed with Econor® at 30 ppm (n=33) or 100 ppm (n=33) for 7 consecutive days in accordance to the label in Japan. No control group was established. Combined clinical scores or CC (min 0, max 12) representing the fecal consistency (score 0-3, 0=normal to 3=severe), pig demeanor (0-2), appetite (0-3), skin condition (0-2) and emaciation (0-2) was recorded daily (Day 0 to Day 9) and 7 days after end of the medication (Day 14) to evaluate possible relapses of SD. Fecal swabs were collected from all pigs at 2 days after treatment (Day 9) to investigate the presence of Bh. Based on the individual CC at Day 0 (CCD0) and Day 9 (CCD9), the individual percentage of improvement (IC) as primary efficacy endpoint was calculated as 100%*(CCD0-CCD9)/CCD0, followed by categorizing each pig into one of four categories; (A) marked improvement (85-100%), (B) good improvement (70-85%), (C) moderate improvement (50-70%) and (D) little improvement (<50%).

Results and Discussion
Both treated groups showed quick recovery from clinical signs with reduction of CC with more than 90% (Figure 1, Table 1). All pigs showed marked or good improvement by treating with Econor®, and 75.8% of pigs with lower dose (30 ppm) and 87.9% of pigs with higher dose (100 ppm) were evaluated as marketed improvement at Day 9, which was 2 days after end of the medication (Table 2). None of the treated pigs was relapsed at Day 14. Bh was not detected from faecal samples at Day 9. Bh isolates (n=46) showed high susceptibility against VAL and TML, and MIC of TS and LCM were both above 12.5 μg/ml (Table 3).

Conclusion
The results demonstrate the superb clinical efficacy of Econor® at 30 ppm and 100 ppm in-feed medication against SD. The results of MIC were in alignment with earlier published data (1, 2).

---

**Introduction**

Brachyspira hyodysenteriae (B. hyo) is the etiological agent of Swine Dysentery (SD), a disease responsible of high economic losses in the swine production. The objective of the present study was to compare the macrolide antibiotic Tylvalosin (Avilnos® ECO Animal Health) with tiamulin by evaluating production parameters, presence of the agent and SD clinical signs.

**Materials and Methods**

A longitudinal study was carried out in a 500-sows, farrow-to-finish herd with antecedents of SD. All the pigs (250) weaning at 1, 3 and 5 and at 2, 4 and 6 weeks constituted the groups GA (Tylvalosin) and GT (Tiamulin) respectively. Pigs from week 7 and 8 were used as control group (CG). The medication, 50 ppm of Tylvalosin and 100 ppm of Tiamulin, was given in the feed in 3 periods of time, 21 to 42, 73 to 83 and 100 to 110 days of age. Five pigs per group were euthanized at 42 and 83 days old for necropsies and sampling for bacteriology and histopathology. All the pigs were weighed at weaning and at 42 days and were sent to slaughter at 105 kg bodyweight. Average daily gain (ADG) and feed conversion rate (FCR) were determined. The percentage of pigs with diarrhoea was recorded at 42, 60, 83, 100 and 150 days of age. The percentage of unthrifty pigs and mortality was also recorded. At slaughter, pigs from the three groups were evaluated as per those euthanized earlier.

Colon macroscopic lesions were recorded as follow: 1) Normal, 2) Oedema, congestion and mucus, 3) Oedema, congestion and red-brown mucus. For histopathology: 1) Normal, 2) Hyperplasia of crypts and calceiform cells and/or presence of abscess, 3) Necrosis. The 187 colon samples were inoculated in blood agar plate with antibiotics and in anaerobic atmosphere for 6 days. Samples for DNA extraction for nox-specific PCR (1) to genera determination were taken with the aid of sterile filter paper when spirochete growth was detected. Duplex PCR for B. hyodysenteriae and B. pilosicoli differentiation (2) was performed from the positive nox-specific PCR. Three strains were processed by biochemical assay.

**Results**

Tables 1 and 2 show the results of the different determinations. The purified strains were identified as negative indol B. hyo. None of the samples were positive to B. pilosicoli.

**Discussion**

The presence of diarrhoea, the pathologic lesions and the isolation of B. hyo indicated that the animals were affected of SD. The GA group presented fewer animals with clinical signs as well as less organism isolation and pathological lesions. This would explain the difference in ADG (52 and 82 gr) and the reduced days to slaughter (5 to 10 days) compared with the GT and GC respectively. The reason of the better activity of Tylvalosin in this field trial could be a higher susceptibility of the brachyspira strain to this drug compared to Tiamulin taken into account the extensive use of the latter in Argentina for many years and particularly on the study farm. A higher Tylvalosin dose rate should be recommended for similar situations since SD was also observed on the GA group.

Introduction
The use of tiamulin (Denagard® - Novartis Animal Health Inc.) for the eradication of swine dysentery caused by Brachyspira hyodysenteriae in outdoor herds has been described (1). Herd eradication is usually planned to eliminate the infection from a chronically infected herd. The chance of success is greatest when high temperatures and dryness prevail (summertime) and at a time when the breeding herd is being moved to a new uncontaminated pasture; both will naturally assist the decontamination process. B. hyodysenteriae has been shown to survive in faeces and slurry for up to 60 days in cold conditions (2).

Diarrhoea was first noticed in a 1,500 sow outdoor breeding herd in mid-September 2008; the diagnosis was confirmed by FAT, and cultures from faeces samples submitted by the private veterinarian in the course of a routine visit two weeks later. The MICs for two of the isolates against tiamulin hydrogen fumarate were 0.031 and 0.125 μg/ml respectively. It was thought that the infection had originated from a nearby farm (3km) which was known to be infected.

The affected unit formed part of a 10,000 sow breeder/nursery/finisher operation comprising two separate production pyramids. Progeny were routinely co-mingled at weaning with weaners from three other unaffected breeding units. This enabled the thirteen nurseries and 23 finisher sites in the pyramid to be filled quickly; stores moved to finisher sites at about 40kg and pig flow was truly “all in/all out” by unit. After consultation, an eradication programme commenced just as reports of diarrhoea were reported in some of the nurseries, which had been recently filled. At this stage there were no reports of dysentery in the finishers.

Materials and Methods
Medication programme
Breeders
The breeding herd was medicated with high levels of tiamulin (Denagard) at 8mg/kg bodyweight for 28 days, achieved by incorporation at 800ppm in the dry sow ration and 500ppm in the lactating sow diet. Resolution of clinical signs would trigger a reduction to 5mg/kg bwt for a further 28 days’ in feed medication.

Nursery pigs
Five nurseries had been recently supplied from the breeding unit and all feed on these units was medicated with tiamulin at 10mg/kg bwt (200ppm). A thorough cleaning and disinfection programme was introduced between batches.

Finishers
Despite the absence of clinical signs, all the finisher pigs in the pyramid, except those selecting for slaughter, were medicated in feed with 10mg/kg bwt (200ppm) tiamulin for 4 weeks. Subsequent breakdowns on finisher sites led to the belief that infection had been present for longer than initially thought. A full cycle of in-feed medication (tiamulin at 10mg/kg bwt (200ppm) for 4 weeks, reducing to 5mg/kg (100ppm) for 4 weeks) successfully eliminated the infection from all the finisher sites.

The in-feed medication regime was complimented by parenteral and water medication with tiamulin (Denagard) in consultation with the private veterinarian to ensure rapid treatment of affected individuals.

Management
Pig flow was adjusted to separate the affected breeding unit and its progeny from all other pigs. Biosecurity procedures were reviewed and standard operating procedures tightened; risk assessments were undertaken and transport logistics were scrutinised and adjusted accordingly. Staff were advised of the situation and movement between farms was limited and controlled. Clothing changes and boots were made available on every site for visitors and disinfectant foot baths were introduced.

Results and Discussion
Sows health improved rapidly and clinical signs resolved within a week of instigating the medication programme. October was a mild and dry month, but November was cold and wet. The clinical response was excellent on all nursery and finisher sites.

The pyramid has remained free of dysentery for over 12 months since the end of medication. Progeny from the affected unit had been considered to be the poorest in the company, but have subsequently outperformed all others (data available).

Swine dysentery eradication by strategic medication without depopulation

Johan Kamp1 Rita Schuttert-Wilps1 Susan Kars-Hendriksen2

Introduction
Swine dysentery (SD) has a major negative effect on the productivity performance. The objective of this study was to eradicate Brachyspira hyodysenteriae from a multiplier herd by medication with tiamulin (Denagard® 45% WSG) without partial depopulation.

Materials and Methods
The 910 sow multiplier herd was chronically infected by Brachyspira Hyodysenteriae over the past years. This resulted in recurrent outbreaks of dysentery in the summer and autumn of 2006. The weaners (8-25 kg) were therefore continuously medicated and the finishers at different sites were underperforming. All sows and weaners were housed at one site. The diagnosis was made based on clinical symptoms, post-mortem findings and confirmed by detection of B. hyodysenteriae in fecal samples of finishers and sows by culture and PCR.

The eradication program consisted of the medication of breeding animals, suckling piglets and weaners combined with thorough cleaning and disinfection of the stables. It was financially impossible to carry out a total or partial depopulation.

Prior to the start of the program, biosecurity was improved, effective rodent control was started, no visitors were allowed and no new animals were introduced. All staff was involved in establishing a cleaning and disinfection protocol.

To investigate if the eradication could be performed without feed medication, solubility and palatability of Denagard 45% in drinking water for gestation sows was tested. Most gestation sows showed a sufficient water intake with 650 gram Denagard 45%/1000 l drinking water. So treatment was only by drinking water and injection. All sows and weaners were medicated with Denagard 45% 9 mg/kg bodyweight in drinking water for 14 days, and then the dosage was reduced to 4.5 mg/kg BW for the next 14 days. This was followed by another 28 days medication with 2.25 mg/kg BW. Suckling piglets were treated with tiamulin injections 10 mg/kg BW on day 1, 7 and 14 after the start of medication. All animals with reduced appetite were injected with tiamulin 10 mg/kg BW. During the program every day all manure was removed. Every 3 days all places possibly contaminated with manure were cleaned and disinfected (Virocid). After finishing the program the herd was monitored on the presence of B. hyodysenteriae.

Results
The eradication program was completed in the beginning of 2007. A few days after starting the medication there were no clinical signs of dysentery anymore. Every month the farm was monitored for clinical symptoms. Routine use of antimicrobials against enteric diseases was no longer required.

Fecal samples of sows, piglets and finishers were screened post-eradication for Brachyspira by PCR regularly (Jan 2008–June 2009) and were all negative.

The reproduction performances improved (see table 1) and so did the growth of the piglets and finishers. After the eradication program the herd performance significantly improved.

Discussion
There are many closed herds for which it will be very costly to perform an eradication strategy with partial or total depopulation. Successful eradication of B. hyodysenteriae without any depopulation is also a reasonable option as indicated by the results. Big advantage is that the pig flow is stable, which at the end translates into normal revenues for the farm. If biosecurity is kept at a very high level it is possible to keep the farm free of SD. All biosecurity measurements like cleaning and disinfection to prevent re-infection from the environment are as important as the medication strategy.

Eradication of diseases fits the current approach of decreasing the use of antibiotics in the Netherlands.

The study results confirm previously published data on SD eradication with strategic medication combined with intensive cleaning and disinfection. In the project described here no partial depopulation was performed.
The drug-susceptibility of Japanese isolates of *Brachyspira hyodysenteriae* in 2008

Yoshikazu Adachi; Hiromi Nakajima; Akihiro Misawa

School of Agriculture, Ibaraki University, Ami-machi, Japan

Introduction

*Brachyspira (B.) hyodysenteriae* isolated from slaughtered pigs in Ibaraki Prefecture in Japan, 2008. The MIC values of *B. hyodysenteriae* isolates to 7 antibacterial agents have been investigated and were compared with those of previous results (1).

Materials and Methods

Eighteen pig isolates of *B. hyodysenteriae* have been identified by PCR using NOX primers and sequencing with primers 3F(5′-GG-GGATGC>GTCTTAAGC-3′) and 500R(5′-AATCCGAGCAACGTTTG-3′) (2). Indole production test was used for identification. The drug-susceptibility test was performed as previously described (3) and carbadox, valunemulin, lincomycin, tylosin, tiamulin, penicillin G, and metronidazole were used.

Results and Discussion

The isolates with over 99.7% homology to *B. hyodysenteriae* ATCC27164 have been identified as *B. hyodysenteriae* and 18 isolates were B hyodysenteriae. As shown in Table 1, carbadox and metronidazole were very effective and MICs were 0.01 > and 0.4>, respectively but carbadox was prohibited to use in pig herds. Valunemulin was effective to the isolates and MIC values were slightly higher than those of previous results (1).

Penicillin G was also effective except for one isolate with MIC of 100 and 17 isolates were less than MIC of 0.4. MIC values of tiamulin were ranging from 13 to 0.1 and MIC values of 9 isolates were less than MIC of 0.4. On the other hand, MIC values of tylosin were ranging from 100 to 3.1 and MICs of tylosin were ≥100 in most isolates. MIC values of lincomycin were ranging from 100 to 0.2. The isolates have acquired the resistance to tylosin and lincomycin and the values of MICs were similar to the previous values(1), while those isolates were still susceptible to valnemulin and tiamulin and the values were slightly higher than previous results(1).

Comparison between two different methods for antimicrobial susceptibility testing of Brachyspira hyodysenteriae

Chiara F. Magistrali1 Lucilla Cucco1 Gloria D’Angelo1 Yuri Gherpelli2 Paolo Bonilauri2 Giuseppe Merialdi3
1. Istituto Zooprofilattico Sperimentale Umbria e Marche, Perugia, Italy; 2. Istituto Zooprofilattico Sperimentale della Lombardia e dell’Emilia - Romagna, Reggio Emilia, Italy; 3. Istituto Zooprofilattico Sperimentale della Lombardia e dell’Emilia - Romagna, Bologna, Italy

Introduction
Antimicrobials are the most relevant tool to control swine dysentery caused by Brachyspira hyodysenteriae in pig herds. Pleuromutillins (tiamulin and valnemulin) and lincomycin are the most important agents used for this purpose, nevertheless, multi-resistant B. hyodysenteriae isolates have been reported in many countries, Italy included. Currently no standard antimicrobial susceptibility testing method is internationally established. Agar dilution technique and broth dilution test methods are available. The aim of this work was to compare the two methods used for antimicrobial susceptibility testing of B. hyodysenteriae isolates in two different Italian laboratories.

Materials and Methods
Isolates: twenty B. hyodysenteriae isolates from clinical cases of Swine Dysentery in Italian pig herds were used during the study. The isolates were tested independently and blindly by the two different laboratories using the methods described below.

Broth Dilution Method: the broth dilution method was performed according to published literature (Rohde, 2004). Briefly, approximately $10^8$ of each isolate in 0.5 ml of BHl broth supplemented with calf fetal serum was added to each well of a MIC panel for Brachypira spp. (VetMIC TM Brachy ver 2, SVA, Uppsala, Sweden), and incubated on a shaker for 4 days in an anaerobic atmosphere (Genbox, Biomerieux, Lyon, France) at 37°C. Reference control strains were used as controls (B. hyodysenteriae B78, ATCC 27164). The concentration tested were from 8 μg/ml to 0.063 μg/ml for tiamulin, from 4 μg/ml to 0.031 μg/ml for valnemulin and from 64 μg/ml to 0.5 μg/ml for lincomycin.

Quick-MIC agar dilution method: a simplified agar dilution method using only antibiotic break point values was applied according to Ronne & Szancer (1990).

The interpretation of MIC values was based upon MIC-breakpoint values reported by Ronne & Szancer, as follows (1990). Tiamulin: ≤1 μg/ml : sensitive (S); >1-≤4 μg/ml : intermediate (I); >4 μg/ml : resistant (R). Valnemulin: ≤1 μg/ml : S; >1-2 μg/ml : I; ≥4 μg/ml : R. Lincomycin: ≤4 μg/ml : S; >4-32 μg/ml : I; ≥32 μg/ml : R. Tylosin: ≤1 μg/ml : S; >1-≤4 μg/ml : I; >4 μg/ml : R.

Results
The results are shown in Table 1 and 2. By broth dilution, 4 isolates were classified resistant to tiamulin, 6 to valnemulin and 7 to lincomycin.

For tiamulin, 8 strains were classified as intermediate by agar dilution, and sensitive by broth dilution, for valnemulin 5 and for lincomycin 7. The isolates classified intermediate for tiamulin by agar diffusion and sensitive by broth dilution showed MIC values above 0,125 μg/ml in the broth dilution test. No isolate classified as sensitive by one of the two methods resulted resistant by the other one.

Discussion
The need of standardization and quality control for antimicrobial susceptibility testing of Brachyspira spp. has been repeatedly pointed out. Broth method has been reported to give MICs lower by one dilution step in literature. The trial results confirm lower MIC values for the tested isolates by using broth dilution method compared to agar diffusion technique. Using the MIC breakpoints thresholds, some isolates classified as intermediate to pleuromutillins and lincomycin by agar dilution technique were classified as sensitive by broth dilution test. Nevertheless, no isolates were classified as resistant by agar dilution technique and sensitive by broth dilution test or vice versa. In conclusion, classification of isolates in different susceptibility groups using the two test methods can occur, in particular for those showing intermediate values.

Evolution of recent antimicrobial sensitivity data of Brachyspira hyodysenteriae in Belgium

Frédéric A. Vangroenweghe; Evelyne De Graef; Mia Vanrobaeys; Cora Miry
DGZ-Vlaanderen, Torhout, Belgium

Introduction
Evolution of antimicrobial resistance (AMR) of Brachyspira hyodysenteriae, especially to pleuromutilins, should be monitored regularly to update the actual treatment possibilities in case of clinical disease or eradication strategies. A study, using strains isolated in 2003, on the link between AMR and clinical effect of treatment to B. hyodysenteriae infections revealed that only 13% of the strains tested were susceptible to lincomycin and just 4% to tylosin (1). Since 2006, recent data are yearly available on B. hyodysenteriae AMR to tiamulin and valnemulin in Belgium.

Materials and Methods
Strains of B. hyodysenteriae were isolated from routine diagnostic samples during 2006-2008-2009 and immediately after isolation, antimicrobial susceptibility testing was performed. Besides the field isolates, available reference Brachyspira strains were also tested (2). Susceptibility testing was performed as previously described (1, 2). The MIC was recorded as the lowest concentration at which no distinct hemolysis was seen in the spot.

Results
The reference strain of B. hyodysenteriae (B78) was more susceptible to valnemulin (MIC < 0.03) than to tiamulin (MIC = 0.06). Results of the field isolates of the different B. hyodysenteriae strains (n = 40 strains per year) are given in Figure 1 for tiamulin and valnemulin. Minimal inhibitory concentrations for 50% (MIC50) and 90% (MIC90) of the strains tested are also given in Table 1.

Table 1. Minimal inhibitory concentrations of tiamulin and valnemulin required to inhibit 50 and 90% (expressed in μg/ml) of B. hyodysenteriae strains isolated in Belgium in 2006-2008-2009

</tbody>
</table>

Discussion and Conclusions
In comparison with previous studies (1), MIC50 and MIC90 were significantly increased for B. hyodysenteriae. Considering that isolates with MIC < 1 μg/ml should be regarded as not responding to therapy in vivo, more than 50% of all isolates obtained in 2009 should be considered resistant to both tiamulin and valnemulin (1).

For valnemulin, the number of resistant strains (n = 27) significantly increased last year and became nearly as high as for tiamulin (n = 29). The fact that an increasing number of strains reaches MIC-values beyond the highest concentrations (MIC > 8 μg/ml) tested for both pleuromutilins is a serious concern for the Belgian pig industry. Especially in relation to eradication protocols, further research focussing at potential alternative control measures is necessary. Farms should be aware to further improve their external and internal biosecurity measures to prevent introduction of new B. hyodysenteriae strains in the farm.

In conclusion, antimicrobial resistance to pleuromutilins has evolved towards a higher prevalence of resistance and higher MIC50 and MIC90 values as compared to previous data.

Case report: therapeutical effect of Vetmulin® premix on a clinical outbreak of Brachyspira murdochii in a fattening herd in Belgium

Frédéric A. Vangroenweghe1 Evelyne De Graef1 Lieven Claerhout2 Henk Lecluyse3 Alain Kanora3
1. DGZ-Vlaanderen, Torhout, Belgium; 2. DAP Curavet, Roeselare, Belgium; 3. Huvepharma NV, Antwerpen, Belgium

Introduction

Spirochaetes belong taxonomically to the order Spirochaetes, which contains several genera such as Brachyspira and Leptospira. The intestinal spirochaetes are included in the genus Brachyspira, which contains at present seven species, of which five are known to be present in pigs: B. hyodysenteriae, B. pilosicoli, B. intermedia, B. murdochii and B. innocens. Porcine diarrheal disease in fatteners is mainly caused by B. hyodysenteriae and B. pilosicoli. In Belgium, B. hyodysenteriae has been diagnosed in 16% of the fecal samples (n = 2264) analyzed through PCR during the last 3 years (1). In bacteriological culture, B. hyodysenteriae was present in 26% of the analyzed fecal samples (2). Besides the major pathogenic B. hyodysenteriae, B. murdochii also occurs in 9% of the fecal samples analyzed through PCR and in 5% of the bacteriological cultures for Brachyspira species. Brachyspira murdochii is generally considered as a minor pathogen (3). The present case report focuses on clinical outbreak caused by B. murdochii in a fattening herd in Belgium.

Materials and Methods

A fattening herd of 600 fattening places went through a period of clinical diarrhea in the group of 60-70 kg. The piglets all originated from one single sow farm. Clinically speaking the diarrhea consisted of flat feces with a slimy aspect without bloody contents. All fattening pigs were strongly contaminated with fecal material. Fecal samples of clinically affected pigs were collected for diagnostic purposes. The samples were cultured through standard anaerobic bacteriological Brachyspira culture and colonies were phenotypically identified to the species level.

Results

Bacteriological culture of Brachyspira resulted in the identification of B. murdochii in pure culture. As no other relevant bacterial species could be isolated from the fecal samples, it was considered to be the agent causing clinical diarrhea in the fattening herd. Following the bacteriological diagnosis, antimicrobial therapy with tiamulin (Vetmulin® premix; Huvepharma) at a dose of 10 mg active substance per kg live weight was started. The antimicrobial was administered through the feed for at least 7 days. Following the therapy, clinical recovery and normal fecal consistency could be observed after 5 days of treatment with Vetmulin®. After the treatment, clinical signs disappeared in the treated group. However, identical clinical symptoms were observed in other untreated fattening herds with piglets originating from the very same farm. In these fattening herds, similar therapy was introduced and resulted in identical therapeutical effect on clinical symptoms.

Discussion

The present case report clearly demonstrates that although B. murdochii is generally considered as a minor pathogen without specific clinical symptoms, occasionally clinical outbreaks can occur. The absence of bloody contents in the feces could indicate that B. hyodysenteriae was not the etiological agent, although clinical signs of B. hyodysenteriae in Belgium are not always associated with bloody feces. The importance of rapid and accurate diagnostics in order to install an efficient therapeutic plan is herewith demonstrated. The good therapeutic response of B. murdochii to the administration of tiamulin preparations is in accordance with several data on antimicrobial susceptibility, showing no significant resistance to tiamulin (4,5).

In conclusion, the present case report clearly shows that B. murdochii is not as apathogenic as generally accepted. A clear relation with other piglets originating from the same farm could be observed, which indicates a possible contamination during the suckling or post-weaning period.

Minimum inhibitory concentration of tiamulin, valnemulin and tylosine for Brachyspira hyodysenteriae, Brachyspira pilosicoli and Brachyspira spp. isolated from pig farms in México

Enrique Corona-Barrera ¹  Pedro Pradal-Roa ² Jesús Munguía ²  Jill Thomson ³

¹. CIR, Biomedicas, Mérida, YUC, Mexico; ². Depto. Prod. Animal Cerdos, Fac Med Vet Zoot-UNAM. Ciudad Universitaria, México, DF, Mexico; ³. Vet Science Division-Scottish Agricultural College, Edinburgh, UK

Introduction

The pathologies caused by the intestinal spirochaetes (IS) Brachyspira hyodysenteriae-swine dysentery and Brachyspira pilosicoli-porcine colonic spirochaetosis have been documented in pig production sector of many countries. These enteropathogens have been identified in México (2). Values for minimum inhibitory concentration (MIC) of the antimicrobials tiamulin, valnemulin and tylosin have already been reported (1,4). The aim of this work was to determine MIC values of the antimicrobials above for Brachyspira specimens isolated from pigs in México.

Material and Methods

A total of 19 Brachyspira specimens, B. pilosicoli (n=6), Weakly β-haemolytic IS (WBHIS) indol –ve (presumably B. pilosicoli, n=11) and B. hyodysenteriae (n=2) were used to determine MIC values of tiamulin (Novartis AH), valnemulin (Novartis AH) and tylosin (USP ref. std) using agar dilution method. Propagation of spirochaetes was done on blood agar plates (Columbia agar, Oxoid, UK + 8.0% horse blood) incubated for 3 days under anaerobic conditions using GasPak (AnaeroGen, Oxoid, UK) jar. The harvest of those plates was used to make a working bacterial suspension adjusted to 1.0 MacFarland standard.

Concentrations from 128 to 0.0125 μg/ml of the antimicrobials were obtained by dilution from mother concentrations of 10,000 mg/l. Wilkins Chalgren (WC) [Anaerobe agar, (Oxoid UK) + 8.0% horse blood] plates containing the antimicrobial dilutions were prepared. Volumes of 10.0 μl of the bacterial suspension of each Brachyspira specimen and 2 replicates were inoculated on WC plates. Control plates (no antimicrobial) were also inoculated for viability of Brachyspira cells. WC plates were incubated at 38 °C under anaerobic conditions in jars for 48 hrs. MIC assays were repeated at least once.

Results

MIC values >4.0 μg/ml are considered as resistant. The MIC values obtained for the antimicrobials of study are shown below.

MIC values:

B. pilo (n=6) Tia 0.025-0.5 μg/ml Val 0.025-0.25 μg/ml Tyl 2.0-16 μg/ml

WBHIS (n=11) Tia 0.5-4.0 μg/ml Val 0.01-0.5 μg/ml Tyl —

B. hyo (n=2) Tia 0.025-0.1 μg/ml Val 0.025-0.1 μg/ml Tyl 2.0-128 μg/ml

Tiamulin MIC values at the level of 4.0 μg/ml were observed on isolates of Brachyspira recovered from the same farm. Control inocula developed the Brachyspira characteristic growth showing that the assay conditions were appropriate and the purity of those cultures was confirmed on Gram stained smear preparations.

Discussion

The MIC values obtained for tiamulin and valnemulin in the present study are among those reported on previous studies (3,5). In the present study a MIC value at the level of 4.0 μg/ml for tiamulin was obtained (that should be interpreted as a resistance value). Tiamulin resistance values have been reported by Czech Republic authors who have tested Brachyspira isolates (n=202) for a 10 year period (1). However in another MIC study using B. pilosicoli isolates obtained since 1996 no resistance was observed (5). The current study is the first one on MIC values of tiamulin, valnemulin and tylosin for Brachyspira. The tylosin high MIC values (up to 16 for B. pilo μg/ml and up to 128 μg/ml for B. hyo) found in this study show resistance, A Brachyspira feature already reported elsewhere (1) and is consistent with results from other authors among the Brachyspira international group as discussed on the last biannual meeting. Performing MIC assays on WC agar implies to adapting cultures on this medium which takes time making the testing more costly.

Conclusion

The MIC values of tiamulin were in some cases at the level of 4.0 μg/ml, this is at the limit of susceptibility-resistance. The MIC values of valnemulin were low (<0.5 μg/ml) showing that Brachyspira is far from being resistant. The technical information presented in this study gives confidence to the use of these antimicrobials, particularly valnemulin for treatment of Brachyspira infections.

Activity of propyl propyl thiosulfinate and propyl propyl thiosulfonate against *Brachyspira hyodysenteriae* field isolates

Álvaro Hidalgo; Jesús Osorio; Héctor Argüello; Ana Carvajal; Pedro Rubio

*University of León, León, Spain*

**Introduction**

*Brachyspira hyodysenteriae* is the causative agent of swine dysentery (SD), one of the most important gastrointestinal disorders in pigs. Treatment and control of SD involve mainly the use of antimicrobial as no commercial vaccines are available. However, field isolates of *B. hyodysenteriae* with decreased susceptibility to one or more of the drugs commonly used for the treatment of SD have been reported (1, 2). These isolates represent a threat to the pig industry.

The antimicrobial properties of plants of genus *Allium* have been known for ages. Accordingly, the effectiveness of some garlic substances (*Allium sativum*) against some human gastrointestinal bacteria have been reported previously (3, 4). However, knowledge on antimicrobial activity of these substances against animal pathogens is scarce.

This study aims to evaluate the potential use of two compounds of natural origin obtained from plants of genus *Allium*, propyl propyl thiosulfinate (PTS) and propyl propyl thiosulfonate (PTSO), to assist in the treatment and control of SD.

**Materials and Methods**

**Bacterial strains and growth conditions.** Forty seven isolates of *B. hyodysenteriae* from the bacterial collection held at the Animal Health Department at the University of León, Spain, were used in this study. Bacterial isolates had been recovered from different farms distributed across Spain between 2001 and 2009. Thawed isolates were grown on fastidious anaerobe agar supplemented with 5% horse blood in an anaerobic atmosphere (10% hydrogen, 10% carbon dioxide and 80% nitrogen) at 39°C.

**Table 1.** MIC<sub>50</sub> and MIC<sub>90</sub> (µg/ml) of PTS, PTSO and PTS + PTSO for 47 Spanish field isolates of *B. hyodysenteriae*.

**Results and Discussion**

The results and MIC distributions of the susceptibility test are shown in Table 1 and Figure 1, respectively.

*Figure 1. Distribution of MIC of PTS, PTSO and PTS+PTSO for 47 Spanish field isolates of *B. hyodysenteriae*.*

Although susceptibility of Spanish *B. hyodysenteriae* field isolates to PTS and PTSO were markedly different, MIC distributions indicated that growth of this bacterium was affected by the use of *Allium* spp. derivatives on their own or combined. PTS presented lower MIC<sub>50</sub> and MIC<sub>90</sub> than PTSO, showing a higher antimicrobial activity against this spirochaete. Accordingly, PTS was able to prevent the growth of all isolates at the tested range of concentrations, while PTSO enabled the growth of more than 20% of the isolates at 400 µg/ml. The combination of both substances retained the PTS antimicrobial effect in spite of decreasing its concentration to 17.5%.

The results of the *in vitro* susceptibility testing suggest that clinical trials should be performed to evaluate the use of PTS and PTSO in the diet of pigs in order to treating and controlling SD.

Detection of a novel *Brachyspira* species associated with haemorrhagic and necrotizing colitis

John Harding1, Manuel Chirino-Trejo1, Champika Fernando1, Mark Jacobson2, Zenon Forster3, Janet E. Hill1

1. University of Saskatchewan, Saskatoon, SK, Canada; 2. Warman Veterinary Services, Warman, SK, Canada; 3. Big Sky Farms Inc, Humboldt, SK, Canada

**Introduction**

Several *Brachyspira* species cause disease in grow-finish pigs, notably *B. hyodysenteriae* and *B. pilosicoli* which cause colitis and typhlitis. *B. innocens*, *B.intermedia* and *B. murdochii* are generally considered non-pathogenic. Described herein are case submissions from 2 unrelated farms experiencing a mucosa-haemorrhagic colitis associated with a novel *Brachyspira* species.

**Farm D**

Fresh and fixed tissues from 3 grow-finish pigs exhibiting bloody diarrhea were submitted from a single source nursery-finisher barn (Table 1). Histologic examination confirmed a necrotizing catarhal colitis. *Brachyspira* sp. was not isolated by bacterial culture from any case. The affected pigs were PCV2-vaccinated and had been pulse medicated with 33g/T tylosine (1 week of 3) from 9 to 15 weeks of age. The incidence of bloody diarrhea in 11 to 24 week old pigs was infrequent. Total annualized grow-finish mortality was 3.5 to 4.5%.

**Farm H**

Four submissions of various types were made from grow-finish pigs exhibiting bloody diarrhea in a single source finisher barn (Table 1). Histologic examination confirmed a mucosa-haemorrhagic and suppurative colitis. Affected pigs were 13 to 16 weeks old, and were PCV2 and erysipelas vaccinated. Diets were medicated with 44 g/T lincomycin from 10 to 16 weeks of age, and with 110 g/T lincomycin for 1 week when significant diarrhea was noted in a group, which included all groups during the submission period. The total mortality rate attributable to bloody diarrhea was estimated to be 1% to 2%.

**PCR and sequence analysis (colon)**

Species-specific PCR assays targeting *B. hyodysenteriae* and *pilosicoli* were negative for all samples. PCR primers designed to amplify a region of the NADH oxidase 1 gene (nox1) of *Brachyspira* spp. yielded a fragment of the expected size and direct sequencing of the nox1 amplicons yielded identical sequences from all samples. The nox1 sequence detected had a maximum of 92% identity to any previously characterized species. Phylogenetic analysis of relevant sequences (Figure 1) shows that the case sequence is distinct from other species which exhibit very little intraspecific diversity, and that its distance from other species is typical of interspecific distances for the genus *Brachyspira*.

**Discussion**

Our results indicate a putatively novel *Brachyspira* spp. associated with haemorrhagic colitis and diarrhea in grow-finish pigs in the absence of other known pathogens including *B. hyodysenteriae* and *B. pilosicoli*. More studies are planned to determine its causality.

Effects of different diets on pigs with naturally-acquired *Brachyspira pilosicoli* infection

Jill R. Thomson; Brian P. Murray; Lorraine E. Henderson; Joan Dick; Colin Morgan

Scottish Agricultural College, Edinburgh, UK

Introduction

The impact of diet on porcine colonic spirochaetal diseases has been demonstrated in a number of studies. Experimentally, *Brachyspira pilosicoli*-infected pigs developed milder disease when fed cooked rice as compared with wheat based diets (1,2), attributed to reduced colonic fermentation and sparse, dry colonic content in rice-fed pigs. Commercial pig grower rations in the UK are mostly wheat based, and those with higher non-starch polysaccharide content can be associated with nonspecific colitis (3). Whether such diets promote or enhance the impact of infectious forms of colitis is poorly understood. This study compared the effects of different diets on pigs with porcine colonic spirochaetosis (PCS).

Materials and Methods

Pigs were acquired from six units with outbreaks of *B.pilosicoli* infection for a series of farm-specific studies. For each trial, twelve diarrhoeic pigs and four normal pigs (controls) were obtained from the farm in question and housed in individual pens for the duration of the study. All pigs were growers (weights between 20 – 40kg at start). During acclimatisation, all pigs remained on the farm’s ration and were tested for enteropathogens, faecal %dry matter (%DM) and intestinal retention time (IRT). On Day 0, six affected and two control pigs were changed to the test ration while the other cohort of 6 affected and 2 control pigs remained on the farm’s ration. The test ration was comprised of barley, soya, fishmeal with vitamin and mineral balancer formulated to the same nutritional specification, and pelleted at the same mill as the farm’s ration. Faecal %DM and brachyspira cultures were carried out 3 times weekly and IRT measurement on days 6 and 12. Mean IRT was measured by feeding known numbers of polythene beads followed by 4-hourly faecal collections. Pigs were weighed on days 0 and 14. On day 15 all pigs were euthanased for pathological examination and bacteriology.

Results

*B.pilosicoli* was isolated from all diarrhoeic pigs during the course of the trials, but not from normal pigs. During acclimatisation, all affected pigs had typical clinical signs of PCS, with faecal %DM values ranging between 16–23%. In all trials, changing to the test ration gave a noted improvement in clinical appearance and an increase in faecal %DM from day 4. Significant differences in mean IRT between the farm’s ration and the test ration were recorded for all trials (p<0.001)(Table 1). In normal pigs, the test ration gave an average increase in IRT of 4.8 hours as compared with the farms’ ration. In pigs with PCS, the difference was more marked, giving an average increase in IRT of 6.6 hours in pigs on the test ration. A significant positive correlation was recorded between mean IRT and growth rate in pigs with PCS. On post-mortem examination all affected pigs were confirmed to have lesions of PCS. A histopathological scoring system for colonic lesions showed significantly higher mean scores (i.e. worse colitis) for pigs on the farms’ ration as compared with test ration.

Discussion

The improvement in the clinical parameters and IRT in pigs with PCS when fed barley-based ration as compared with wheat-based rations suggested that the dietary constituents had direct effects on enteric physiological processes and disease expression. In view of the matched dietary specifications, the increased growth rates achieved by PCS-affected pigs that were fed the barley-based ration could be attributable to an increase in IRT and to a reduction in both the severity of diarrhoea and the colonic inflammatory lesions.

**Introduction and Objectives**

The research group at León University (Spain) is working on different topics associated with *Brachyspira* species. The bacterial genus *Brachyspira* consists of several species of intestinal spirochetes with the capability of colonizing a broad spectrum of hosts. *B. hyodysenteriae* and *B. pilosicoli* have been commonly detected in pigs suffering gastrointestinal disorders in Spain (1). However, there is no information about other species within the *Brachyspira* genus recovered from swine faeces. The purpose of this study is to give an overview of the different non-pathogenic *Brachyspira* species that we have detected in pigs from Spain.

**Material and Methods**

A total of 67 Spanish field isolates of *Brachyspira* spp. from 54 farms were included in the analysis. All isolates were weakly β-haemolytic, recovered from pigs between 2006-2009 and came from the collection held at the University of León. None of the isolates had been designed into the *B. hyodysenteriae/B. pilosicoli* species by culture and PCR detection routinely used in our laboratory (2, 3). A partial sequence of NADH oxidase (*nox*) gene was used for the identification of the isolates. Sequence data for well-known isolates and reference strains retrieved from Genbank were also included in the study. Sequence and sequencing analysis was performed according to previously described procedures (4). The genetic relationships between strains were visualised by constructing a dendrogram using the 'maximum composite likehood' model and the neighbour-joining tree in MEGA version 4 (www.megasoftware.net) (5).

**Results**

All the isolates used were pure cultures and PCR confirmed as different from *B. hyodysenteriae* and *B. pilosicoli*. Information of partial *nox* sequences allocated most of the isolates to the three non-pathogenic species *B. murdochii* (31), *B. innocens* (26) and *B. intermedia* (7). The three remaining isolates could not be included into any of the *Brachyspira* species which naturally infect pigs. Isolates H29 and H51 were recovered from Iberian pigs belonging to 2 different herds. The analyzed *nox* sequence of isolates H29 and H51 got 63 nucleotide substitutions (7.4%) with regard to the sequence of the *B. hyodysenteriae* isolates. *Nox* gene information confirmed previous classifications and showed larger heterogeneity in *B. intermedia* isolates than in the other species. None of the isolates were included in the strongly β haemolytic species *B. hyodysenteriae* and “*B. suanatina*” even though we have check that several of the weakly haemolytic isolates gave weak positive bands to *B. hyodysenteriae* PCR used for diagnostic purposes, mainly *B. intermedia* isolates. We have found *B. murdochii* and *B. innocens* much more prevalent than *B. pilosicoli* and *B. intermedia* in swine herds in Spain.

**Discussion**

The isolates were identified as *B. murdochii* (46.3%), *B. innocens* (38.9%) and *B. intermedia* (10.4%). Three of the isolates (4.4%) could not be included into any of the *Brachyspira* species which infect pigs. Therefore, in this study on weakly haemolytic intestinal spirochaetes in Spanish pigs, we have found new groups of intestinal spirochetes which differ from previous descriptions and could possibly be proposed as new *Brachyspira* species. More isolates should be identified in order to confirm this finding.

A field experience using oregano essential oil in six swine herds with hemorrhagic bowel syndrome

Robert W. Evelsizer¹ Darryl Sanden² Martha A. Mellencamp¹
1. Ralco Nutrition, Inc., Marshall, MN, USA; 2. PIGS Inc., Fairmont, MN, USA

Introduction

Hemorrhagic bowel syndrome (HBS) is a condition of finishing pigs between 2 to 6 months of age that is known to cause sporadic, sudden mortality. It has been theorized that intestinal volvulus may account for most, if not all, of what has been described as HBS (1). Some suggest that excessive gas production in the caudal intestine is the underlying cause of HBS. Post mortem observations include a pale carcass with abdominal distension and gas distended intestines that are markedly reddened and filled with blood-stained watery fluid. The jejunum is thin walled. The stomach is filled with feed. In a recent paper, the name “Porcine Intestinal Distension Syndrome” (PIDS) was proposed to more accurately reflect the nature and cause of this condition (2). Investigation of a condition known as “whey bloat”, which appears to be identical to HBS or PIDS, has demonstrated an increase in abdominal pressure sufficient to cause impairment of venous return through the mesenteric veins (3). This results in massive pooling of blood in the intestines and ultimately leads to multiple organ failure and sudden death. Actual volvulus is not necessary for HBS and is absent in a majority of cases. Reduction of HBS mortality with in-feed administration of antibiotics has been reported (1). This paper describes a field investigation in which oregano essential oil (OEO) was applied either in the water or feed in six herds that were experiencing HBS. Results showed significant reduction in death loss on these farms.

Materials and Methods

An experienced grow-finish field supervisor (D.S.) who oversaw 60,000 finishing pigs per week had commonly encountered HBS on several of his farms. Factors associated with HBS on these farms related to feed intake patterns. These included genetics, weather, diet changes, out of feed events, feeder type, and water intake. He had taken several approaches to resolving this problem, including increasing feed particle size, reducing out of feed events, water chlorination, and antibiotics. After noticing that a farm feeding an OEO product had a lower rate of HBS, he began to implement OEO in either feed or water on his other farms in an attempt to reduce HBS.

Results and Discussion

A summary of recorded deaths from six farms before and after OEO use is shown in Table 1. No changes in management or how deaths were recorded were made. OEO in the water or feed was associated with an 87.5% reduction of HBS mortality. Odds ratio analysis (4) showed that OEO-treated pigs were 8.5 times more likely to survive than untreated pigs (5% CI: 5.45 to 11.96). On one farm, OEO was fed in one barn, while the other barn served as the “control”. In the OEO barn, death loss from HBS dropped to very low levels, while the control barn continued to experience the same number of HBS deaths. OEO has been shown to inhibit many species of bacteria, including Clostridium perfringens (5). It is theorized that OEO may reduce gut fermentation due to alteration of intestinal microflora, resulting in a reduction in observed HBS.

Investigation into the cause of hemorrhagic bowel syndrome in grower pigs on commercial farms in South Africa

Annemarie Labuscagne¹ B. T. Spencer² J. A. Picard² M. C. Williams²
1. Charles Street Veterinary Consultancy, Pretoria, South Africa; 2. Department of Production Animal Studies, Faculty of Veterinary Science, University of Pretoria, Pretoria, South Africa

Introduction
Over the last five years generally excellent pig farmers in South Africa, with optimal management systems, have reported to consulting veterinarians that some of their grower pigs die acutely without prodromal signs, especially during summer. Most of these pigs appear to die from what can be described clinically and pathologically as hemorrhagic bowel syndrome (HBS). It tends to affect the best grown pigs close to market age, making it an expensive disease. Because of this, it was decided to investigate the syndrome in more detail.

Experimental Design
37 Necropsies were done by pig veterinarians. Only those carcasses that had marked intestinal congestion, with red contents, were selected for sampling: For histopathology a 1 cm thick slice of intestine was collected from the ileum (30cm proximal to the ileo-caecal valve), mid section of jejunum and from the duodenum (10 cm distal from the stomach) for histopathology. For bacteriology a 6cm piece of ileum, taken just cranial to the histopathology sample, was removed. Once the intestinal contents had been removed, a mucosal scraping was made. The slide was stained using the Gram's staining method. Another mucosal scraping was made by rubbing the ileal mucosa with a cotton-tipped swab and cultured aerobically as well as anaerobically. Histology sections were made using standard methods and the sections were evaluated for the presence of lesions.

Results
The average age of the sampled pigs was 16 weeks and the range was from 9 – 22 weeks of age. Mortalities tended to occur in the early hours of the morning. At necropsy the skin was usually pale, without signs of trauma. Bacteriology cultures only revealed C. perfringens in a heavy, almost pure culture, where it was cultured from 12 (40%) of the samples. Histological lesions characteristic for enterotoxigenic Clostridium infection were found. Large, Gram-positive bacilli were sometimes abundant in sections and mucosal smears of the intestine. The lesions included necrosis, haemorrhage and congestion

Discussion
The discrepancy between the histological observation of Clostridia-like bacteria and culture of C. perfringens was disappointing but not unexpected. This anaerobic bacterium can be overgrown by commensal bacteria. Furthermore, prolonged sampling times after death, and suboptimal preservation methods, may have negatively impacted on the viability of the bacteria.

The most likely cause of HBS in this study is Clostridium perfringens. Modern genetics has resulted in a commercial pig with improved average daily gain (ADG), feed conversion ratio (FCR) and leaner meat but perhaps because of this they are more predisposed to metabolically-induced diseases such as HBS. Farms included in this study had growth rates above the national average. The pigs are probably pushed to their physiological limits from an early stage. These pigs are intolerant to mistakes in management or feeding2, especially when rations are high in carbohydrates (typical South African rations), which under certain circumstances can lead to the proliferation of C. perfringens11. The extremely high ambient temperatures experienced in summer on all of these farms can lead to a decreased appetite during the day, with a compensatory increase in feeding at night. This could lead to over engorgement, with the delivery of increased amounts of intestinal carbohydrate and protein. This, in turn, could lead to enteric microflora proliferation, which is supported by the fact that most of the deaths are discovered early in the morning, with mortalities probably occurring early (04h00) in the morning. The above hypothesis might explain why HBS is more prevalent in summer.

Conclusions
Clostridium perfringens most likely plays a major role in haemorrhagic bowel syndrome (HBS) in South African piggeries during the hot summer months in rapidly growing pigs.

Case report of Gastric Ulcers in grower pigs affected with persistent Porcine Respiratory disease complex (PRDC)

Sasiwimon Talummuk; Rapeepat Kunalingtip; Metta Makhanon
Novartis (Thailand) Limited, Bangkok, Thailand

Introduction

Gastric ulceration is an important disease in pigs. It is a direct or indirect cause of pigs death. The gastric ulcer can affect pigs at any ages but the highest rate of ulceration occurs in 3-6 months of age. Lesion of gastric ulcer is sited at pars oesophagia. There are a lot of risk factors including some infectious agents such as PCV2 and Helicobacter –pylori-like-bacteria and non-infectious causes such as stress, management, and nutrition(1, 3 ). However, there are also other unknown causes. Clinical signs are depended on the causes of disease and varied from no clinical sign to sudden death. Gastric ulcer is indirect cause of mortality in case of PRDC disease due to anorexia and stress from some pathogens including PCV2 (4). If the stomach is empty more than 24 hours, gastric ulcer can develop. This report is the case of severe death caused by gastric ulcer in a Thai pig farm and discuss how to handle the case successfully.

Materials and Methods

Farm history: the multiple unit fattening pig farm with conventional housing(909 grower pigs per house) and commercial pellet feed is used. Herd heath status is positive to PRRSV and PCV2. There is no Mycoplasmal vaccination. Pigs showed respiratory and diarrhoeal signs one week after weaning with almost 10 % mobility. The grower pigs show more severe clinical signs including fever(38°-39°C), nasal discharge, lethargy, labored abdominal-breathing, severe coughing, pale, feed intake drop to 0.6 kg per days, and diarrhoea (Fig1). Highest morbidity (100%) and mortality (12%) is at 14 weeks old. Culling rate of the weak pigs is 27.93%. Total loss is 39.93%.

Necropsy finding: Post mortem two 14 wk old pigs. The lesion were pale skin, cranioventral pneumonia, total lung score approximately 50-60%(Fig 2), diffuse blood in stomach(Fig 3), gastric ulcer score 3 (Fig 4) (2, 5), flabby heart, pale kidney, no feed content in gastrointestinal organ, severe colitis and ulceration. Screening test by directed smear was positive to Balantidium coli.

Laboratory diagnosis: lung, blood content and large intestine are collected for bacterial culture. Pool organs of lung, lymph node, kidney, and spleen are collected for PRRS and PCV2 identification by PCR.

Treatment: All pigs were individually injected with Denagard®(tiamulin) 20% injection at 10 mg/Kg body weight for 3 days and water medication with Denagard® (tiamulin) 45% at 10 mg/Kg body weight for 5 days.

Results

The organisms isolated from lung lesions are Mycoplasma hyorhinis, Pasturella multocida and Streptococcus suis. Alpha Hemolytis streptococcus is isolated from large intestine. PRRS and PCV2 are positive by PCR. Helicobacter-like bacteria can be cultured from blood content in stomach. Clostridium perfringens is not found. There is no Walfarin used in this farm. Clinical signs improve slightly after treatment at late time of infection.

Discussion

According to this case, PRDC can induce severe of gastric ulceration and cause of high loss due to the mortality, morbidity and culling rate(1, 3). Route of medical administration and early treatment are the key factor for the successful treatment. Therefore, water medication and injection is more effective route when feed intake drop(4).

Clinical, pathological and laboratorial investigations of a severe outbreak of acute ulcers in pigs

Nuria Llanes¹ Carmen Alonso¹ Joaquim Segales¹.²
¹. CRESA, Bellaterra, Spain; ². Departament de Sanitat i Anatomia Animals, Bellaterra, Spain

Introduction
Gastric ulcers in pigs have been extensively studied (1). Annual mortality due to gastric ulcers is estimated to be between 0.5 and 0.75%. Therefore, its economical weight on the pork industry is high. The specific causes of gastric ulceration are not well known, but a number of factors have been pointed as risky (1). A severe case of acute gastric ulcers affecting several farms from an integration company located in a high density pig rearing area in North-Eastern Spain allowed the study of potential risk factors associated with such condition.

Materials and Methods
An estimated number of 5000 pigs died because of acute gastric ulcers during a 4-month period. Pigs corresponded to a 40.000-sow company that produce around 900.000 finishing pigs per year. It was known that other pig producing companies in the area had also a similar problem. The majority of affected pigs weighted between 30 and 40 kg and no previous clinical signs were found prior the gastric ulceration outbreaks. Most affected farms were in good health conditions before the appearance of the problem.

Acute gastric ulceration with massive haemorrhage appeared in 90% of the dead animals. Mesenteric oedema, hepatomegaly and soft, orange-yellowish livers were found also at necropsy in 80% of the deaths. Mortality rate rapidly increased from 0.5-5% (normal mortality values in fatteners) to 30-40% in most severely affected farms.

A number of laboratorial analyses were performed, including necropsy and histopathology (with in situ hybridization to detect Porcine circovirus type 2 (PCV2), haemogram, hepatic enzyme determination, measurement of vitamin E and selenium in blood and feed, mycotoxins in livers and raw feed material, heavy metals in liver and perirenal fat, and a general toxicological analysis on feed, raw feed material and livers.

In the meantime, in order to counteract the problem, the feed particle size was increased in size (from 700 to 800 μm). Concomitantly, a dramatic change in the diet formulation was performed: reduction of wheat content from 45 to 25%, a source of fibre was added (soybean hulls at 2%), sodium bicarbonate was added at a dose of 10 kg/ton and levels of vitamin E and selenium were increased from 10 and 0.2 to 40 and 0.5 ppm, respectively. Feed were served in mash form in most affected farms. Moreover, vitamin E and selenium were also given in pigs as injection. Finally, ranitidine (inhibitor of gastric acid production) was added in the water of some farms.

Results
Clinical response to farm actions: Injection of vitamin E and selenium had a positive response in some of the farms.

Pathology: Most consistent lesion, besides gastric ulceration, was massive hepatic centrolobular necrosis and or liver plate disruption with massive loss of hepatocytes, suggesting either a chronic intoxication or hepatosis dietetica. PCV2 was not detected in tissues of affected animals.

Haemogram and biochemical determinations: Most significant results were severe anaemia and increased levels of hepatic enzymes in serum

Vitamin E and selenium determination: Low levels of vitamin E (<0.5μg/ml) and selenium (0.78 μg/ml) were found (2).

Other analyses: No significant mycotoxins levels or heavy metals were detected in analysed samples. Toxicological analysis was indicative of peroxidation in the feed.

Discussion
Clinical response and performed analyses pointed to a deficiency in vitamin E and selenium. However, it is very likely that other factors were involved in the triggering of the problem due to the erratic appearance of the cases. Peroxidation and free radicals on the feed may have accounted as major predisposing factors for the clinical situation observed.

Occurrence of gastric ulcers in Swedish pigs
Katarina Karlsson; Malin Cerne
Swedish Animal Health Service, Falkenberg, Sweden

Introduction
Gastric ulceration is common in pigs throughout the world. Increased incidence of gastric ulcers has paralleled intensive husbandry practices (2, 5). The syndrome may have an economic impact because of increased mortality rate (2, 4) and decreased weight gain (1, 6). It is also an issue of animal welfare as gastric ulcers may cause pain. Abattoir surveys in different countries demonstrate the prevalence of lesions of the pars oesophagea ranging from 32 - 99 % (2). In several surveys possible risk factors have also been investigated. There is no published survey describing the prevalence of gastric ulcers among pigs in Sweden.

Materials and Methods
Our study was carried out during one week in September 2007, at the abattoir of Kristianstad in the south of Sweden. A total of 19 360 finishing pigs and 436 sows were slaughtered during the same period. Out of these we examined a total of 3 858 stomachs, randomly selected, mostly from finishing pigs. The stomachs were examined directly after being cut open and emptied. Alterations of the pars oesophagea were graded according to Dansk Svineproduktions index of ulceration (3). The categories of alterations were; category 1 healthy stomachs, category 2 stomachs with parakeratosis, category 3 stomachs with both parakeratosis and small erosions, category 4 extended erosions, ulcers and scares, category 5 strictures of various severities and category 6 bleeding ulcers.

Results
Out of 3 858 stomachs, 1 893 (49.1 %) were normal without any alterations of the pars oesophagea. 1 260 (32.6 %) were judged as category 2 and 258 (6.7 %) as category 3. We found 379 (9.8 %) in category 4 and 57 (1.5 %) in category 5. Finally 11 stomachs had bleeding ulcers (0.3 %).

Discussion
Ulceration of the oesophageal region of the stomach is a common and well known condition of finishing pigs throughout the world. In our study we found about 49 % of the examined stomachs to be normal and without any alterations of the pars oesophagea but almost 51 % had some kind of alterations. Most of the alterations found were mild and are not considered to have any impact on the performance of pigs (2). Approximately 12 % of the examined stomachs had serious alterations like extended ulcers, scars, strictures and in some cases bleeding ulcers. Stomachs with similar contents and similar alterations clustered, which indicates that they belonged to the same farms.

Gastric ulceration in 30 fattening herds in Sweden

Malin Cerne; Katarina Karlsson
Swedish Animal Health Service, Falkenberg, Sweden

Introduction
Ulceration of the oesophageal region of the stomach is a common condition of finishing pigs throughout the world. Increased incidence of gastric ulcers has paralleled intensive husbandry practices (2,5).

Many abattoir surveys from different countries have shown various prevalences of gastric ulcers. In several surveys possible risk factors have also been investigated.

Well known risk factors for gastric ulcers in pigs include reducing particle size of the feed and pelleting, as does withholding feed for 24 hours (1,6). Other factors that have been associated with the development of gastric ulcers in pigs are infection with Helicobacter, infection with PCV2 (7) and treatment with NSAID. It also appears that access to straw may compensate for several of the risk factors.

In a pre-study of the occurrence of gastric ulcers in Swedish Pigs, we found that stomachs with similar contents and similar alterations clustered, which indicates that they belonged to the same farms (3).

Materials and Methods
Our study was carried out during one week in September 2007, at the abattoir of Kristianstad. We examined 460 stomachs from 30 randomly selected farms. The stomachs were examined directly after being cut open and emptied.

The alterations of the pars oesophagea were graded according to Dansk Svineproduktions index of ulceration (4). We recorded six different categories of alterations. Categories 1, 2 and 3 were healthy stomachs, stomachs with parakeratosis and stomachs with mild erosions in pars oesophagea respectively. These alterations are not considered to affect performance or well-being in pigs (2). Categories 4, 5 and 6 were stomachs with severe erosions, ulcers, scars and strictures. These alterations are considered to affect the pigs in a negative way.

Results
405 stomachs were judged as category 1, 2 or 3.
55 stomachs were judged as category 4, 5 or 6.
70 % of the stomachs judged as category 4, 5 or 6 originated from 4 of the 30 examined farms (no 6, 10, 28 and 30), fig 1.

Discussion
As several of the risk factors have something to do with feed, feeding or housing it is not surprising that pigs from the same farm have the same alterations in pars oesophagea.

In an Australian survey from 2002 one found differences in prevalences between farms, but also between regions/states (6). The regions had different kinds of climate and different conditions for crops. There is probably a difference between regions in Sweden. The abattoir in Kristianstad serves the southern part of Sweden. In this area it is common to feed pigs with surplus products from the food industry, such as products from bakeries, dairies, distilleries, crisps- and chocolate producers. It has not been investigated what impact these products have on the prevalences of gastric ulcers.

Gastric ulceration has been reported frequently in PMWS-affected pigs, although no direct connection between PCV2 infection and this lesion has been established. At the time of our survey PMWS was widespread in the southern part of Sweden.

Esophagogastric ulcer: differences in hematological values comparing depending on non-glandular mucosa lesional stage

Guillermo Ramis1 Serafín Gómez2 Juan J. Quereda3 José J. Cerón3 Francisco J. Pallarés2
François Joisel4 Catherine Charreyre4 Sophie Longo4,5 Antonio Muñoz1
1. Universidad de Murcia, Murcia, Spain; 2. DPTO Anatomía y Anatomía Patológica Comparadas, Universidad De Murcia, Murcia, Spain;
3. Hospital Clínico Veterinario, Universidad de Murcia, Murcia, Spain; 4. Merial S.A.S., Lyon, France; 5. BPC, Labruguière, France

Introduction
Esophagogastric ulcer is a widespread disease affecting pigs of different ages, especially to finishers. The ethiology of the disease is multifactorial, influencing nutritional, genetic, pathologic and management factors on its development and severity. The pathogeny has not been completely understood yet (1). The aim of this study was to assess the hematological and blood biochemical values in animals showing different esophagogastric lesional stages.

Material and Methods
Eighty commercial pigs 1, 3, 6, 9, 12, 15, 18 and 21-week old (n=5 each group), were randomly selected. The animals were humanely euthanized and a macroscopical evaluation of non glandularis mucosa lesional stage was carefully done. Blood samples were taken on EDTA and dry tubes to recover whole blood and serum from each pig.

A complete hematological study was performed including white blood cells count (WBC), red blood cells (RBC), hemoglobin (HG), hematocrite (HT), mean corpuscular volume (MCV), mean corpuscular hemoglobin concentration (MCHC), platelets count (PTL), red blood cells volume distribution (RDW-SD), mean platelets volume (MPV), and total proteins (TP), using an Automatic analyzer SYSMEX F-800 (Japan)

The macroscopical lesional stage results were included in two categories for statistical analysis: apparently normal (AN), and abnormal (ABN). The abnormal category included all the stomachs showing some kind of alteration, including pre-ulcerous changes as parakeratosis and erosions.

Data were analyzed by means of Student t-test comparation using SPSS v. 15.

Results
Twenty stomachs were macroscopically classified as normal, while 60 stomachs showed some kind of non glandularis mucosa alteration. There were significant differences between groups for RBC, MCHC, RDW-SD and MPV. The values for every parameter are shown in the following table:

Discussion
Some changes in hematological values such us decreased RBC or MCV had been previously described (2). We have found significant differences in some hematological values comparing groups, but most of them (RBC, MCV, MCH and RDW-SD) are into the different reference intervals published (3, 4). The MPV is the only value under references values in abnormal stomachs, and could be related to increased coagulation derived from slow continuous blood loss, suggested also by reduced (even not significant) MCHC. The reduced MPV indicates a quick replacement of platelets.

Discussion
Even when significant differences in some hematological values comparing groups have been found, all of them are into reference values (2, 3) except for ALP and iron. It should take into account that some biochemical values can vary over the life of the animals and we have analyzed animals from 1st to 21st weeks of life. The iron value is much lower in abnormal group compared with normal group, and this parameter could be related to chronic loss of blood. Another hypothesis would be a reduced iron content derived from feed deficiencies for this metal. But, interestingly, has been previously recorded how the deficiency in nutritional iron results in a significant acid gastric secretion, reducing the lesional stage of the animals (4). So, in this case the lower iron value in lesionated animals should be related to iron losses. The iron seric value could be a help to diagnosis in cases of esophagogastaric alteration.

Neonatal Diarrhea in Danish pig farms – a questionnaire among veterinarians

Peter Astrup1 Kirsten V. Larsen1 Sven E. Jorsal2 Lars E. Larsen2
1. Intervet/Schering-Plough Animal Health, Skovlunde, Denmark; 2. DTU Veterinarinstitutet, Copenhagen, Denmark

Introduction
During the recent years neonatal diarrhea of unknown etiology seems to have occurred in many sow herds. The disease can usually not be effectively controlled by known vaccination or treatment strategies (1). The aim of this investigation was to systematize the perception of the character of the disease among Danish veterinarians.

Material and Method
A questionnaire, considering different management factors, clinical symptoms and laboratory as well as autopsy findings was developed. Two technicians were trained in interviewing veterinarians with the questionnaire as basis. Interviews were made from March through August 2009. Sixty-four veterinarians specialized in pig production were interviewed about their perception, without further documentation, of neonatal diarrhea in sow herds.

Results
Sixty-one of 64 veterinarians knew of this disease in one or more of their herds. The veterinarians interviewed were estimated to represent more than 50 % of the Danish pig production. Based on the questions the following answers were given (brackets indicate the percentage of veterinarians approving the statement in question).

• Neonatal diarrhea has increased during the recent years (95%)
  • In affected herds the prevalence of litters with clinical signs is between 30 and 70% (66%).
  • The piglet incidence in the litter is 70-100 % (61 %).
  • There is no relation between litter size and clinical signs (79%).
  • Mortality in the farrowing unit is increased with 0-5 %-point (56%), but can increase to more than 20%-point above normal.
  • Diarrhea is yellow (100 %) and watery (99 %) in some cases foamy and pasty (15 %) and more seldom green colored (10%).
  • Onset of clinical signs is from immediately after birth with maximum frequency 2-3 days after birth, where after frequency decrease and diarrhea disappears 7-10 days after birth (table 1).
  • Autopsy findings are non-specific: Flaccid dilated intestines (93%) and hyperemic intestines with watery content (48 %).
  • At laboratory examinations Clostridium perfringens type A (85%), Non-hemolytic E. coli (82%), Clostridium difficile (16%) and a few hemolytic E. coli or rotavirus have been found. Clostridium perfringens type C has not been found.
  • There is no obvious relation between use of sow vaccinations and clinical signs.
  • No obvious relation between management and clinical signs (54%).
  • Health status (95%), hygiene in farrowing unit (65%), hygiene in dry sow facilities (85%) and purchase of breeding stock (85%) has no impact on clinical signs
  • Low age (gilts) increase the risk of clinical signs (73%).
  • Poor feeding with colostrum is a possible or certain cause of clinical signs (74%).
  • Quality or source of feed can not be related to increased incidence (87%). Wet feed (31%), high protein in sow feed (34%) or toxins in feed (11%) might pose a risk. A few vets point at rapeseed as a specific risk factor.

Table 1. Number of vets out of 61 that see diarrhea on a specific day after birth.

Discussion and Conclusion
Based on the questionnaire the disease can best be described as a new type of diarrhea with increased incidence in Danish pig production. It is a watery to creamy diarrhea with non-characteristic pathological findings and without detection of a certain etiological agent. Nevertheless, Non-hemolytic E. coli and Clostridium perfringens type A are isolated with high frequency. The morbidity is very high and the mortality low. Especially litters after gilts and young sows are at risk of being affected.

These findings are in accordance with reports from other parts of the world with intensive pig production and underline the need for further investigations to clarify the nature of the disease.

Farrowing progress (chronopart) and enzootic neonatal diarrhoea: observational study in nine commercial herds

Jean-Noel Sialelli2 Fabien Vautrin2 Yannick Lautrou3 Isabelle Oswald4 Nathalie Quiniou5 Guy-Pierre Martineau1
1. National Veterinary School, Toulouse, France; 2. Farm’apro, Lamballe, France; 3. ESA Angers, Angers, France; 4. INRA Toulouse, Toulouse, France; 5. IFIP, LeRheu, France

Introduction
In some area of France, almost 20% of the farms are concerned with enzootic neonatal diarrhoea (END) (Sialelli et al., 2009). On-farm investigations conclude that many different bacteria such as Clostridium perfringens type A, Clostridium difficile, Enterococcus durans and others may be isolated but not consistently (Gin, 2008). Our hypothesis is that END origin at the sow level. The aim of this study was to describe the parturition in herds with END in comparison of herds without END.

Material and Methods
Selection of herds: among 100 herds from the same Coop (COOPERL-Arc Atlantique, Brittany, France), nine commercial herds were retained according to presence or absence of END but also on the level of productivity, hygiene, management and stockmanship: 4 herds were regularly affected by END and 5 herds without any history of diarrhea. The farrowing has been followed in 26 sows (Table 1).

Measures: chronoparts (individual time at birth of littermates), piglets’ weight at birth and at 24 h of age (in order to estimate colostrum production) and colostral data (IgG) were obtained.

Results and Discussion
Only data on farrowing duration is reported. Data on IgG in colostrum and piglets’ sera has been previously reported (Sialelli et al., 2009).

Parities 1 and 2 sows presented more risk to develop piglets’ END (OR=3.6, p<0.05). Duration of farrowing was longer in affected sows in affected herds than in unaffected ones. In affected herds, the duration of farrowing of unaffected sows was intermediate between unaffected sows and sows from control herds (Table 1).

Pattern of farrowing is different according to the size of the litter (Figure 1).

Conclusion
END is probably a consequence of a problem at the sow level. Investigations are under evaluation to approach farrowing in herds affected by long farrowing (Sialelli et al., 2010).

Introduction
At weaning, the digestive flora of piglets is unstable and is considered as a key factor of enteric disease. Alternative solutions to antibiotics or other products such as ZnO are proposed and give effective and repetitive results.

Symbiotic (prebiotic and probiotic) are shown to be one of these solutions. To have the widest comprehensive of this approach, the practitioner has to mix physiology, bacteriology, pathology, immunology, etc. It is why we propose to summarize the control of enteric flora at weaning by a jigsaw with 7 different pieces.

Control of enteric flora at weaning: the jigsaw
The seven pieces are illustrated in Figure 1.

Piece 1: CBH action.
Due to the manufacturing technique, some specific Lactic Acid Bacteria1 are adapted to starch medium and bring a lot of α-amylases. Lactic acid produced improves pancreas secretion and impact on assimilation of carbohydrate chain (CBH) metabolism.

Piece 2: Enterocyte energy management.
Better balance of digestive flora which decrease basal energy metabolism needed and impact (improve) on FCR.

Piece 3: Struggle between bacteria.
The competition / exclusion effect and environmental changes impact on natural defense at the mucus level.

Piece 4: Cell booster.
Stimulation of cell mucine and defensive production and reinforcement of tied-junctions impact on natural defense at the cell level.

Piece 5: Cytokine release.
Interaction with intestinal immune system modulating cytokine pro-inflammatory synthesis, increasing APC (Antigen Presenting Cell) activity, stimulating cytokine IL-12 synthesis (linked to Th1 and Th2 balance), improving IgA production and finally impact on gut immune system at the lamina propria level.

Piece 6: Regulation.
Regulation of oral tolerance, key of intestinal homeostasis, with improvement of cytokine IL10 secretion impact on gut immune system at the lamina propria level.

Piece 7: Greater TAS (Total Antioxidant Status)
Improving glucose assimilation, it improves NADPH regeneration with anti-oxidant function, added to the anti-oxidant enzyme and scavengers brought by the Symbiotic impact on TAS (decrease deleterious effect of oxidative stress as catabolism).

Discussion
According to recent results, we showed that it is worth to use symbiotic to get repetitive effectiveness than only prebiotic or probiotic. Although the interaction between Symbiotic and digestive tract is complex, we are able to analyze via the proposed jigsaw.

Using symbiotic1 as feed additive in trials, zootechnical effects has been statistically observed (FCR: Pelenc 2009; ADG: Criqui 2003), as well as immune response (Borghetti 2009). During studies on other species we systematically showed a better total anti-oxidant status (Laude 2008).

Conclusion
We can claim that the Symbiotic is acting on different goals on the digestive tract.

Evaluation of a microwave procedure for fecal dry matter determination

Ken S. Pedersen; Klaus Pedersen; Helle Stege; Jens P. Nielsen

University of Copenhagen, Frederiksberg, Denmark

Materials and Methods

A normal household microwave oven with a maximum effect of 700 Watt was used in the study. Fecal samples were dried to constant weight using the procedure previously described (3). Fecal dry matter content was calculated as: Dry matter = (weight of container and dried feces – weight of container) / weight of wet feces.

Three different studies were conducted. Study 1: Intra- and inter-serial variation were evaluated in a fractional three-way factorial design. The 3 factors were main fecal sample, operator and replica. Fecal subsamples (observational unit) were obtained from 4 main fecal samples with different consistencies. The analyses were repeated by 2 persons (operators). From each main fecal sample 8 fecal subsamples were heated together (replica). Coefficient of variation (CV) for fecal dry matter content was calculated. Data were analyzed by a linear mixed model (replica). Coefficients of variation (CV) for fecal dry matter content was calculated. Data were analyzed by a linear mixed model (replica). Coefficients of variation (CV) for fecal dry matter content were further evaluated by linear regression. All statistical analyses were performed in STATA/IC 11.0.

Study 2: Effect of weight of wet feces was evaluated. Two fecal samples representing 2 different fecal consistency scores were prepared. A total of 80 subsamples representing 5 different weights categories of wet feces were prepared. The categories were 0.5 gram, 1.0 gram, 1.5 gram, 2 gram and 3 gram. From each consistency score 8 subsamples from each weight category were heated together. All samples were evaluated by the same person. Data were analyzed by linear regression.

Study 3: Agreement between microwaves and freeze-drying was evaluated. Eighty fecal samples representing different fecal consistencies were collected in a herd. Two subsamples from each fecal sample were prepared and fecal dry matter was determined by microwaves and freeze-drying. A Band-Altman plot was constructed and Lin's concordance correlation coefficient for agreement was calculated. Trends of agreement in relation to increasing dry matter content were further evaluated by linear regression. All statistical analyses were performed in STATA/IC 11.0.

Results

For the intra- and inter-serial variation an overall CV of 0.03 was determined. Replica and operator accounted for 12% of the variation while 88% of the variation was with-in replicas. Confidence limits (95%) for any future fecal subsample examined by any operator in any replica was calculated to be +/- 0.85% dry matter.

Weighing off 0.5 gram of wet feces gave significant (p<0.001) different dry matter content than the other weight categories of wet feces. The other weight categories gave the same dry matter content.

Lin's concordance correlation coefficient for agreement between microwaves and freeze-drying was 0.94. On average the dry matter values was 1.7% higher in freeze dried samples compared to samples prepared by the microwave procedure. The difference was increasing by 0.18% dry matter (p<0.001) for each 1% increase in fecal dry matter of the examined sample.

Discussion

The observed repeatability for the microwave procedure was considered acceptable for determination of fecal dry matter. The variation distribution implies that homogenization of the original fecal samples before analysis is important and that the variation due to the microwave procedure itself and different operators can be neglected. The microwave method gave consistent results using 1 to 3 gram of wet feces for the determination. This implies that a minimum of 1 gram of wet feces should be used. The microwave procedure showed a high level of agreement with freeze-drying, although slightly higher dry matter values were obtained using freeze-drying. Neither method can be regarded as gold standard, but the current study show that similar results can be obtained with both methods. The increasing difference between the two methods with increasing dry matter content indicate that the results of the current study may only be valid for feces collected from weaners and growers. Feces from older pigs may contain a higher level of fecal dry matter which may influence the results.

In conclusion: The microwave procedure offers a fast, repeatable, robust and accurate method for determination of fecal dry matter.

Diurnal variation of fecal dry matter in pigs

Ken S. Pedersen; Klaus Pedersen; Helle Stege; Jens P. Nielsen
University of Copenhagen, Frederiksberg, Denmark

Introduction

Classification of pigs as having diarrhea or not is important for results and interpretation of research in enteric diseases. Recently an objective procedure for determination of fecal dry matter (DM%) based on microwave drying has been described (1). Diurnal fecal dry matter variation may influence the outcome of clinical examinations and the results of research.

The objective of the current field study was to investigate the variation in fecal dry matter and diarrhea classification within one day for pigs with and without diarrhea. The quantitative excretion of Lawsonia intracellularis from the same pigs was also determined and will be reported elsewhere in these proceedings.

Materials and Methods

A cross-sectional study with follow-up was designed. A Danish farrow-to-finish herd with a history of L. intracellularis was selected at convenience. Pigs were selected from a batch of 350 pigs with an approximately age of 8 weeks. Within the batch, 20 pigs with diarrhea and 10 pigs without diarrhea were selected at convenience. Fecal samples were collected five times (9am, 11am, 1pm, 3pm and 5pm) from the rectum of each pig. Defecation was triggered by rectal digital manipulation if necessary. The fecal samples were at all times kept chilled. Fecal dry matter content was determined for all fecal samples 24 hours after collection by the microwave method as described previously (1). The examined pigs were re-classified into non-diarrheic (DM%≥18.8), semi-diarrheic (18.8≥DM%>13.1) or diarrheic (DM%≤13.1) based on DM% (2) of the fecal sample from the first time point.

The data was analyzed in a linear regression model (LogDM% as outcome, time points as independent variables) with a repeat measurement structure using the mixed procedure in SAS, version 9.1.

Results

A total of 29 pigs and 144 observations were included in the analysis. Seven pigs were classified as non-diarrheic, 9 were semi-diarrheic and 13 were diarrheic at the first time point. A significant change in mean DM% between time points was observed for both non-diarrheic (p = 0.01), semi-diarrheic (p = 0.01) and diarrheic pigs (p = 0.02). The combined analysis of all pigs showed a significant (p<0.01) lower mean DM% at the last time point (5pm-7pm) compared to the other time points.

Only one initial non-diarrheic pig stayed non-diarrheic all day. The other 6 initially non-diarrheic pigs changed classification once or twice during the day. Five of the initial semi-diarrheic pigs stayed diarrheic all day. The other 4 pigs changed from diarrheic to non-diarrheic and back. Eleven initial diarrheic pigs stayed diarrheic all day while 2 pigs changed to non-diarrheic and back, table 1.

Discussion

The results of the current study shows that fecal dry matter content can change during the day and that time of day is important for classification of pigs as diarrheic or not. This indicates that examination of pigs at the same time of the day may be important in research studies. It does also have implications for monitoring of diarrhea at both individual and herd level in veterinary practice. Stress caused by several times of handling and fixation in a period of 10 hours may have contributed to the observed decrease in mean fecal dry matter content during the day. A larger sample of pigs is needed to determine whether a true diurnal variation in fecal dry matter exists. In conclusion, the current study supports the existence of a within day variation in fecal dry matter.

**Intestinal pathogens in acute diarrhea in weaners: A case control study in 20 Danish herds**

Ken S. Pedersen¹ Øystein Angen² Sven E. Jorsal² Helle Stege¹ Jens P. Nielsen¹

1. University of Copenhagen, Frederiksberg, Denmark; 2. National Veterinary Institute, Technical University of Denmark, Frederiksberg, Denmark

**Introduction**

Recurring therapeutic batch medication of acute outbreaks of diarrhea in weaners is a common cause of antibiotic consumption in Danish pig production. The objective of the current study was to investigate the prevalence of selected pathogens in outbreaks of acute treatment indicated diarrhea in pigs between 10 and 70 days post weaning. Results of clinical and pathological investigations are reported elsewhere in these proceedings.

**Materials and Methods**

A case control study was conducted. Herds were selected by multistage sampling. All herds serviced by six specialized swine veterinarians from the same vet practice at Zealand and fulfilling the inclusion criteria were selected. The criteria were recurring therapeutic use of in-feed or in-water medication for diarrhea at room level in pigs between 10 and 70 days post weaning. Only herds representing modern intensive production systems were selected. One outbreak of acute diarrhea was investigated in each herd. All herds were visited the day following notification from the farmer/veterinarian of an acute treatment requiring outbreak of diarrhea and the farmer was not allowed to medicate before the pigs were examined. If the pigs had received antibiotic batch medication within the last 7 days of the examination day, the outbreak was excluded from the study. A sample of 80 pigs in each herd was selected by systematic random sampling among all pigs in the nursery room where the outbreak of acute diarrhea occurred. The selected pigs were subjected to a clinical examination and fecal samples were collected. Among the examined pigs a simple random sample of 8 pigs with diarrhea and 8 pigs without diarrhea was selected and euthanized. Intestinal content was examined for rotavirus by an ELISA method and Escherichia coli, Brachyspira spp. and Salmonella spp by standard culturing methods. Dry matter (DM%) was determined for the fecal samples. DM% ≤ 18.8 was considered as diarrhea (1) and was used (if necessary) to reclassify the pigs as diarrheic (cases) or non-diarrheic (controls) in the statistical analysis. Chi-sq test was applied for unconditional testing of different pathogen prevalence in pigs with and without diarrhea.

**Results**

Twenty-four non-diarrheic and 12 diarrheic pigs (determined at clinical examination) were reclassified according to the DM% determination. Eight pigs were excluded from analysis. Results are displayed in Table 1. Infection with one or more of the listed pathogens was demonstrated in 76% of the pigs with diarrhea and 69% of the pigs without diarrhea. There were no significant (p>0.05) differences between the prevalence of pathogens found in pigs with and without diarrhea:

</tbody>
</table>

* Demonstrated by bacteriological culturing

**Discussion**

The non-significant differences in the prevalence of pathogens found in pigs with and without diarrhea could imply that the detected infections were not the cause of diarrhea. It may also imply that the non-diarrheic pigs were in the incubation phase of diarrhea development or that some pigs were able to resist the infections without having diarrhea. In the latter case the results imply that it does not matter whether samples for microbiological examinations are collected from pigs with or without diarrhea. However, a quantitative evaluation of the pathogens present in the two groups might tell a different story. Further conclusion awaits the remaining microbiological examinations by quantitative real-time PCR for detection of PCV2, Lawsonia intracellularis, B. pilosicoli and E. coli.

Frequency of enteropathogens in diarrheic and non-diarrheic neonatal piglets

Eduardo C. Cruz Jr.1 Felipe M. Salvarani1 Isabella S. Alberafo1 Rodrigo O. Silva1 Francisco F. Lobato1 Edel F. Stancioli2 Roberto M. Guedes1
1. Universidade Federal de Minas Gerais, Veterinary School, Belo Horizonte, MG, Brazil; 2. Institute of Biological Sciences, Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil

Introduction

Enteric diseases represent the most important cause of losses in neonatal piglets due to antimicrobial use, labor, reduced weaning weight and mortality (1). The most important agents involved with enteric disorders up to 7 days of age are enterotoxigenic Escherichia coli (ETEC), Clostridium perfringens types A and C, Clostridium difficile, Rotavirus and Isospora suis. There is little information regarding the frequency of these agents in Brazilian swine production systems. As a result, the aim of this study was to establish the frequency of enteropathogens in diarrheic and non-diarrheic neonatal piglets.

Material and Methods

Sixty 1 to 7-day-old piglets from 15 different swine farms (2 diarrheic and 2 non-diarrheic piglets, age matched, per farm) were euthanized and evaluated. A fresh stool sample was taken from each animal and submitted to different analysis, such as: E. coli isolation and typification using PCR multiplex for virulence factors (2); Rotavirus detection using poliacrylamide gel electrophoresis (PAGE); C. difficile toxins detection using an ELISA kit; C. perfringens isolation and typification (type A or C) based on a multiplex PCR; and a flotation fecal test for detection of I. suis oocists. Jejunum, ileum, colon and cecum segments were collected and formalin fixed for histopathological evaluation. This project was approved by the ethics committee for animal experimentation of the Universidade Federal de Minas Gerais.

Results

C. perfringens type A was the most frequent agent detected, being present in 43.3% of the diarrheic piglets and in 83.3% of the non-diarrheic ones. However, for all C. perfringens type A, 76.9% of the diarrheic animals were β2 gene positive, while 64% of the non-diarrheic animals had the β2 gene. No C. perfringens type C was detected. C. difficile was the second most frequently detected agent, present in 23.3% and 10% of diarrheic and non-diarrheic piglets. Rotavirus and E. coli were the third most important enteropathogens (Table 1).

Eight piglets out of 10-ELISA positive for C. difficile had significant neutrophilic colitis. Three of four Rotavirus PAGE positive animals had necrosis of the tip of villi. Only one animal had cocobacilar bacterial colonies adhered to enterocytes compatible to ETEC. No histologic lesion was attributed to C. perfringens type A even though there were some positive β2 results.

Discussion

Our results were similar to YAEGGER (3) who found 47% and 48% for C. perfringens type A and C. difficile, respectively, in young piglets with diarrhea. However, one should be careful as C. perfringens type A and C. difficile are part of the normal flora and were also detected in non-diarrheic piglets. As a result, there is no easy diagnosis and the results should be interpreted with cautious. Histopathological findings should also be considered. Rotavirus was not highly prevalent but was present in a significant number and should not be forgotten. ETEC frequency was low, as demonstrated in different studies (3). It is important to emphasize the relevance of performing the detection of virulence factors in order to diagnose relevant ETEC strains.

Clinical and laboratory investigations in 10 French pig herds dealing with enzootic neonatal diarrhea

Thomas Gin1 Jean Le Guennec2 Hervé Morvan3 Guy-Pierre Martineau1
1. National veterinary school, Toulouse, France; 2. Labofarm, Loudeac, France; 3. LDA22, Ploufragan, France

Introduction

Although non fatal, enzootic neonatal diarrhea (END) is still a problem in many French swine high producing herds[1]. Dealing with this issue, veterinarians have to perform a diagnosis in order to well implement the treatment and the prevention. In this paper, we focus on the diagnosis approach of END.

Materials and Methods

The study was conducted in 10 French farrow-to-finish pig farms (see Materials and Methods in: Gin et al., 2010). In order to identify the onset of diarrhea, piglets were watched 3 times a day and during 7 consecutive days. Four piglets from 2 different litters, having diarrhea for less than 12 hours, were euthanized and on-farm necropsied. Microbiological analyses were performed on samples from the small and large intestine, kept at 5°C after the necropsy. Histological examinations were performed on samples (kept in formaline 10%) from duodenum, jejunum, ileum and helicoidal part of the colon. Microbiological and histological analyses were performed by LDA22 (Ploufragan, Côtes d’Armor, France) or by Labofarm (Loudéac, Côtes d’Armor, France), depending on the location of the farm.

Results

Although herds were selected for END, 2 farms remained diarrhea free during the week of investigation. This is an illustration of END variability between different batches within the same herd.

Clinical investigation highlights that END is an issue in very good herds (average of 11.4 piglets weaned per sow per litter) where producers and veterinarians are implementing a lot of interventions: zootechnical interventions (cross-fostering, change of the processing date…) and medical interventions (antibiotics, symbiotics, autogenous vaccines,…). However, nothing seems to be working and, sometimes, it is getting worse.

Necropsies highlight prevalence of mesocolon edema observed in 6/8 herds (17/27 piglets) but with different etiological diagnosis. Therefore, there is no link between a specific pathogen (like C. difficile) and mesocolonic edema.

On 8 etiological herd diagnosis, there were 2 cases of Enterococcus durans, one case of C. difficile, one case of both, C. difficile and E. durans, 3 cases of C. perfringens type A, one case of rotaviral diarrhea and none with E. coli.

Discussion

In human medicine, especially in hospital, daily interventions can quickly spread a pathogen like C. difficile for example[4]. Recently, it was shown that C. difficile is a concern in intensive care units for cats and dogs5. In a given herd, a farrowing room could be compared to an hospital. The producer is like a nurse: he/she is going from litters to litters, moving animals and performing some treatments. During all these interventions (zootechnical and medical), the producer can easily spread a “pathogen”. This is called a nosocomial disease and it may be a “new” risk factor of END.

Moreover, always in human medicine, antibiotics can induce diarrhea and Antibiotic-Associated Diarrhea6 starts to be better understood (Figure). This is called a iatrogenic disease and it may also be another “new” risk factor of END.

Finally, Enterococcus durans diarrhea occurs mainly in litters from parity 1 and 2 sows, 3 to 5 days after birth. Before having a very watery diarrhea, piglets are often vomiting. Usually, the whole litter is having scour and death occurs quickly if an appropriate antibiotic treatment (such as florfenicol or amoxicillin) is not implemented. Acute enteritis with a small intestine full of water is observed during necropsies. Histological analyses reveal gram positive cocci bind to the jejunal and ileal epithelium.

To conclude, this field study shows that neonatal diarrhea is changing with “new” pathogens (E. durans) and, beside other new identified risk factor[1], other risk factors such as nosocomial and/or iatrogenic diseases have to be considered.

Diagnostic of post-weaning diarrhoea on the farm level
Albert Sundrum; Amke Goebel; Christina Werner
University of Kassel, Witzenhausen, Germany

Introduction
Post-weaning diarrhoea (PWD) is a multi-factorial disease. Clinical symptoms are often linked to a combination of different factors such as low feed intake after weaning, low hygiene, low age at weaning, low piglet live weight at weaning, and a high number of piglets per pen (Madec et al., 1998). Associated with the myriad of stressors to which the piglets are subjected in the weaning process, are marked changes to the digestive and absorptive capacity. Therefore, intake of creep feed and diet composition can have severe impacts on the occurrence of PWD (Callesen et al., 2007) too. Although organically reared piglets are, in general, six weeks of age at weaning, and are kept with a high space allowance, post-weaning diarrhoea is a severe problem in organic pig production (Bonde & Sörensen, 2006; Sundrum et al., 2010). Due to restrictions in the use of antibiotics in organic livestock production, there is a need to focus primarily on the implementation of preventive measures. When health problems are recognised, it is of high importance to make an accurate diagnosis and identify the farm-specific causes to enable the elimination of relevant risk factors. The objective of this study was to assess, qualitatively, the possible causes of weaning diarrhoea in an on-farm approach on those organic farms which have previously reported about PWD problems.

Material and Methods
Case studies were performed on six organic sow herds in Germany, affected with PWD problems. Clinical examinations and data on critical control points (CCPs) were assessed on the farms in an interval of 6 months. On the first visit a comprehensive interview was carried out with the herd manager gathering information on performance level, mortality and morbidity rates, hygiene management, feeding regime, and medicine usage. Piglets were housed in stables with outdoor runs. Weaning age averaged 44.8 days. Feed was purchased from an independent feed mill, creep feed and post-weaning diets were analysed for crude nutrient content.

Faeces were collected on each farm via swabs from five clinical healthy and five piglets suffering from postweaning diarrhoea, respectively. Faeces were analysed microbiologically for content of haemolytic E. coli. Differential analysis includes salmonellosis, swine dysentery, porcine proliferative enteropathy and porcine colonic spirochetosis.

Preliminary Results
The second visits on the farms have just started so that currently only preliminary results have been obtained.

The examination of the CCPs showed that all farms showed more or less severe deficits in the hygiene management and in the nutrient regime, although varying in their details considerably between the farms. Laboratory analyses provided proof for the presence of different strains of haemolytic E. coli, Brachyspira pilosicoli and Lawsonia intracellularis, independent of the health status of the piglets.

After interpretation of all data, farm specific measures have been recommended to the farmers. Effects of the implementation of measures will be assessed on the second farm visit.

Implications
Effective clinical management includes the identification of risk factors and the implementation of changes aimed at reducing the incidence of PWD. Further investigations should be directed towards the impact of hygiene management and feeding regime on piglet susceptibility to GIT disorders and enteric infections. The development of diagnostic tools to be used on the farm level should be enforced to enable appropriate and promptly counteractive measures.

Is pathomorphology sufficient for diagnosis of enteritic infections?
Sabine Elicker1 Daniela Philadelphy1 Franz Schilcher1 Louis Fischer3 Herbert Weissenböck1 Wolfgang Sipos1

Introduction
Enteritides continue to be amongst the most important factors that limit the profitability and efficiency in pig industry. For this reason exact diagnosis is needed in order to avoid great economic losses [1, 2]. Therefore the aim of this retrospective study was to look for possible relations between diarrhea-causing pathogens and pathological findings of the gastrointestinal tract of swine suffering from enteritis to possibly provide a useful tool for diagnosis in the field.

Materials and Methods
Results of the clinical, pathomorphological, and bacteriological examinations from 444 pigs (29 suckling and 314 weaned piglets, 88 fatteners, and 13 sows) all suffering from diarrhea, which were submitted to the Clinic for Swine at the University of Veterinary Medicine Vienna over a period of three years, were analysed with pathological findings only being taken into account in cases of monoinfection. Pathological findings were classified as serous-catarrhal enteritis, hemorrhagic-necrotizing enteritis, fibrinous enteritis, ulcerative enteritis, thickening of the ileal or colonic mucosa, mesenterial edema, lymphoplasmacytic enteritis, lymphocyte depletion of the MALT, and crypt abscesses.

Results
Infections with one or more bacterial pathogens could be detected in only 72.1 % of investigated pigs. However, no causative pathogen was found in the remaining 27.9 %. Most frequently, E. coli could be isolated (59.0 %), followed by infections with L. intracellularis (10.4 %), Cl. perfringens (9.7 %), Brachyspira spp. (5.0 %) and Salmonella spp. (1.4 %). Monoinfections with one of these pathogens were determined in 122 animals. Pathomorphologically, in most cases (63.9 %) a lymphoplasmacytic enteritis could be diagnosed irrespective of the pathogen. A reliable hint for a mutual occurrence of a specific pathogen and a corresponding pathomorphological finding was only seen in infections with L. intracellularis. In the majority of these cases (87.5 %) the ileum exhibited a thickening of the mucosa.

Discussion
The only correlation between a specific pathogen and a pathomorphological finding could be demonstrated for L. intracellularis-infections. Therefore, it can be concluded that all other bacterial pathogens causing enteritic infections in pigs do not go hand in hand with specific lesions.

In a large proportion of cases no causative pathogen could be isolated. When taking into account that in most cases a lymphoplasmacytic enteritis could be diagnosed, an infection by some viral pathogen is conclusive. As a consequence these results may give a hint towards PCV2 being a possibly important pathogen also in cases of diarrhea. However, we did not prove this assumption by further molecular diagnostic techniques.

Clinical case of diarrhea with E. coli F4 in late fattening pigs: is it relevant?

Philippe Leneveu1 Marianne Bertrand2 Alassane Keita3 Hervé Morvan4 Roland Foret5 Catherine Belloc6

Introduction

Aetiology of Grey Scour Syndrome (GSS) is a matter of question in France. Lawsonia intracellularis (LI) and Brachyspira sp (Br) have been isolated from faeces of pigs with GSS in some cases but not in the majority of concerned farms (1). However, the prevalence of LI is as high as in the others countries (2). Escherichia coli is the most common pathogen found in GSS but its role as a causative agent is questionable. This paper discuss a case of late colibacillosis.

Materials and Methods

A field investigation was carried out in a selected farrow to finish farm (200 sows) concerned by GSS and heterogeneity. An outbreak of diarrhoea usually occurred during post weaning (8 weeks of age) followed by GSS until 12 weeks. A batch of 308 pigs was monitored from weaning to slaughter. Several clinical evaluations were conducted, with sampling of faeces and blood. If we observed an increase in GSS intensity or otherwise at the end of the follow up (145 days), it was planned to euthanize 9 pigs at laboratory: 3 with clinical signs of diarrhoea or doubtful body condition, 3 lean pigs (lp) and 3 control pigs (without diarrhoea). Digestibility was evaluated by analyzing colonic content: flora, digestibility of organic material (DO, %) evaluated by the use of indigestible part of the feed as a marker and volatile fatty acids (Vfa, g/l).

Results

Two main outbreaks of liquid diarrhoea with general clinical signs occurred at 48 and 97 days of age respectively. For the first one, 3 different E. coli were found on 3 necropsied pigs. Only non typable E. coli has been identified for the second one (sickest pigs were under treatment at sampling time). At each herd examination some pens were concerned by diarrhoea (evident or doubtful situation) with a maximum of 50% of the pens at 77 days. As GSS was mild, pigs were euthanized at 145 days (Table 1). Diarrheic pigs didn’t seem to be sick but E. coli F4 was found attaching the small intestine on the two heaviest.

This farm was positive for LI and this batch had seroconverted between 109 days (1+/16 pigs, ELISA) and 145 days (6+/16). Necropsy of lean pigs didn’t give relevant information: peritonitis / no lesion / pneumonia and pleuritis respectively. No histological lesion of PCV2 was found on any pig.

Digestibility of organic mater wasn’t depreciated on these diarrheic pigs but their fermentation in colon was low (Vfa).

Discussion

Normal digestibility on these diarrheic pigs is relevant with their weight and aspect. Hence, due to the lack of other clinical signs and their optimal weight, we can wonder on the real impact of this late colibacillosis. Moreover, the batch had not been treated and nothing happened. We can also wonder if the diarrhoea is due to the colibacillosis, to the lack of fermentation in the gut or the both. This case suggests then to minimize the importance of E. coli isolated on fattening pigs not showing global clinical signs (situation different from postweaning diarrhoea).

Therefore one hypothesis could be a mix of different profiles for GSS in France: profile of economic importance when due to LI for example; profile of more doubtfully economical importance when associated with E. coli only.

Authors thank Boehringer Ingelheim for its financial support in this field investigation.

Prevalence of enterotoxigenic Escherichia coli (ETEC) virulence genes isolated from scouring piglets in Taiwan

YF Sun; MH Liao; MC Lee; SP Chen
ATIT, Miaoli, Taiwan

Introduction
Enterotoxigenic Escherichia coli (ETEC) are associated with diarrhea in neonatal and post-weaning piglets, and these infections constitute an important problem relating to farrowing in modern intensified piggery management. The strains of ETEC associated with intestinal colonization in piglets resulting in hypersecretory diarrhoea express F4, F5, F6, F17, F18 and F41 fimbriae and/or STa, STb and LT enterotoxins. Most studies of the prevalence of fimbrial adhesins and enterotoxins of porcine ETEC isolates have been conducted, until recently, by the use of polymerase chain reaction (PCR). Previous studies using enterotoxin genes cloned into a nontoxigenic fimbriated strain have suggested that both LT and STb play an important role in dehydrating diarrheal disease in piglets <1 week old and also enhances bacterial colonization of the intestine. Little is known about fimbriae associated with piglet ETEC-induced scours in Taiwan. Therefore, our aim was to investigate the prevalence of toxin and fimbrial genes among E. coli isolated from diarrheic piglets obtained over a 3-year period (2007-2009) in Taiwan.

Materials and Methods
Between 2007 and 2009, a total of 426 E. coli strains were isolated from piglets with diarrhea at sucking and weaning periods on 12 pig farms in Taiwan. After incubation at 37˚C for 18 hr on MacConkey’s and Blood agar plates, single colonies were selected and identified as E. coli. The identification of β-hemolysin in all of E. coli strains were conducted visually after overnight growth on SBA. The detection of fimbrial and enterotoxin genes was performed by PCR. E. coli reference strains were used as positive control for each virulence factor detected by PCR, and a non-pathogenic commensal E. coli strain was used as a negative control. PCR for the identification of fimbrial (F4, F5, F6, F18 and F41) and enterotoxin (STa, STb and LT) genes was carried out as previously described (Do et al., 2005). Amplification procedures were carried out in a thermal cycler (TaKaRa, PCR Thermal Cycler Dice). Reactions were incubated at 94˚C for 3min for 1 cycle, then 94˚C for 30 sec, the melting temperature for 30 sec and 72˚C for 90sec for 35 cycles, followed by a final incubation 72˚C for 3min. The PCR products were analyzed by electrophoresis on 1.5% agarose gel, and the amplicons were visualized under ultraviolet light after ethidium bromide staining.

Results
A total of 426 E. coli isolates were screened for those genes by PCR. The prevalence of pathogenic ETEC among E. coli strains from field isolates was 114(26.8%) strains in the present study. Of these 114 isolates, 103 (90.4%) carried at least one ETEC virulent gene and 44 (38.6%) carried genes for the fimbrial adhesins. Percentages of E. coli strains carrying each virulence factors were as follows: F4 (6.14%), F5 (8.78%), F6 (13.16%), F18 (10.53%), STa (84.2%), STb (85.09%), LT (43.86%). We assessed whether the presence of enterotoxin genes (STa, STb, LT and Stx2) could be correlated with the presence of fimbrial genes (Table 1). STa/STb enterotoxin genes were co-expressed in F5, F6 and F18 of the ETEC strains. STa/STb/LT were found to co-express with F4 and F41 genes. STa enterotoxin was found to co-express with F6 and F18.

Discussion
The present study was conducted to provide baseline information on the significance of specific ETEC serogroups and pathotypes associated with diarrhea in piglets. These results suggest STa/STb was the most prevalent pathotype in diarrheal piglets, which is different from the findings in USA (Zhang et al., 2007). A highly prevalent toxin in USA is STb (72.6%). Different patterns of fimbrial gene expression were detected in ETEC from different pig farms in Taiwan. Therefore, vaccination and vaccine development based on fimbrial adhesion antigens needs to consider the spectrum of these antigens detected in pig farms in Taiwan.

Prevalence of virulence genes of Escherichia coli isolated from diarrheic pigs in Korea
Byeong Y. Jung; Jae W. Byun; Ha Y. Kim; Dong H. Shin; Hyoung S. Kim; O S. Lee
National Veterinary Research & Quarantine Service, Anyang, Korea

Introduction
Escherichia coli strains such as enterotoxigenic E. coli (ETEC), and shiga toxin-producing E. coli (STEC) are associated with diarrhea and edema disease in pigs. Adherence factors (F4, F5, F6, F18, F51, adhesion involved in diffuse adherence [AIDA]-I, and porcine attaching and effacing-associated factor [paa]), heat-stable enterotoxins (STa and STb), heat-labile enterotoxin (LT), and enteroaggregative E. coli heat-stable enterotoxin 1 (EAST1) have been known to be virulence factors of ETEC (1). Shiga toxin 2e (Stx2e) produced by STEC plays an important role in the pathogenesis of edema disease in postweaned pigs. The objective of this study was to determine the prevalence of virulence genes among E. coli isolated from pigs with diarrhea in Korea.

Materials and Methods
One hundred thirty five E. coli were isolated from diarrheic pigs on different farms in 2009 in Korea. Pigs were divided with four different age groups, suckling (≤3 weeks of age, n=65), postweaning (>3 weeks to <10 weeks, n=40), growing (≥10 weeks to <17 weeks, n=22), and finishing (≥17 weeks, n=8), respectively. After incubation at 37˚C for 18 hr on MacConkey agar plate, a single colony was pick up and identified as E. coli by VITEK 2-Compact system (bioMerieux, France). β-Hemolysis was defined as a zone of complete erythrocyte lysis surrounding a bacterial colony observed after an overnight grown at 37˚C on a blood agar plate. The isolates were grown overnight in tryptic soy broth and stored at –80˚C after the addition of 10% glycerol until further use.

For PCR test, 12 sets of oligonucleotide primers (Bioneer, Korea) used to detect the genes encoding for the following virulence factors: adherence factors (F4, F5, F6, F18, F41, AIDA-I, and paa) and enterotoxins (STa, STb, LT, STx2e, EAST1). The PCR assay for detection of virulence factors of the isolates was carried out as described previously (2).

Results
Of 135 E. coli isolates, 78 (57.8%) were shown to be positive for the genes encoding more than one of the virulence factors. Forty eight isolates (35.6%) carried both adherence factors and enterotoxins. A presence of diverse patterns of genetic profiles in virulence was observed, and the most prevalent pathotype was EAST1 only (n=15, 11.1%), followed by EAST1/paa (n=11, 8.1%), and paa only (n=7, 5.2%), respectively.

The prevalent pathotypes were determined by age. F4, LT, EAST1, and paa pathotypes were detected all age groups of pigs, whereas F5 was not detected in this study. F4 was the most prevalent in the postweaning pigs (22.5%) compared with the suckling (13.8%), finishing (12.5%), and growing (9.1%), respectively (P>0.05).

Almost all the virulence genes tested (F4, F6, F18, LT, STa, STx2e, EAST1, and paa) were more prevalent in β-hemolytic E. coli than in non-hemolytic E. coli (P<0.05). On the other hand, prevalence of STb and AIDA-I in this study was higher in non-hemolytic E. coli than β-hemolytic E. coli, but this difference was not significant.

Discussion
The isolates showed the diverse patterns of virulence genes with LT/EAST1/F4 (n=5), followed by EAST1/F4 (n=3), EAST1/F4/paa (n=3), STa/F6/F18/paa (n=3), and EAST1/STb/AIDA-I (n=3), respectively. The isolates of E. coli that harbor genes for adherence factors or enterotoxins are classified as ETEC, and pathogenic ETEC that cause colibacillosis must have both of them (3). The EAST1 gene was reported commonly found in E. coli isolated from diarrheic pigs. Frydendahl (4) reported that 65.8% of the isolates carried the EAST1 gene, however, E. coli isolated from pigs without diarrhea also carried this EAST1 gene (5). On the other hand, paa gene was demonstrated to be necessary for development of lesion caused by EPEC strains (6). However, paa gene was detected nearly even in isolates from diarrheic and non-diarrheic pigs, suggesting that the paa gene may not be a virulence factor in diarrhea (5).

In this study, we found that EAST1 was most prevalent in diarrheic pigs in Korea, followed by paa, and F4, respectively. And also, we found that almost all the virulence factors tested in this study were more prevalent in β-hemolytic E. coli than in non-hemolytic E. coli.

Introduction

In Cuba, gastroenteric disorders are the cause of the 31% and 37% of mortality in suckling and weaned piglets respectively. Taking decisions when an outbreak starts is difficult as specific diagnose of enteric pathogens is depressed (Cabrera and García, 2009). The present survey has the aim of contributing to the knowledge of the colibacillosis epidemiology in Cuba, specifically for F4+ and F18+ Escherichia coli.

Materials and Methods

1044 sera samples were randomly collected from gilts (6-8 months old) in 34 piggeries spread in the three main Cuban regions. The complement inactivated serum was treated with kaolin and tested for anti-F4 and anti-F18 Ig at the fix dilution of 1/15 in duplicates. Both fimbriae were purified by mechanical sharing protocol using the strains IMM01 (F4ac-LT-STb+) and 107/86 (F18ab-SLTIIv+). For F4 it was followed an indirect double antibody ELISA and for F18 a direct one. For the data analysis, that included the optical density values (OD), was fitted a mixture modeling in R (package “flexmix”)(Leisch, 2004).

Results

F4 and F18 are highly prevalent in Cuba. A three components model was fitted for F4 as represented by the 3 thinner curves (Fig 1), while the thicker is the estimated mixture model. The cut-off points were given by the curves intersection: between weak and moderately positives was 0.775, while between moderately and highly positives was 1.343. Fig 2 shows the description of farms (finest cluster division) depending on the OD of serum samples, different letters mean different geographical areas. Piggeries were clearly distributed in each component showing a different epidemiologic situation. For F18 OD, only a one component model was found and the Box plot description was homogeneous.

Discussion

Considering a no previous vaccination against F4, the distribution of F4 OD in three components with the 14% and 42% classified as hard and moderately positive respectively, means that in Cuba is a high prevalence or association of F4+ E. coli in diarrhea episodes. From 1997 to 2001, Lazo et al., (2005) clinically reported a 43.8% of morbidity and 29.3% of lethality due to swine enteric colibacillosis in V. Clara, Cuba. Verdonck et al., (2002) mentioned that the slower immune response following a F18+ VTEC infection and the resulting longer excretion increases it’s spreading, it can justify in part the F18 OD distribution, but F18+ ETEC strains have to be considered. In a later study F4-Sta-STb+, F18-VT2e+, F18-LT-STb+ E. coli were isolated from diarrheic piglets in a Cuban province (de la Fé, P., Butaye, P., Goddeeris, B., Cox, E., manuscript under preparation).

Conclusions

F4+ and F18+E. coli are widespread in Cuban piggeries as proved by serological survey and mixture modeling. A more effective diarrhea prevention and control is needed.

Influence of different housing systems and feeding regime on E. coli problems of post-weaning piglets in Central Vietnam

Nguyen Quang Linh; Hoang Nghia Duyet; Nguyen Thi Thuy
Hue University of Agriculture and Forestry, Hue City, Vietnam

Introduction
Post-weaning diarrhoea (PWD) is a significant gastrointestinal disease in pigs. It is considered a multifactorial disease associated with proliferation of enterotoxigenic *Escherichia coli* in the intestinal tract of affected pigs. The aim of this study was to analyse risk factors related to the occurrence of post-weaning diarrhoea on Vietnam piglet producing farms. In Central Vietnam, many pig farms have the problems for piglets after weaning periods, there is no vaccine for the prevention and control, it was impact on their farm income and decrease pig production in Vietnam.

Materials and Methods
The data of a follow-up study of 72 conventional piglet producing farms was used in the case-control study. The selection of the 36 PWD case and 36 control piglets. All of piglets were raised on 6 pig farms that was based on the use of antimicrobials for treating diarrhoea in weaned pigs and the answers related to the occurrence of diarrhoea after weaning in the questionnaire. Four intermediate farms were excluded from the statistical analysis. Altogether 36 factors related to herd characteristics, weaner pig management and pig health were studied. The median number of sows was the same breed and feeding situation on the case and the control farms, respectively. The significances of the univariable associations between the explanatory variables and the outcome variable were tested, and in the multivariate analysis linear models were applied.

Results
An decreased risk of PWD was associated with the regimen of feeding levels, twice a day and feed restriction after weaning (P = 0.05; compared to feeding three or more meals a day or the use of *ad libitum* feeding) and with a rotation housing system of sows on the farm (P = 0.01; risk decreasing with increasing housing systems for sows removed from farrowing pens). Temperature and humidity control was associated with a decreased risk of PWD (P = 0.03; compared to manual temperature and humidity control).

Discussion
Temperature and humidity for resistance to pathogenic bacteria that is a global threat and therefore increasing attention is being paid to the prudent use of feeding control[1]. Gastrointestinal diseases of growing pigs, which are economically important for pig production worldwide [2] and enteric bacterial infections. The total of feeding levels in pigs and that gastrointestinal diseases were the most common indications for prescriptions in this age group[1]. PWD is considered to be a multifactorial factors[2]. Recently weaned pigs are variously predisposed to enteric disorders. Newly weaned pigs are stressed by nutritional, psychological, environmental and physiological factors [3]. At weaning the feed is changed from milk to a weaner diet, piglets are separated from their sow and often moved from the farrowing pen and mixed with unfamiliar pigs. Weaned pigs also lose passive intestinal immunity provided by antibodies in sow’s milk. After weaning there are alterations in stable in farrowing pens until 2 weeks after weaning. During the first two weeks after weaning, pathogenic *Escherichia coli* plays a significant role in the etiology of PWD [1,2], although infection with pathogenic *E. coli* does not unequivocally lead to the development of diarrhoea in weaned pigs. Housing systems with pathogenic *E. coli* strains are likely sources of infection for weaned pigs, but the infection can also be acquired before weaning. The susceptibility for diarrhoea after weaning has been associated with management related factors such as low feed intake during the first week after weaning, excessive feed intake, low number of meals, the hygiene and management level, a low weaning weight and age, moderate cold stress, draught, texture of feed, number of feeder spaces per pen and vaccinating gestating sows against *E. coli*. A satisfication of temperature and humidity in the housing during first two weeks after weaning with a decreased risk of PWD. This study was done to provide information on risk factors related to the occurrence of PWD on weaning piglet producing farms.

**Introduction**

Diseases caused by *E. coli* have been a recognised problem for as long as pigs have been raised. Different categories of *E. coli* have been associated with diarrhoeal disease in animals worldwide with Enterotoxigenic *E. coli* (ETEC) and Shiga toxin-producing *E. coli* (STEC) being the most common (DebRoy & Maddox, 2001). The objective of this study was to compare the distribution of virotypes of pathogenic *E. coli* isolates from diseased pigs in two geographically distinct countries, Vietnam and Canada.

**Materials and Methods**

*E. coli* isolates obtained from diseased pigs (diarrhoea, sudden death or edema disease) in 2007 and submitted to the NIVR in Vietnam or the FMV in Québec, Canada, were initially tested by PCR for the presence of defining genes of ETEC and STEC pathotypes. They were then virotyped by colony hybridisation (Ngeleka et al., 2002) for detection of the presence of 20 virulence genes most commonly found in animal pathogenic *E. coli*.

**Discussion**

Our results demonstrate that the most important pathotypes associated with diarrhea, ETEC F4, ETEC F18, and ETEC F5, and edema disease, STEC F18, are present in both countries. On the other hand, typing using additional virulence genes permitted further discrimination of the isolates, which demonstrated that distinct virotypes predominate in each country. Interestingly, the ETEC-F18 pathotype, was very frequently observed in Vietnam, but was not identified in isolates from Quebec. Thus, virotyping is a valuable tool for monitoring the geographical distribution of virotypes worldwide and the emergence of new pathogenic variants. We are presently setting up a database for the global surveillance of animal pathogenic *E. coli*.

Identification of virulence genes of E. Coli in diarrheic pigs in the preweaning and postweaning period by simple and duplex PCR assay

Jorge R. Lopez
Universidad Nat. Autonoma de Mexico, México, DF, Mexico

Introduction
Diarrhea in pigs from the nursery and post-weaning are mainly of infectious origin and cause economic losses of great magnitude. Strains of enterotoxigenic E. coli (ETEC) and E. coli that produce Shiga toxins (STEC) cause this disease. The virulence factors such as fimbriae and toxins produced by this bacterium are involved in the establishment of the disease. Fimbriae and most common toxins produced by E. coli are F4, F5, F6, F18, F41, Sta, Stb, LT and Stx. In the present study, the aim was to identify virulence genes of E. coli associated with porcine diarrhea using PCR.

Material and Methods
One hundred and sixty six fecal samples obtained from pigs with diarrhea in five Mexican farms, shows that 113 belong to pigs with diarrhea and 53 to pigs without diarrhea. E. coli strains were isolated in Eosin Methylene Blue (EMB) solid media and MacConkey subsequently underwent biochemical tests. The extraction of DNA from the isolates was done according to Zhang (5). PCR assay simple and duplex using eight specific oligonucleotides as primers were used for the identification of the eight virulence genes (LT, Sta, Stb, Stx1, Stx2, F18, F41 and F4). The conditions of the PCR’s used were in accordance to what has already been reported, with some modifications (1, 2, 3, 4). Amplification products were identified by agarose gels and stained with 2% ethidium bromide. Reference strains were used as positive and negative controls for each one of the genes.

Results
One hundred and fifty samples corresponded to E. coli, where 110 (73.33%) were positive for one or more virulence factors of ETEC and EHEC, of which 30 (52.7%) were from nursing piglets and 41 of weaned pigs. Strains from piglets without diarrhea, 39 (84.8%) had one of the genes studied (Table 1).

Discussion
Sta was the toxin detected in 31%, consistent with studies by Thuy N., Do et al., Cicuta M.E. et al. and Chen X et al. (6,7) The F41 fimbriae gene was found in more than 59% unlike other countries where F41 is detected in less than 3%. This is of great importance, since it is a new finding and allows us to consider that the strains of E. coli isolated from pigs in Mexico, exhibit different virulence gene profile from those reported by other countries (Table 2). There were 19 combinations; the most frequent was Sta/F41 at 11.3%. This work is of great importance, since it is one of the first made in Mexico on the detection of virulence genes of E. coli in nursing and weaned pigs, using this technique suggests that both the fimbriae and toxins are important for the presentation of diarrhea in nursing and weaned pigs. For this reason, our work in a second step will allow us to develop a rapid and accurate diagnostic method of this enteric disease related to E. coli infections.

Comparing PCR-methods diagnosing fimbriae and toxins with serotyping of E. coli

Sigbrit Mattsson; Lennart Melin; Per Wallgren
Dept of Animal Health and Antimicrobial Strategies, Uppsala, Sweden

Introduction

Serotyping of E. coli from piglets with diarrhoea gives a historical view of disease patterns, but is laborious as there are more than 170 O-serotypes of E. coli (1). The panels used must for practical reasons be limited, and despite continuous updating around 50% of the samples often turn out as O?. As the most essential for clinicians are to achieve knowledge of whether the strains are potentially pathogenic or not (2) diagnosing presence of adhesion fimbiae and enterotoxin production instead of serotyping is tempting. Thus, PCR-methods have replaced serotyping in many laboratories.

Despite change of method, still only around 50% of the samples in Sweden were diagnosed as potentially pathogenic. When these PCR-positive isolates were serotyped, in general only O149 and O147 were diagnosed. Thus, it appeared that some information received by serotyping had been lost. Therefore the aim of this work was to serotype E. coli isolates previously diagnosed by PCR.

Materials & Methods

E. coli from pig herds with diarrhoea during 2009 were analysed for presence of toxins (LT, STa, STb, VT2e) and adhesion fimbiae (F4, F5, F6, F18, F41) by multiplex PCR systems. All isolates were thereafter serotyped with a panel of 16 different O-groups, previously confirmed to be the most common in Swedish pigs with diarrhoea caused by E. coli. Also, the MIC-values to 12 different antimicrobial substances were analysed (3).

Results and Discussion

As seen in the Fig 1 & 2, serotyping identified 126 out of the 306 samples scrutinised (41%). The PCRs identified 110 isolates as potentially pathogenic (36%). Generally these strains belonged to serotypes O149 or O147. Serotypes O8, O9, O45 and OX179 were never identified by the PCR systems. Together PCR and serotyping identified 149 strains as potentially pathogenic (52%).

The resistance pattern was favourable (3) and fairly equal for different categories of E. coli (Figs 2 & 3). More than 91% of the strains were sensitive to 8 of the 12 substances tested. Sixteen strains (5%) were resistant to 4 substances or more.

In conclusion, PCR will diagnose some E. coli strains that express common pathogenic factors. However, some potentially pathogenic serotypes may remain undetected. Serotyping is still a diagnostic tool to use as a complement to PCR in herds with diarrhoeic problems.

Vaccination with Coliprotec® vaccine for the prevention of post-weaning diarrhea associated with F4(K88)-positive enterotoxigenic Escherichia coli (ETEC)

Eric Nadeau1 Danielle Tremblay1 John M. Fairbrother2
1. Prevtec Microbia, Saint-Hyacinthe, QC, Canada; 2. University of Montreal, Saint-Hyacinthe, QC, Canada

Introduction
ETEC harboring F4 (K88) fimbriae are recognized as the major cause of post-weaning diarrhea (PWD) (1). A genetically inherited receptor for F4 (F4R) located in the villous brush border facilitates binding of ETEC-F4 to intestinal villi leading to colonization and disease. Antimicrobials are frequently used on farms to treat PWD but emergence of resistance has been observed for causative strains (2). The objective of this controlled challenge study was to evaluate the efficacy of a single oral dose of Coliprotec® (Prevtec Microbia Inc.), an avirulent live E. coli vaccine, to prevent PWD caused by ETEC-F4 in situations of low and high infectious pressure.

Materials and Methods
The study consisted of 2 trials, each including a group vaccinated with Coliprotec® and a group receiving sterile water as a placebo. Trial A (low infectious pressure) consisted of 20 pigs per group with 5 and 8 RF4-positive pigs for the vaccinated and placebo groups, respectively. Trial B (high infectious pressure) consisted of 20 and 21 pigs, with 18 and 20 RF4-positive pigs, for the vaccinated and placebo groups, respectively. For both trials, weaned pigs of 18±1 days of age were introduced into isolation facilities on day 0. At day 1, pigs received an oral dose of the Coliprotec® vaccine using a syringe, as per label instructions, or placebo. On day 8, all pigs were challenged via gavage with the virulent ETEC-F4 strain EcL 8559. The challenge inocula contained 5x10⁸ and 1x10⁹ CFU per pig for the trials A and B, respectively. Necropsies were carried out on day 11. Efficacy parameters included ileal colonization of the challenge strain (day 11), fecal excretion of the challenge strain, accumulation of fluid in the intestines (day 11; scored from 0 for normal to 3 for presence of more liquid or totally liquid), diarrhea (scored from 0 for normal to 4 for totally liquid), and daily weight gain (DWG).

Results
Trial A: The prevalence of pigs excreting the challenge strain at days 9 and 11 was significantly lower (p<0.0001) for vaccinated (0 and 26%) than for placebo pigs (100% for both days). The colonization level of the challenge strain in the ileum was also lower (p<0.0001) for vaccinated (4.0 x 10⁶ CFU/g) than for placebo pigs (1.4 x 10⁷ CFU/g). Severity of diarrhea and accumulation of fluid in the intestines was significantly lower for vaccinated than for placebo pigs (Table 1). Finally, DWG was significantly higher after challenge for vaccinated than placebo pigs (Table 1).

Trial B: All pigs of both vaccinated and placebo groups excreted the challenge strain on days 9 to 11. However, vaccination significantly reduced (p<0.0003 for each day) the level of excreted challenge bacteria in feces by 1.4, 1.7 and 2.5 LOG for days 9, 10 and 11, respectively. The colonization level of the challenge strain in the ileum was also lower (p<0.0001) for vaccinated (8.5 x 10⁴ CFU/g) than for placebo pigs (4.1 x 10⁴ CFU/g). As observed in trial A, severity of diarrhea, accumulation of fluid in the intestines and weight loss were significantly lower for vaccinated than for placebo pigs (Table 1).

Discussion and Conclusion
This controlled challenge study demonstrate the efficacy of an oral single dose of Coliprotec® to significantly reduce intestinal colonization, excretion, accumulation of fluid in the intestines and diarrhea when the overall infectious pressure is either low or high. In both situations, vaccination with Coliprotec® induced a significant protection after virulent ETEC-F4 challenge in 18±1 day-old weaner pigs resulting in normal growth rates after challenge compared to the rapid weight loss observed for unvaccinated pigs.

Control of neonatal diarrhea with commercial vaccines

SeungYoon Lee; PilSoo Jeong
Hanbyol Farm Tech, Gyeonggi-do, Namyangju-city, Korea

Introduction
Neonatal diarrhea causes poor weaning weight and high pre-weaning mortality. Recently, some farms have had this problem quite a long time. We tried to control piglet diarrhea with different commercial vaccine at two different large herds.

Materials and Methods
Two herds have around 1,500 sows each were selected for this trial. A herd has had piglet diarrhea problems for about one month(Fig1). B herd has had this problem for about one year(Fig1). Laboratory results of each herd show multiple bacterial and viral infections(Table1). Three commercial vaccines were inoculated to pregnant sows in this trial(Table2,3).

Results (see below)

Discussion
Neonatal diarrhea causes poor survival rate before weaning and weaning weight. Most of neonatal diarrhea in Korea caused by multiple agents including Rotavirus, Porcine epidemic virus(PED), Clostridium and pathogenic E. coli. Vaccine A contain multiple viral and bacterial antigen except PED virus and shows better results for controlling neonatal diarrhea in these two herds(Fig2,3). Weaning weight increased by 0.4kg per a head. Low parity sows shows neonatal diarrhea more often than high parity sows(Fig4).

Effects of Tilmicosin and Apramycin on proliferation of enterotoxemic Escherichia coli and release/production of shiga toxin 2e

Masuo Sueyoshi; Tomoko Kuroda; Ryoko Uemura; Hiroshi Nagatomo
Department of Veterinary Hygiene, Faculty of Agriculture, University of Miyazaki, Miyazaki, Japan

Introduction
The fatal accidents of piglets resulting from treatment of edema disease with antibiotics have made vets to hesitate the use of antibiotics to this disease. Various efforts have been made in the field for the treatment of edema disease, but no control or treatment methods has been established. We reported that the susceptibilities of the isolated Enterotoxemic E. coli (ETEEC) had diminished in regard to antimicrobials[1]. Furthermore, we found that more shiga toxin (Stx) 2e accumulated in the bacterial cells than was released into supernatant[2]. Therefore, evaluation of the direct effect of antibiotics to ETEEC in an experimental system will give useful information for selecting appropriate antibiotic in the field. In this study, in vitro effects of Tilmicosin (TMS) and Apramycin (APM) on proliferation of ETEEC and release/production of Stx were investigated.

Materials and Methods
The strains used for this study were ETEEC MVH 269 (O 139 serotype, stx2e+, fedA+, LT-, ST-, beta-hemolytic+) isolated from the pigs with E. coli enterotoxemia. As test antibiotics, TMS, APM, Ampicillin (ABPC) and Enrofloxacin (ERFX) were used. For examination of MIC, agar plate dilution method was used, according to CLSI (2002). The organism was inoculated into BHIB (Difco, USA). The medicated BHIB was prepared at the final concentrations of *1 and *50 of MIC. Non-medicated BHIB was used as the control. The organism suspension was inoculated into each substance or control BHIB with final bacterial concentration of approximately 8.0 log10cfu/mL and cultured in the shaking incubator for 4 hrs at 37°C. Then, each BHIB was measured for the number of viable colibacilli. BHIB diluted properly with PBS was smeared to TSA (Difco). For the preparation of released Stx2e, after centrifugation (8,000rpm, 10 min) of BHIB, supernatant was filtered with a 0.20 um filter. For the preparation of produced Stx2e, after ultrasonic fragmentation in ice, BHIB was centrifuged and supernatant was filtered. Vero cell sheets were cultured on 96 well microplate. After incubation for 72 hrs with 5%CO2 at 37C, CD50 (50%Cytotoxicity Dose) was determined.

Results
MICs of ETEEC MVH269 for TMS, APM ABPC and ERFX were 64ug/mL, 4ug/mL, 256ug/mL and <0.125ug/mL, respectively.

In the TMS medication, the number of viable colibacilli significantly decreased at x50 MIC compared to the control. No significant differences were observed in released Stx2e at both x1 and x50 MIC, whereas produced Stx2e decreased dose-dependently (Fig. 1a, 1b). In the APM medication, the number of viable colibacilli decreased at 50x MIC (Fig. 2). The amount of released /produced Stx decreased compared to the control (Fig. 2a, 2b). On the other hands, in the ABPC and ERFX medication, the number of viable colibacilli decreased significantly at 1x MIC and 50x MIC. However, in the ABPC, the amount of released Stx markedly increased compared to control.

Discussion
ETEEC (MVH269) strain tested was not susceptible to ABPC, highly susceptible to ERFX and APM, and moderately susceptible to TMS. The reduction rate of viable colibacilli of TMS and APM were comparable to ABPC or ERFX, but the reduction rate of produced Stx2e was higher, suggesting the possibility that TMS and APM inhibited Stx2e production.

Comparison of Porcilis® Coli 6C with another vaccine by measuring maternally derived antibody levels of E. coli virulence factors in piglets

Rut Menjon Ruiz1 Antonio Ubiiego2 Teresa Abizanda2 Jorge Sistac2 Jesus M. Bollo1 Marta Jimenez1 Jesus V. Lopez1
1. Intervet/Schering-Plough A.H., Alcobendas, Spain; 2. Piensos Mazana, Capella, Spain

Introduction
Enterotoxigenic E. coli associated with neonatal diarrhea may posses one or more F4(K88), F5(K99), F6(987p) and F41 fimbriae, with K88 having the highest prevalence (1). Adequate immunization of sows is fundamental for providing piglets with effective protection against this disease via the colostrum (2).

The object of the study was to compare the levels of specific antibodies against the main E. coli virulence factors in piglets from sows vaccinated with Porcilis® Coli 6C and another commercial vaccine with the same indication (vaccine B)

Materials and Methods
The study was performed during 2009 in two phases on a breeding farm with 2400 sows in northern Spain.

Thirty sows from different production cycles were selected together with their piglets: 20 primiparous sows and 10 multiparous (same parities per group). These were divided into two groups (Porcilis coli 6C and Vaccine B). The vaccines were administered at 70 and 90 days of pregnancy.

After farrowing, 3 piglets were randomly selected from each litter (n=90). Blood samples were taken at 7 days of age to measure the level of maternally derived antibody (MDA) specific for the main E. coli virulence factors, acquired via the colostrum. A specific ELISA test (internal ISPAH test) was used, which detects titers against K88ab, K88ac, K99, 987P antigens in serum or colostrum. Titers are expressed in log2 titers. Titers lower than 6 log2 are considered to be negative.

Statistical analysis was performed using the General Linear Model (GLM-SPSS 15.0 for Windows), the Mann-Whitney U-test. The Pearson’s chi-square test was used for comparisons of means, and the Levene test for comparison of variances.

Results
The results of the serum sample assays showed significant differences in the mean antibody titers of both groups.

Table 1: Mean log2 antibody titers (± SD)

<table>
<thead>
<tr>
<th></th>

</tr>
<tr>
<td>Vaccine B</td>
<td>7.84±0.32</td>
<td>8.89±0.34</td>
<td>8.26±0.25</td>
<td>8.56±0.19</td>
</tr>
</tbody>
</table>

The distribution of the mean antibody titers for all the virulence factors studied was more uniform in piglets from the Porcilis® Coli 6C group (p<0.01), only the titers against K88ab in primiparous sows failed to show a statistically significant difference (Graph 1, Graph 2).

Graph 1: Distribution of Ab titers in multiparous sows

Graph 2: Distribution of Ab titers in primiparous sows

When comparing animals with negative titers for K88ab and K88ac antigens, a higher percentage of negative titers was found in the group of piglets from sows vaccinated with Vaccine B (p<0.05) (Graph 3)

Graph 3: %age piglets with <6.00 Ab titers

Discussion
Porcilis® Coli 6C induced both higher MDA against the most prevalent E. coli virulence factors, and higher titers against the main virulence factor (K88) than another vaccine with the same indication. Consequently, Porcilis® Coli 6C confers stronger protection against the main antigen involved in neonatal diarrhea in piglets.

Vaccination with SUIVAC EDT® against oedema disease – a field study

Anne Jørgensen2 Magne Haugum1 Hilde M. Juul1 Anja Kristoffersen1 Bjarne Bergsjø1 Bente Fredriksen2 Bjørn Lium1

1. National Veterinary Institute, Oslo, Norway; 2. Animalia, Oslo, Norway

Introduction

Oedema disease in pigs is usually caused by infection with F18-positive and verotoxin 2e producing hemolytic E. coli O 138, O 139 or O 141. In some herds this infection may cause considerable economical losses due to high mortality in pigs during the first 1-4 weeks after weaning. This field trial was performed to assess the efficacy and safety of a commercial vaccine against oedema disease in weaned pigs.

Materials and Methods

Herd

Two conventional herds where high mortality due to oedema disease in weaned pigs had been a persistent problem for some years were selected to participate in this trial. The diagnosis oedema disease was confirmed by autopsy and bacteriology positive for haemolytic E.Coli O 138, O 139 or O 141.

Herd 1: integrated production with 22 week batches with 56 sows per batch.

Herd 2: piglet production with 3 week batches with 48 sows per batch.

Study design

A double blinded randomized block design study, with herd and litter as block factors, was performed in 2008-2009. A total of 1980 piglets were vaccinated at 2 and 4 weeks of age. Within each litter, the piglets were randomized to get either Suvac EDT (n=981) or placebo (phosphate buffered saline) (n=999). Weaning took place a minimum of three days after last vaccination. Clinical symptoms and adverse reactions were recorded from weaning to 30kg. Post mortem examination was performed on all piglets that died or were euthanized during the study period. Only pigs with characteristic pathological lesions, and from which haemolytic E. coli O 138, 139 or O 141 were isolated, were diagnosed as “dead due to oedema disease”.

Statistical analysis

To evaluate the association between the probabilities of getting oedema disease and placebo contra real vaccination, a mixed effect logistic regression model taking into account the effect of herd and litter was used. The analysis was done in R 2.9.1 (1), library lme4 (2).

Results

A total of 82 pigs (4.1 %) died during the study period. Haemolytic E. coli O139 was identified in 54 pigs with pathological lesions indicating oedema disease. Another 9 pigs had pathological changes consistent with oedema disease but negative bacteriology. Nineteen pigs died of other reasons. Table 1 shows the distribution of confirmed cases of oedema disease per herd and treatment.

Table 1. Distribution of piglets n (%) that died of oedema disease.

<td>39/981 (4.0)</td>
<td>15/999 (1.5)</td>
<td>54/1980 (2.7)</td>
</tr>
</tbody>
</table>

The odds ratio for getting oedema disease was 0.33 for vaccinated animals (p = 0.002). When litter was used as random effect, herd did not contribute with further explanation in the model. The Suvac EDT vaccine was safe and did not produce marked adverse reactions.

Discussion

In this field trial the prevalence of postweaning mortality due to oedema disease was markedly reduced in pigs vaccinated with Suvac EDT compared to pigs in the placebo group. The results indicate that vaccination may be a good alternative to high doses of zink oxide as food additive or treatment with antiserum to prevent oedema disease in weaned pigs. A higher beneficial effect of vaccination with VT2e-toxoid against oedema disease has previously been documented in a Danish study (3)

Acknowledgements

We would like to thank the veterinarians Håvard Okkenhaug, Eli Maria Stenklev, Øyvind Skei and Regina Boch for practical work in the herds.

Comparison of the antimicrobial resistance of pathogenic *Escherichia coli* in diseased pigs in Vietnam and Quebec, Canada

Thuy N. Do¹ Darren J. Trott² Éric Nadeau³ Clarisse Desautels⁴ John M. Fairbrother⁴

1. National Institute of Veterinary Research, Hanoi, Vietnam; 2. The University of Adelaide, Adelaide, SA, Australia; 3. Prevtec Microbia Inc., Saint-Hyacinthe, QC, Canada; 4. Reference laboratory for *E. coli*, Faculté de médecine vétérinaire, Université de Montréal, Montréal, QC, Canada

**Introduction**

*Escherichia coli* is an important cause of a wide range of diseases in production animals and humans worldwide, including pigs. In certain cases, animals are a reservoir of infection for humans, either by direct contact, contamination of the environment, or via contaminated food. The objective of this study was to compare the distribution of antimicrobial resistance of pathogenic *E. coli* isolates from diseased pigs in two geographically distinct countries, Vietnam and Canada, with differing antimicrobial use.

**Materials and Methods**

*E. coli* isolates obtained from diseased pigs (diarrhea, sudden death or edema disease) in 2007 and submitted to the NIVR in Vietnam or the FMV in Québec, Canada, were initially tested by PCR for the presence of defining genes of ETEC and STEC pathotypes. They were then virotyped by colony hybridisation (Ngeleka et al., 2002) for detection of the presence of 20 virulence genes most commonly found in animal pathogenic *E. coli*. The isolates were examined by the disk diffusion test to identify antimicrobial resistance.

**Results**

**Discussion**

The antimicrobial resistance profiles generated can be considered to be representative of each geographical region. Some interesting similarities and differences were demonstrated between the two data sets. Overall, very high rates of resistance were found to tetracycline in isolates from both countries, Canada and Vietnam (95 and 92%, respectively). Interestingly, all the Vietnamese isolates were sensitive to ceftiofur and apramycin, whereas no resistance was recorded for enrofloxacin with the Canadian isolates. The similarities and differences in antimicrobial resistance between the two countries could be attributed to variation in veterinary antimicrobial regulation and usage between Canada and Vietnam. This was definitely the case for tetracycline, ampicillin, and sulfa drug use in both countries, and ceftiofur and apramycin use in Canada, and enrofloxacin use in Vietnam. Frequent usage of agents in the past, such as chloramphenicol in Vietnam and nitrofurantoin in Canada also was associated with resistance. Other factors may include the distribution of serotypes and pathotypes between the two countries, and differences in farrowing shed management.

Introduction

Vaccination has been one of the most effective ways of preventing disease. Oral delivery of vaccine induces both humoral and cellular responses against mucosal infections. Thiolated eudragit as delivery system have been known to exhibit pH dependent, permeation enhancing, enzyme inhibitory and mucoadhesive properties to improve the peroral absorption efficiencies.

Intestinal infections with Escherichia coli are an important cause of diarrhea and mortality in pigs. Especially enterotoxigenic E. coli (ETEC) infections immediately after birth and weaning are responsible for significant economical losses due to diarrhea, growth retardation, and mortality. The infections are mainly caused by the fimbrial colonization factor F4 (K88) and F18 (F107). In this study, Eudragit-cysteine conjugate were prepared and characterized for the fimbriae of E. coli.

Immune stimulating activity of F4 and F18–loaded thiolated Eudragit was checked in murine macrophage cell-line.

Materials and Methods

F4ac and F18ab and ac were detected by PCR amplification from E. coli strains in Korea as described by Lee et al. The fimbria proteins were purified as described by Wim et al. Briefly, the selected E. coli strain were cultured in cultured in tryptic soy broth at 37°C overnight with shaking. The bacteria were harvested and suspended with PBS. F18 fimbriae were purified by heat shock (60°C for 20min) and F4 fimbriae by homogenizing the bacterial suspension using an Ultra Turrax at 24,000 rpm for 15 min. It was centrifuged at 8,500 rpm for 20 min and then 10,000 rpm for 40 min. The solubilized fimbriae were precipitated with 20% (w/v) ammonium sulphate.

Thiolated Eudragit were prepared according to the procedure previously developed by Quan et al. Raw 264.7 was cultured in 12 well plates containing 2.2 X 105 cells per well with DMEM supplemented with 10% FBS at 37 °C under 5% CO2. After a 18 h incubation, they were stimulated with 1 ug/ml of each fimbria protein loaded TEMs. LPS (1 mg/ml) and unloaded TEMs were used as positive and negative controls, respectively. After stimulation, secreted concentrations of TNF-α and IL-6 were measured by ELISA method.

Results

Average particle sized of TEMs(thiolated Eudragit), F4 loaded TEMs and F18 loaded TEMs are 4.2 ± 0.75 μm, 4.7 ± 0.50 μm and 4.5 ± 0.37 μm, respectively. The morphologies of TEMs, F4 and F18-loaded TEMs were observed as spherical shapes. The particle sizes of TEMs became bigger after loading of fimbria proteins into TEMs. Production of TNF-α from raw 264.7 cells was increased in a time-dependent manner after exposure to F18-loaded TEMs, F4-loaded TEMs, TEMs and LPS. Secretion of IL-6 from raw 264.7 cells was increased in a time-dependent manner after exposure to F18-loaded TEMs, F4-loaded TEMs and LPS.

Discussion

The size of microspheres is quite important to target vaccines for uptake into the mucosal associated lymphoid tissues (MALTs) of the gut. Also, the majority of the microspheres below 10 mm in diameter were needed to be transported through the efferent lymphatics within macrophages. Therefore, it will be expected that F4-loaded TEMs and F18-loaded TEMs will be effective for delivery. Production of TNF-α and IL-6 in F4-loaded TEMs and F18-loaded TEMs were higher than production in only F4 and F18 proteins. Compared to F4 protein, F18 protein and F18–loaded TEMs produced more TNF-α and IL-6. Therefore, F4 and F18–loaded TEMs could be considered as a candidate for oral vaccine of enterotoxigenic E. coli.

Efficacy of the booster dose of SUISENG®: a novel friendly adjuvanted vaccine against neonatal colibacillosis and clostridiosis

Nicolas G. Liaño; Xavier Gibert; Mercè Roca; Marta Sitjá

HIPRA, Girona, Spain

Introduction

This work shows the results of one study where the safety and the efficacy of SUISENG® (a vaccine against the Neonatal Piglet Colibacillosis, C. perfringens and C. novyi enterotoxicosis) were assessed. Applying the basic vaccination and the Revaccination to pregnant sows, the efficacy was evaluated by means the serological response, the transfer of maternal immunity and the clinical signs in challenged piglets with two pathogenic strains of E. coli.

Materials and Methods

SUISENG® was used to vaccinate pregnant gilts. The basic vaccination scheme consists of two doses: the first dose at approximately 6 weeks before farrowing and a second dose at approximately 3 weeks before farrowing. Revaccination on next subsequent gestation, administering one dose 3 weeks before the expected date of farrowing.

The piglets from the second parturition were challenged using two heterologous pathogenic strains to induce neonatal colibacillosis.

Results

Serological response in sows and transfer of maternal immunity

Next is shown the IgG profile against the F4ac in the sow sera after the immunization. The rest of valences included in the vaccine followed a similar profile. (See figure 1.a)

The figure 1.b shows the presence of antibodies against each valence in the colostrum/milk samples of the sows. The serology of the piglets sera demonstrated the presence of specific antibodies against all the valences.

Figure 1.a and 1.b. Serological response in sows and presence of antibodies against each valence in the colostrum.

Clinical sign of colibacillosis

The clinical signs after the challenge were evaluated by means a score record during 8 days. Next (figure 2.a) are the results of this score, significant differences between treatments for both challenges were found (p>0.05).

In the same way, the mortality rates of each group are shown below (see figure 2.b). Significant differences between the Suiseng and the Placebo were demonstrated for the two challenges.

Figures 2.a and 2.b. Clinical signs and mortality rates of each group respectively.

Discussion and conclusion

The results of this study demonstrated the efficacy of SUISENG® after a booster dose against the experimental infection with enterotoxicogenic E. coli. The vaccination reduced significantly the clinical signs and the mortality of the piglets suffering from colibacillosis.
Increased antimicrobial resistance for colistin of haemolytic Escherichia coli strains from clinical cases in Belgium using the E-test

Frédéric A. Vangroenweghe; Evelyne De Graef; Cora Miry; Frans Castryck
DGZ-Vlaanderen, Torhout, Belgium

Introduction
The last few years, acquired resistance to colistin in Escherichia coli (E. coli) has been described quite frequently. It has been shown that the standard agar dilution test is not a reliable method for the detection of colistin resistance in several bacterial species. Therefore, the need for a reliable test to check colistin susceptibility of pathogenic E. coli strains in routine diagnostics was rather high. A practical study, comparing 4 different antimicrobial susceptibility tests revealed that the E-test was the most reliable alternative agar-based colistin susceptibility testing method for use in E. coli strains (1). The objective of the present study is to evaluate the evolution of results obtained following the introduction of the E-test in the diagnostic laboratory procedure.

Materials and Methods
All samples from the content of the small intestine -positive for hemolytic E. coli- were tested using the E-test (AB Biodisk) with direct reading of the minimal inhibitory concentration (MIC) and expressed in μg/ml. The interpretation towards susceptibility or resistance was performed according to Table 1.

Table 1. Interpretation of antimicrobial susceptibility testing to colistin using the E-test

<table>
<thead>

<td>&lt; 4</td>
</tr>
<tr>
<td>intermediately susceptible</td>
<td>4 - 16</td>
</tr>
<tr>
<td>resistant</td>
<td>&gt; 16</td>
</tr>
</tbody>
</table>

Results
The distribution of antimicrobial susceptibility testing of the (haemolytic) E. coli strains isolated from diagnostic bacteriology of samples from small intestines in the period 2006-2009 are presented in Figure 1. Overall, an evolution from 8% intermediately susceptible strains to colistin in 2006 to 28% in 2009 could be observed. On average, 150 strains of haemolytic E. coli were tested in routine diagnostics yearly.

Discussion and Conclusions
Colistin is used worldwide as an oral antimicrobial agent for the prevention and treatment of neonatal and weaning-associated E. coli infections in piglets.

Considering its extensive use and the fact that antimicrobial formulations are often underdosed (2), it is not surprising to find an increasing colistin resistance in veterinary E. coli strains (3).

Figure 1. Distribution of antimicrobial susceptibility results with the E-test obtained from (haemolytic) E. coli strains isolated in diagnostic bacteriology from 2006 till 2009. S: susceptible, I: intermediate, R: resistant

Following introduction of a more reliable antimicrobial susceptibility testing method, using the E-test, the occurrence of a high percentage intermediately susceptible E. coli strains could be observed in Belgium. This is in accordance with the information provided by veterinary practitioners concerning the decreasing efficacy of colistin in the treatment and prevention of E. coli infections, especially after weaning. Monitoring of the further evolution of antimicrobial susceptibility will be necessary in order to guarantee treatment success when applying colistin in antimicrobial formulations for piglets post-weaning.

Acknowledgements
The financial support of Veepoiler-varken in the development and introduction of the E-test into the routine diagnostic procedure is greatly acknowledged.

Results
Serological response in sows and transfer of maternal immunity
Two IgG serological profiles were observed. For the F4ab, F4ac, F5, LT and CpC valences high antibody titres were obtained after the first dose of the vaccine. In the case of F6 and CnB valences, two doses of the vaccine were needed to achieve high antibody titres. (See figure 1.a)

The presence of specific antibodies was demonstrated in the colostrum/milk samples of the sows. The transfer to their offspring was confirmed with the serology of the piglet sera. (See figure 1.b)

Clinical sign of colibacillosis
The clinical signs after the challenge were evaluated by means a score record during 8 days, as well as, the mortality rate (%) of each group. Next are the results of this score and percentages, significant differences between treatments were found in all the studies. (See figure 2).

Discussion and conclusion
The results of the two studies demonstrated the efficacy of Suiseng (applying the basic vaccination scheme) against the experimental infection with enterotoxigenic E. coli. The vaccination reduced significantly the clinical signs and the mortality of the piglets suffering from colibacillosis.
The effect of Saccharomyces cerevisiae supplement on surviving and resistance in piglets before weaning

Jan Bernardy; Dana Kumprechtova

University of Veterinary and Pharmaceutical Sciences, Brno, Czech Republic

Introduction

Addition of Saccharomyces cerevisiae (SC) to the prestarter premix may provide early stimulation of the immune system of the piglets before weaning. Cell walls of SC contains beta-glucans, an immunomodulator that can enhance the innate immune system providing protection against bacterial (1) and viral infections (2). Mechanisms of action include activation of macrophages, neutrophils, and NK cells, along with B and T lymphocytes and increased phagocytosis and cytokine production in macro-phages (3). Our previous results show better ability of piglets stimulated by SC to reduce mortality and enterotoxigenic E. coli strains (ETEC) in faeces of pre-weaning piglets. The objection of the study was not only confirm our previous results (4), but also closer understanding of interaction between SC and ETEC and its impact to the resistance to the diarrhoea and chance of survival of piglets before weaning.

Material and Methods

Farrow to finish farm with 500 sows was used for the study, separated into multiple outlaying sections. Sows from two farrowing sections were included into the trial, randomly allocated into the groups giving birth concurrently, 16 sows each. There were 156 piglets live born in one group (avg 9.75 per sow) and 192 in another group (avg 12.00 per sow). The first group (SC group) of breeding sows and piglets received standard feed and pre-starter premix, supplemented with SC culture at 1000 ppm (Actisaf Sc47, Lesaffre Feed Additives, France) each. The second group of sows and piglets (C group) was fed by the same feed without SC supplementation.

Piglets and sows were rectally swabbed – sows before and after the farrowing and piglets every week until the weaning at 28 days of age, cultivated and haemolytic strains of E. coli were further examined to the pathogenic factors. Symptoms of diarrhea and mortality were checked, as well as pre-starter consumption at daily basis; piglets were weighed weekly and ADG was calculated. The data were evaluated by non-parametric ANOVA Kruskal-Wallis test and visualized by Statistica v.9 software.

Results and Discussion

Number of enteropathogenic E. coli in SC group significantly decreased in compare to Controls in the second and third week (p=0.030 and 0.044 respectively). The SC dietary supplementation reduced significantly number of ETEC colonies at 2nd and 3rd week about 8 and 14% (p=.03 and .044) respectively (week three – Figure 1), followed by lower or nil diarrhea symptoms and lower mortality, reduced about 1.03 piglet per litter (p=0.04) in SC group (Table 1). The major part of the response seems to be caused by changes in intestinal microbiology, including enhanced numbers of favourable microorganisms and decreased numbers of potentially pathogenic bacteria (E. coli, etc.) together with higher fermentation along the intestines. Some investigations have been made with varying diet composition or supplementing with different substances of animal or plant origin.

However, positive effects on the gut have often been more variable and sometimes inconsistent (5). However, measurable effects of these factors on intestinal physiology and muco-sal immunology are not clear or at least difficult to interpret, our results declare measurable impact on number of ETEC strains and lower pre-weaning mortality in the group fed by diet enriched with SC.

Foundation of Biomedical Research, Academy of Athens, Athens, Greece

Introduction
Postweaning diarrhea due to Escherichia coli (PWD) is a transmissible diarrhoea mediated by enterotoxins and observed mainly after weaning, causing major losses in weaned piglets worldwide (1). The aim of this field study was the assessment of possible antimicrobial activity of Pumpkin based on the reduction of E. coli postweaning diarrhoea prevalence in weaned piglets. This trial was part of the SAFEWASTES specific targeted research project financed by the European Union (Framework Project 6).

Materials and Methods
This study was carried out on a commercial pig farm in northern Greece with a capacity of 250 sows under production. The farm was selected due to previous history of E. coli PWD occurrence. Under a randomized block design 150 healthy and genetically similar weaned piglets at 4 weeks of age were divided into 3 groups (5 pens of 10 piglets each with equal sex ratio/group. The negative control group (NC), received feed formulated with 99% basic diet and 1% corn starch from trial day 0 (weaning day) until the end of the trial after 28 days. The second group received feed formulated with 99% basic diet and 1% pumpkin (P1), while the third received feed formulated with 97.5% basic diet and 2.5% pumpkin (P2.5) for the same time period. Average daily weight gain (ADWG), average daily feed intake (ADFI), feed conversion ratio (FCR) and pen diarrhea score (DS) were recorded. Additionally, faecal samples were collected at day 0, 14 and 28 of the trial for E. coli shedding quantitative analysis (strains K88, K99, F18, F41, 987P) and Salmonella spp and Clostridium spp presence.

Results and Discussion
The mean DS for the total trial period did not differ significantly between the 3 treatment groups, although there was a slight improvement in P1 and P2.5 groups (graph 1). Faecal analysis did not reveal the presence of Salmonella spp or Clostridium spp. Referring to E. coli shedding the P1 and P2.5 groups showed a better (not significantly) performance (graphs 2a,b,c).

Table 1: ADWG (kg), ADFI (kg), FCR (Mean±SD)

</tr>
</tbody>
</table>

The results of the trial showed that pumpkin at 1% and 2.5% inclusion rates did not show a clear positive antimicrobial effect against E. coli infection in weaners. However, in P2.5 group scores of almost all the recorded parameters were better than the negative controls.

Oregano essential oil improves sow and piglet performance – a summary of three field investigations

Martha A. Mellencamp, Robert W. Evelsizer, Ron Dvorak, Rafael Cabrera, Jim Hedges, Denise Mouat, David Cadogan, Malcolm Mottram

Introduction

Oregano essential oil (OEO) is a phytogenic feed additive with a spicy, aromatic flavor that stimulates appetite and promotes feed intake. OEO is being studied because of its well documented anti-bacterial, anti-fungal and anti-oxidant activities and for its ability to support a healthy gut (1). University of Minnesota research (2) showed that inclusion of OEO in sow gestation and lactation diets increased number of piglets born alive, increased litter birth weight and improved average daily gain of piglets. The authors attributed higher piglet growth to the higher quality colostrum (increased IgG and immune cells) produced from sows supplemented with OEO. This report summarizes three field investigations of the effects of OEO on sow and litter performance. In trials 1&2, OEO was fed during gestation and lactation diets. In trial 3, OEO was given in water for 10d at farrowing. Results showed that feed intake, reproductive performance and litter health were significantly improved for OEO-fed sows compared with controls.

Materials and Methods

In trials 1&2, OEO or control diet were fed during gestation and lactation (Table 1). Feed intake and reproduction traits were used to assess sow performance. Litter health and performance were assessed by preweaning mortality, litter gain, and incidence of scours. In trial 3, OEO was delivered in water for 3d prior and 7d after farrowing, which allowed us to compare litter health only. Statistical analysis (Chi-square, ANOVA Proc Mixed, SAS) and odds ratios (3) were performed for each study.

<sup>a</sup>Grams/metric tonne; <sup>b</sup>Milliliters/liter of stock solution metered at 1:128.

Results

In trial 1, lactation feed intake was increased for OEO-fed sows compared with control sows (P<0.001) (4). OEO-sows weaned an additional 0.6 pigs/litter (P<0.001), and pre-weaning mortality was 3.3% lower than controls: 11.1% and 14.4%, respectively (P=0.06). OEO-fed sows had fewer litters affected by *Isospora suis* scours (P=0.001), and litter medications were reduced (P=0.027). Odds ratios showed that litters from control sows were 2.2 times more likely to scour than those from OEO-sows (95% CI: 1.42 to 3.3). In trial 2, OEO-fed sows weaned an additional 0.38 pigs/litter (P=0.026), and litters were healthier, as shown by reduced scours (P=0.008). Litters from control sows were 3.5 times more likely to scour than those from OEO-fed sows (95% CI, 1.58 to 7.80).

Trial 3 was conducted on a farm with lab-confirmed neonatal scours caused by *Clostridium perfringens* type A. Results showed that OEO-sows weaned 0.74 additional pigs/litter than control sows (P<0.001). Pre-weaning mortality was reduced from 16.0% for control sows to 6.4% for OEO-sows (P<0.001). Odds ratios showed that litters from OEO-sows were 2.8 times more likely to survive than control litters (95% CI, 2.09 to 3.76). Financial analysis showed that return on investment ranged from 3.9:1 to 9.7:1.

Discussion

These three studies demonstrated that dietary OEO improved sow reproductive performance and delivered better litter health. Litters from OEO-fed sows had reduced preweaning mortality, increased litter weights, and lower incidence of scours than litters from control sows. OEO litters were healthier and more robust than control litters. These results may be attributed to the anti-bacterial and anti-oxidant activity of OEO, which improves sow gut health and colostrum immunity, leading to healthier piglets (2). OEO is an economical way to deliver more full value pigs at weaning.

Foundation of Biomedical Research, Academy of Athens, Athens, Greece

**Introduction**

The use of probiotics containing Bacillus cereus var Toyoi in weaners, finishers, sows and their litters has positive effects on their health and performance (1), as well as on the reduction of incidence and severity of PWDS (2). Recently, it was also noticed that Benzoic Acid improved piglets’ performance (3). The purpose of this study was to assess the efficacy of a probiotic containing Bacillus cereus var Toyoi spores (Toyocerin\(^a\)) and Benzoic Acid (VevoVital\(^b\)) on health and growth performance parameters in weaning pigs, against negative controls. The study was financed by Rubinum SA through the Research Committee of Aristotle University of Thessaloniki.

**Materials and Methods**

The study was carried out on a commercial farrow-to-finish pig farm in Greece (420 sows under production). The farm had a history of PWDS due to E. coli and it was free of Brachyspira hyodysenteriae & pilosicoli, Salmonella spp., Cryptosporidium spp., rotavirus and coronaviruses.

The animals of each weekly batch were allocated into 4 experimental groups [8 pens x 10 piglets/pen = 80 piglets/group x 4 groups=320 piglets]. The trial groups were as follows: (a) NC: No treatment. (b) TOYO group: Same feed as in the controls plus Toyocerin\(^a\) at a dose of 1 x10\(^9\) B. cereus var Toyoi spores / kg feed, (c) BA group: Same feed as in the controls plus VevoVital\(^b\) at a dose of 5 kg/kg feed (5000 ppm benzoic acid) and (d) TOYO+BA group: Same feed as in the controls plus Toyocerin\(^a\) at a dose of 1x10\(^9\) B. cereus var Toyoi spores and VevoVital\(^b\) at a dose of 5 g/kg feed.

Morbidity, mortality and growth performance data including body weight (BW), average daily gain (ADG), average daily feed intake (ADFI) and average feed conversion ratio (FCR) were recorded at weaning day and then every 7 days (until 35th day) and for the total trial period. Diarrhoea score (DS) and daily DS/pig was calculated on litter basis after a daily monitoring. On the day of weaning, 4 piglets/pen were randomly selected for faecal sampling. Samples were subjected to microbiological examination for the determination of E. coli counts, as well as for the presence of ETEC strains.

**Results and Discussion**

Morbidity rates were significantly decreased in TOYO and TOYO+BA groups compared to NC (P<0.05), but there were no significant differences in mortality rates. The mean DS for the total trial period is given in Table 1. E. coli ETEC strains presence and counts (x 10\(^6\)) in faecal samples are shown in Table 2.

a,b,c Means with different superscripts in the same row differ significantly

The mean BW of piglets increased significantly in the 3 treatment groups compared to NC group (P<0.05). There were no significant differences in ADFI between all groups, except a reduction in BA group at the total period of day 0 – day 35 after weaning. The ADG and FCR were significantly higher in all medicated groups compared to the NC group (P<0.05). In conclusion, the addition of Toyocerin\(^a\) or VevoVital\(^b\) in weaners’ feed improved their health and growth performance compared to the negative controls. However, the most beneficial effects were obtained in the combination of Bacillus cereus var Toyoi spores with benzoic acid.

The use of acidifiers and probiotics in piglets' ration and its effect on their performance after weaning

José Cristani1 Maria C. Thomaz2 Sandra D. Traverso1 André Thaler Neto1 Juliana Lazaroto1 Daniela Miyasaka3
1. UDESC, Lages, SC, Brazil; 2. UNESP, Jaboticabal, SP, Brazil; 3. Ouro Fino Agronegocios Ltda, Ribeirão Preto, Brazil

Introduction
Probiotics are used on animal feeding with the aim of to increase meat, milk, eggs yield. Its utilization has been widely investigated, mainly during the last years, because of the forbiddance of any antibiotics as a growth promoter among all countries in the world (1). This study aimed to evaluate the efficiency of acidifiers and probiotics as growth promoters in piglets. They were fed from 21 to 63 days of age to have investigate the performance or percentage of piglets delivered to units of growth and termination.

Materials and Methods
A total of 630 piglets (castrated males and females) from a commercial herd were weaned with 21 days of age, weighing in average 6.3 Kg. The randomized block design was used, being the pen with 14 piglets the experimental unit, with 5 treatments performed in 9 replications and density being 0.33m32/pig. Piglets received water and ration ad libitum. Treatments were as following: 1 – Negative Control – Basal Diet (DB); 2- Antibiotic – DB + 20ppm doxiciclin; 3- Acidificant – DB + acidificant (4Kg/ton of ration from day 21 to 49, and 2kg/ton of ration from day 50 to 63); 4- Probiotic – DB + probiotc (Saccharomyces cerevisiae var. boulardii - 100g/ton of ration); 5- Probiotic + Acidificant – DB + associations of treatments 3 and 4. The acidificant used was a blend of organic acids composed of 10% citric acid, 10% fumaric acid, 10% phosphorac acid, 30% benzoic acid and 40% of vehicle. The daily feed intake (CDR), gain of weight (GPD) and food conversion (CA) as well as the percentage of piglets delivered were evaluated in three periods: 1 (days 21 to 35), 2 (days 21 to 49) and 3 (days 21 to 63). The percentage of piglets delivered was calculated based on the relation between piglets weighing 18Kg on day 63 and the total number of piglets used in the experiment.

Results and Discussion
The CDR, GPD and CA for animals from the different experimental groups are showed on table 1. On period 1 only CDR was not influenced by treatments (P<0.05), being the highest GPD and CA, observed in piglets that were fed with antibiotic containing ration. The same group presented, on periods 2 and 3 the highest (P<0.05) CDR and best GPD and CA in comparison to the others. The same way, the percentage of piglets to the units of growth and termination (Table 1) was influenced (P<0.05) by the treatments, being the group fed with antibiotics the one that showed the best performance. The low percentage of piglets delivered impairs the realization of efficient cleaning and disinfection, and dirty pens result in an increase of negative effects caused by infectious agents that are present. Animals maintained in such conditions tend to present sub-clinical or opportunist diseases, what might increase the rate of waste (refugo?) and increase the lot yield causing economic losses due to extra expenses with feeding, medicines and labor.

Conclusion
Animals fed using antibiotics as growth promoters after weaning obtained the best performance if compared to animals fed using acidifiers and probiotics.

The influence of acidifiers and probiotics in the feed of post weaned piglets and their effect on diarrhea and total and fecal coliforms

José Cristani1 Maria C. Thomaz2 Sandra D. Traverso1 André Thaler Neto1 Daniela Miyasaka3 Juliana Lazaroto1
1. UDESC, Lages, SC, Brazil; 2. UNESP, Jaboticabal, SP, Brazil; 3. Ouro Fino Agronegocios Ltda, Ribeirão Preto, Brazil

Material and Methods

A total of 630 piglets from a commercial herd were weaned with 21 days of age, weighing in average 6.3 Kg. The randomized block design was used, being the pen with 14 piglets the experimental unit, with 5 treatments performed in 9 replications and density being 0.33m2/pig. Piglets received water and ration ad libitum.

Treatments were as following:
1- Negative Control – Basal Diet (DB);
2- Antibiotic – DB + 20ppm doxiciclin;
3- Acidifiant – DB + acidifiant (4kg/ton of ration from day 21 to 49, and 2kg/ton of ration from day 50 to 63);
4- Probiotic – DB + probiotc (Saccharomyces cerevisiae var. boulardii - 100g/ton of ration);
5- Probiotic + Acidifiant – DB + associations of treatments 3 and 4.

The acidifiant used was a blend of organic acids composed of 10% citric acid, 10% fumaric acid, 10% phosphoric acid, 30% benzoic acid and 40% of vehicle. The occurrence of diarrhea was daily evaluated during the first 15 days post-weaning, according to the scores: 0: firm stool, with normal consistency; 1: less consistent stool; 2: loose stool; 3 liquid stools. Diarrheal stool were considered for scores 2 and 3 (2). On days 10 and 20 post-weaning, 3 piglets per treatment were slaughtered and a portion from jejunum was aseptically collected refrigerated and sent to the laboratory for total and fecal coliforms counting (3).

Results and Discussion:

Table 1 shows data regarding the incidence of diarrhea for total and partial post-weaning periods. For the total period, from day 1 to 15 post-weaning the lowest incidence of diarrhea (P<0.05) was observed for piglets that received ration added of antibiotics. Table 2 shows data regarding the amount of fecal and total coliforms between days 10 and 20 post-weaning, an increase of fecal and total coliforms was observed for animals from all treatments on day 10, which was followed by a reduction on day 20 post-weaning. These results coincide with the incidence of diarrhea that has started on day 4 post-weaning, increasing until day 10 and then reduced until day 15 being practically controlled at that point.

Conclusion

In commercial swine herds with high health challenge, the use of alternative products is not able to prevent post-weaning diarrhea in an appropriate

<sup>a,b</sup> Same letter in the same line are not different according to F-test (P>0.05)
Introduction
Since 2003, the incidence and severity of disease associated with toxigenic Clostridium difficile (Cd) have increased in hospitals in North America (1,2). These increases have coincided with the emergence of a new, highly virulent, and more resistant epidemic strain (PFGE NAP1, Toxinotype III). The origins of this strain have yet to be determined. Various strains of Cd, including NAP1, can be isolated from food animals and retail meat (3-5); however, the predominant strain from food animals is NAP7 (3). Because Cd has been isolated from food animals and meat, it has been proposed that Cd may be transmitted via food sources (3-5, 6). The objective of the present study is to compare the prevalence of Cd in multi-age production groups within a Texas integrated swine operation.

Materials and Methods
Composite fecal samples (n = 2936, representing approximately 10 pigs/sample) were collected monthly for 36 months (2004-2006) from asymptomatic, clinically healthy, multiple-age swine from 12 separate farms at 3 geographical locations in Texas. Cultivation of Cd was accomplished by alcohol shock and enrichment techniques described for feces (3). PCR was used to characterize Cd for toxin A&B genes, tcdC gene deletion, tox-inotype, binary toxin gene, and pulsed field gel electrophoresis (PFGE) genotype (7). Cd isolates were tested for susceptibility to 11 antibiotics.

Results
In total, 252 Cd were isolated: 175 from farrowing, 37 from grower/finisher, 14 from nursery, and 26 from breeding animals. Of the isolates, 66 were PFGE pattern NAP7, 173 variant pattern (with 91% similarity to NAP7), and 4 other patterns. There were 236 Toxinotype V, 7 Toxinotype V-like, 7 Toxinotype XI, and 2 of unknown toxinotype; 250 isolates had the 39 bp deletion for the tcdC gene; 252 isolates were positive for binary toxin; and 238 were Toxin A+/B+, 7 were A-/B+, and 7 were A-/B-. All isolates were sensitive to amoxicillin/clavulanic acid, piperacillin/tazobactam, and vancomycin; and the majority were sensitive to chloramphenicol, metronidazole, and tetracycline. The most prevalent resistance observed was for cefoxitin, imipenem, and ciprofloxacin. Intermediate resistance was seen for clindamycin and ampicillin.

Discussion
The majority of swine isolates came from the farrowing barn and this agrees with others in that young animals are more prone to be colonized with Cd than older ones (3,7,8). The predominant genotype among our isolates was PFGE pattern NAP7 and Toxinotype V, and this agrees with that reported for pig and calf isolates (6, 8). Although the predominant strain in our study has been recovered from humans (6), none of our isolates were of the human epidemic strain (NAP1, Toxinotype III). Antibiotic sensitivities were consistent with those reported in an earlier study (7). Our isolates appear to have less resistance than observed for human clinical strains (9). On the basis of our study, we conclude that young animals have a higher prevalence of Cd than older swine. If Cd is indeed a potential food-associated organism, the lower carriage rate of Cd in market-age pigs in our study would suggest a reduced transmission risk to the food chain.

Development of a sandwich ELISA for C. difficile toxin A for in-process control of protective antigen production in vaccine development

Botond Siklódi; Imre Tóth; József Sipos; Ágnes Horváth; Benaouda Kadra

Ceva-Phylaxia, Budapest, Hungary

Introduction

Clostridium difficile is among the 5 most important pathogens causing diarrhea in swine (Songer 2006). Vaccination is a promising measure in fighting the agent (Aboudola 2003, Ghose 2007). A reliable analytical tool for controlling the protective antigen(s) in production process is of paramount importance in vaccine development and production. We have developed a sandwich-type ELISA for quantitative detection of C. difficile toxin A (TcdA) using the same monoclonal antibody (mAb) as capture and detector reagents. With this method we are able to quantitatively detect TcdA in the form of bioactive toxin as well as in the form of toxoid.

Materials and Methods

ELISA procedure: Each incubation step except with TMB substrate is performed in a thermo-regulated shaker followed by 4 washing cycles. Nunc Maxisorp ELISA plate is coated with capture mAb diluted 1:1000 in carbonate buffer (pH 9.6) for 60 min at 37 °C. Standards and samples are incubated for 60 min at 37 °C. Detector mAb is diluted 1:500 in PBS supplemented with 0.05% Tween-20 and 0.5% milk powder, and incubated for 60 min at 37 °C. Conjugate is used in 1:2000 dilution in the same buffer as above, and incubated for 30 min at 37 °C. TMB substrate in 0.1 M acetate buffer (pH 5.5) is incubated for 30 min at RT in dark, and color reaction is stopped by 2 N sulphuric acid.

Results

Quantitation limit of the validated ELISA method determined by an eight-point standard curve (Graph 1) is 10 ng/ml. No cross-reaction has been found with toxin B (TcdB). Intra- and interassay variation is within 10%.

Discussion

This ELISA is a reliable and convenient method for monitoring the optimization process of C. difficile fermentation aiming at the most economical production of the protective antigen TcdA in vaccine development. The method is also used for the quantitative detection of toxoid as long as the epitope conformation is preserved after formal inactivation of the bioactive toxin.

Dietary supplementation of BMD® in sow diets enhances nursing piglet immunoglobulin status

Daniel A. Nelson1 Samuel K. Baidoo2
1. Alpharma Animal Health, East Bethel, MN, USA; 2. University of Minnesota, Waseca, MN, USA

Introduction

BMD® (bacitracin methylene disalicylate, Alpharma Inc., Bridgewater, NJ) is approved by the FDA in the USA for the control of clostridial enteritis in suckling piglets caused by Clostridium spp. susceptible to bacitracin when fed to sows at 275 ppm (250 g/ton) starting 2 weeks prior to farrowing and throughout lactation. Thirteen previous studies1,2 have documented an improvement in pig weaning weights in those pigs nursing sows consuming BMD. This experiment was conducted to determine the effect of BMD supplementation in sow diets from day 99 of gestation and throughout lactation on the immunoglobulin status of sows and piglets and sow milk nutrient composition.

Materials and Methods

Crossbred sows (Topigs, Landrace X Yorkshire; n=16; parities=2.4±0.28) were randomly assigned to one of two dietary treatments. Diet 1 was a non-medicated corn-soybean meal control diet and Diet 2 was Diet 1 supplemented with 275 ppm BMD. Sows were fed their respective diets from day 99 of gestation through weaning. Piglet blood samples (1 pig/litter/period) and sow blood and milk samples were taken on day 0, 9, and 18 of lactation.

Results and Discussion

No differences were observed between treatments for sow milk crude protein, fat, ash or sow milk immunoglobulin status (Table 1). The average sow serum immunoglobulin status was not affected by treatment (Table 2). The average IgA content of piglet serum was not affected by treatment. However, the overall average IgG status in the serum of piglets nursing sows consuming BMD was significantly (P<0.04) enhanced and was more than twice that of pigs nursing Control sows (Table 2). Because there is virtually no placental immunoglobulin transfer in pigs, the higher IgG serum content of pigs nursing sows consuming BMD had to be derived from the IgG of colostrum. The IgG concentration of colostrum was numerically greater in BMD-fed sows. In conclusion, BMD supplementation did not affect sow milk nutrient composition nor sow milk or serum immunoglobulin status but did enhance the immunoglobulin status of piglets. The greater serum IgG concentrations of piglets nursing sows consuming BMD may contribute to the heavier pig weaning weights reported in previous research.

Antimicrobial susceptibility of Clostridium perfringens type A isolated from neonatal pigs with and without diarrhea in Minas Gerais, Brazil

Felipe M.Salvarani; Roberto Mauricio C. Guedes; Isabella S. Albefare; Eduardo C. Cruz Júnior; Rodrigo Otávio S. Silva; Priscylla S. Pires; Guilherme G. Alves; Francisco Carlos F. Lobato

Escola de Veterinária da Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil

Introduction

Clostridium perfringens a spore-forming anaerobic bacilli, Gram-positive, and strictly-to-oxygen-tolerant, is widely distributed in the environment and in the intestinal tracts of domestic animals. It has been recognized as one of the most important causes of diarrhea in neonatal pigs. C. perfringens types A and C and C. difficile are the main pathogenic clostridia in swine (5). Antibiotics recommended for the treatment of C. perfringens-associated diarrhea include amoxicillin, tylosin, and tetracycline, but there are few data about this microorganism susceptibility to these substances, in Brazil. The aim of this study was to determine the in vitro susceptibility of C. perfringens type A to seven relevant antimicrobials for swine production.

Materials and Methods

Fifty C. perfringens type A isolates, each obtained from different piglets (25 diarrheic and 25 non diarrheic) were evaluated. All strains were obtained in swine herds in Minas Gerais, Brazil. The following antibiotics, manufactured for analytical purpose, were tested: amoxicillin, ceftiofur, florfenicol, josamycin, lincomycin, tetracycline, and tylosin. Minimum inhibitory concentrations (MICs) were determined on Brucella’s agar plates containing doubling of the antibiotics, from 0.25 to 256 μg/L, and with 5% of sheep blood, vitamin K (1μg/ml), and hemin (5μg/ml). All strains were tested twice and, for negative control, Bacteroides fragilis (ATCC25285) was included in every test plate. All MICs values were determined using the National Committee for Clinical Laboratory Standards (NCCLS) (3).

Results

MICs values of each antibiotic for C. perfringens type A are summarized in Table 1. All isolates were susceptible to amoxicillin and ceftiofur. Forty four samples (88%) were considered susceptible to tylosin and only 6% of the strains were resistant. Thirty eight strains (76%) were susceptible to florfenicol but 10 (20%) were considered resistant. In contrast, 42 (84%) and 36 (72%) of the C. perfringens type A were resistant to tetracycline and lincomycin, respectively.

Discussion

Several studies using different C. perfringens samples also demonstrated too high-level resistant (MIC > 16μg/ml) to tetracycline, an antimicrobial commonly recommended for treatment of C. perfringens-associated diarrhea in animals including piglets. Important to Clostridium species can carry tetracycline resistance genes (2,4,6). Most C. perfringens strains from chickens and turkeys used by WATKINS et al (6) were considered resistant to lincomycin with high MICs (> 8 μg/ml). However the present study showed that amoxicillin, ceftiofur, florfenicol, and tylosin have a good effect against C. perfringens strains, as described elsewhere (1,4,6,7). These results emphasize the importance of conscious use of antimicrobials and the relevance of hygiene and vaccination as preventive measures.

Implementing the 5-week BMD® feeding program produces heavier pigs at weaning than feeding BMD only during lactation

Daniel A. Nelson1 Roy A. Schultz2

Introduction

BMD® (bacitracin methylene disalicylate, Alpharma, Inc, Bridgewater, NJ) is approved by the FDA in the USA for the prevention of clostridial enteritis in suckling piglets caused by Clostridium spp. susceptible to bacitracin when fed to sows starting 2 weeks prior to farrowing and throughout lactation. Thirteen previous studies12 have documented the benefits of feeding BMD during this 5-week period, including heavier piglet and litter weaning weights and reductions in piglet mortality and sow lactation weight loss. The 14-day pre-farrow BMD feeding period is sometimes perceived as too difficult to implement. Therefore, two separate studies conducted by large swine integrators and reported herein evaluated the benefits of feeding 275 ppm (250g BMD/ton) only in lactation or starting 2 weeks prior to farrowing and throughout lactation (5-week).

Material and Methods

In the first study a total of 106 sows were allotted to treatment (non-medicated or BMD in lactation) via parity and line. BMD was added to the lactation diets of test sows to provide 275 ppm. BMD feeding began when sows were moved into farrowing rooms (an average of 2 days pre-farrow) and continued until weaning. Total number liveborn and stillborn pigs/sow, mortality/litter, number of piglets weaned/sow, individual live pig birth weight within 24 hrs post-farrowing, and individual weaned pig weight were recorded. In the second study contained 3 treatments: 1) Non-medicated 2) BMD only in lactation 3) BMD fed 2 weeks prefarrow and throughout lactation. A total of 568 sows of common genetic base were blocked by location within farrowing room and balanced by parity to treatment. Similar gestation and lactation diets were fed to all treatment groups with the exception that BMD was added to supply 275 ppm for the treatment groups. Sows were individually weighed before farrowing and at weaning. Entire litters were weighed at birth, after fostering and at weaning. In lactation, sows were given ad-libitum access to feed.

Results and Discussion

In Study 1, there were no differences between treatments in the total number of pigs born, the number of pigs born alive, the number of pigs that were stillborn, the number of mummies, the number of pigs weaned nor the number of pigs that died/litter. Weaning weights of pigs nursing sows consuming BMD were significantly (P=0.02) greater (6.0 vs 5.8 kg/pig). In Study 2, net sow weight post-farrowing, post-weaning, and net sow weight loss in lactation were not different among treatments. The number of pigs started and weaned/sow, and pre-weaning mortality were not different among treatments. Adjusted 22-day piglet weaning weights were significantly (P<0.05) greater (+0.3 kg/pig) for pigs nursing sows consuming BMD for the 5-week period compared to pigs nursing Control sows (6.7 vs 6.4 kg/pig respectively). The adjusted 22-day piglet weaning weights of pigs nursing sows fed BMD only in lactation were intermediate (6.5 kg/pig) and not significantly different from pigs nursing Control sows or pigs nursing sows consuming BMD for the 5-week period. This is a logical observation as the two-week prefarrow BMD feeding period begins to reduce clostridial shedding before sows enter and “seed” the farrowing crate. In both studies, BMD increased pig weaning weight by 0.2 kg/pig when used only in lactation, and by 0.3 kg/pig when used for 2 weeks prefarrow and throughout lactation in Study 2 (Figure 1). In the presence of Clostridium perfringens type A and C, dietary supplementation of sow feed with 275 ppm BMD will improve the daily gain and weaning weights of nursing pigs. Implementing the 5-week BMD feeding program produces heavier pigs at weaning than feeding BMD only during lactation.

In vitro susceptibility of porcine C. perfringens Type A isolates to tylosin in Czech Republic

Martina Masaříková; Jiří Smola
Veterinary and Pharmaceutical Sciences Brno, Brno, Czech Republic

Introduction and objectives
Enteritis caused by the Clostridium perfringens Type A range among the most important piglets diseases in the Czech Republic. The causes underlying the spread of the infection are still unclear. Our hypotheses suppose a relation with the absence of the previously used antibiotic growth promoters, and a possible fall in sensitivity, alternatively an acquired resistance of the virulent isolates Clostridium perfringens to the antibiotics frequently used in therapy in pig herds. The aim of the study was to establish the MIC values of tylosin and to prove the emergence of resistance in the porcine Clostridium perfringens, isolated from piglets with enteritis.

Material and Methods
The Clostridium perfringens isolates (280) were acquired in 2004-2007 via cultivation of rectal swabs of piglets aged to 7 days with diarrhoea from 83 different pig herds. The identification of Clostridium perfringens was based on the demonstration of the species-specific gene (cpa) by PCR, another molecular genetic examination was performed to differentiate between Types A and C of Clostridium perfringens (1). Isolates of Clostridium perfringens Type A were selected as the basic set for further testing. The MICs of the tylosin (E. Lilly & Co., Elanco) were established using the agar dilution method according to CLSI M11-A5 (2001), the interpretative criteria adopted from Prescott (2).

Results
In the year 2004, the largest group were susceptible isolates (43,9 %), followed with 38,2 % intermediate isolates, at least (17,9 %) were resistant isolates of Clostridium perfringens Type A. Next year get to significant increasing (84,5 %) of susceptible isolates at the expense of isolates intermediate susceptible (3,4 %) and resistant (12,1 %). In 2006 still predominated susceptible isolates (56,9 %), nevertheless others categories increased to approximately 20 %. In 2007, the largest group were continuously susceptible isolates (66,7 %), but resistant isolates increased too (25,9 %), see Graph 1. The assessment of the dynamics of the susceptibility and resistance of porcine Clostridium perfringens Type A isolates from the MIC90 point of view shows resistance level to tylosin with the range from 8 to 16 mg.l⁻¹, see Table 1.

Discussion
Because of a lack of data on the susceptibility of Clostridium perfringens Type A isolates of porcine origin, we had to compare our results with the isolates obtained from poultry and dogs. For instance in the USA was reported a few times lower MIC₉₀ of tylosin (2 mg.l⁻¹) in chickens Clostridium perfringens isolates obtained from necrotic enteritis cases (3). MIC₉₀ of tylosin in Clostridium perfringens isolated from clinical cases of enteritis in dogs in USA was also lower, concretely 1 mg.l⁻¹ (4). MIC₉₀ of tylosin higher than those ascertained in our study have been published only in USA in Clostridium perfringens isolated from turkeys with necrotic enteritis (256 mg.l⁻¹) (3). MICs of tylosin calculated in Belgium for poultry isolates of Clostridium perfringens ranged from 0.03 μg.ml⁻¹ to 1 μg.ml⁻¹ (5), while MIC values of our porcine isolates of Clostridium perfringens Type A in same year ranged from 0.125 mg.l⁻¹ to >16 mg.l⁻¹.

Conclusions
Obtained MIC₉₀ values (16 mg.l⁻¹) of tylosin in isolates from newborn piglets are showing acquired resistance which is probably a result of frequent feed incorporation of the drug in swine. Furthermore acquired resistance had enabled to this subpopulation of Clostridium perfringens to take selective advantage in intestinal microflora of gilts and sows first in new born piglets.

Clostridiosis in the farrowing room with an atypical onset: a clinical case
Claudio Mazzoni1 Valeria Raffi1 Carlo Rosignoli2 Paolo Bonilauri2 Brunella Spaggiari2 Daniela Gelmetti2 Lucia Gibelli2 Giulia Maioli2 Silvia Faccini2 Michele Dottori2 Francesco Tonon1 Andrea Luppi2
1. Libero professionista, Reggio Emilia, Italy; 2. Istituto Zooprofilattico Sperimentale della Lombardia ed Emilia Romagna - Brescia, Brescia, Italy; 3. Libero professionista, Conegliano Veneto, Italy

Introduction
Clostridia are large, gram-positive, spore forming rods. Clostridium perfringens type A and C are the most important species, producing toxins responsible of enteritis in pigs. Infection is transmitted from piglet to piglet and the sows are the most important source of infection (4). Antibiotics are used for therapy, in particular β-lactam antibiotics (2) and tylosin (3).
In this work the Authors describe a clostridial enteric disease in several suckling piglets (one-day old) occurred in a herd in the Northern Italy and characterized by an atypical onset.

Materials and Methods
The clinical case took place between December 2008 and January 2009 with an increasing mortality rate in suckling piglets. Fourteen suckling piglets, belonging to a pig herd in Northern Italy and showing a syndrome characterized by death 12 hours after the onset of clinical signs, were submitted for necropsy to the Istituto Zooprofilattico Sperimentale Lombardia and Emilia Romagna, Laboratory of Reggio Emilia.
The intestinal contents and several organs were taken for microbiological cultures and histological examination.
Histology was performed on formalin-fixed paraffin-embedded tissue sections stained by Ematoxilin-Eosin and Gram methods. Genes for toxins α and β2 were detected, using a multiplex polymerase chain reaction method, from C.perfrigens isolated (see results) (2).
Toxicological investigations on sow feed were carried out to evaluate the presence of zearalenon, aflatoxins B1, B2, G1 and G2, ochratoxin A and fumonisins B1 and B2.

Results
Clinical signs observed 24 hours after the birth in the suckling piglets, were characterized by jaundice, lethargy and diarrhoea. The death occurred during the 12 hours after the onset of clinical signs. Gross lesions were characterized by necrosis of small intestine mucosa and liver degeneration with foci of parenchymal necrosis. Later, during the evolution of the clinical case, the dead piglets showed haemorrhagic-diarrhoea, intestinal hyperemia and mesenteric oedema, especially in jejunum and ileum.
C.perfrigens was isolated from the small intestine of several piglets (1 x 107 ufc of C.perfrigens from each gram of intestinal content). Genes for toxins α and β2 were detected and the C.perfrigens isolated was genotyped as type A. Histological examination of samples collected during the necropsy showed vacular liver degeneration, necrotic enteritis and multiple gram-positive, spore-forming bacterial colonies in the lumen. The results of the toxicological investigations on sow feed showed values under the legislative about maximally allowed.
A drug-treatment against C.perfrigens, using a long acting macrolid on piglets in the first 12 hours after the birth, led to a complete solution of the syndrome.

Discussion
In this work the Authors described a syndrome characterized by death, 12 hours after the onset of clinical signs in the suckling piglets. The syndrome did not appear to be related to dietary or any other specific management factor. The clinical signs of the disease, the gross lesions observed, the results of laboratory investigations and response to therapy suggested a diagnosis of clostridiosis due to a beta2 toxin-producing C.perfrigens type A strain.

B. licheniformis for C. perfringens control in sows

Robert Lantz1 Inge Knap2 Douglas Cook2 William Minton3
1. Chr. Hansen, Hoersholm, Denmark; 2. Akey, Lewisburg, OH, USA; 3. Four Star Veterinary Services, Chickasaw, OH, USA; 4. Chr. Hansen, Milwaukee, WI, USA

Introduction
Clostridium perfringens related scours is a form of diarrhea that affects young pigs and has been reported worldwide. The objective of this study was to determine the effectiveness of Bacillus licheniformis (Chr Hansen strain) in reducing the shedding of Clostridium perfringens in sows and the resulting Clostridium perfringens related scours in baby pigs.

Materials and Methods
The trial was conducted in the fall of 2009 in a 5,000 sow commercial farrow to wean operation using PIC genetics and Akey nutrition, (Lewisburg, Ohio, USA) The sow farm had 2 separate gestation barns, and 1 farrowing building comprised of 16 rooms of 64 farrowing crates each. The gestation barns had separate dedicated feed lines, 2 separate feed systems run through the farrowing facilities.

The entire herd was split into one of two groups. The groups of gestating sows were placed either on a standard control diet or on a standard diet containing B. licheniformis (1.6E+6 cfu/gram of feed). The sows were maintained on these diets throughout gestation. Once the sows entered the farrowing facilities, the groups maintained their integrity with the control sows being placed on a control farrowing and lactation diet. The sows that had received B. licheniformis in gestation continued to receive B. licheniformis (1.6E+6 cfu / gram of feed) in the farrowing and lactation diet. Both the control diet and B. licheniformis diets where identical with the exception of the B. licheniformis being added to the treatment diet.

A total of 12 sows from each of the two groups were randomly selected for fecal sample collection. Fecal samples were taken directly from the rectum of the sow and analyzed at the Iowa State University Veterinary Diagnostic Laboratory (Ames, Iowa, USA) to determine C. perfringens type and count. Samples were collected in gestation (approximately 38 days pre-farrowing and before the treatment group was placed on B. licheniformis), as sows were moved to farrowing (average 4.5 days pre farrow) and then again in lactation (average 2.5 days post farrow). In addition, feed samples where collected throughout the trial to determine the presence and level of B. licheniformis in the feed. At approximately 15 days of age, fecal samples were collected from at least 1 pig from each sow (both control and treated) to determine the presence of B. licheniformis in the pigs.

All samples were stored at -34 °C until shipment to the ISU VDL. Samples were shipped overnight, on dry ice, in insulated containers and placed at -70 °C upon arrival at the ISU VDL. Samples were thawed at room temperature; each sample was well mixed and immediately diluted for the standard plate count procedure (Quinn et al. 1994). Any isolates with typical colony morphology and double zone of hemolysis were gram stained for confirmation as large gram positive rods. These were recorded as C. perfringens. Twenty four of the isolates were submitted for Genotyping by the “Multiplex polymerase chain reaction assay for genotyping C. perfringens (Meer and Songer 1997).

Results
In gestation - treated sows (B. licheniformis) started with 5.6 times more clostridium type A than the control group (7.7E+5 vs 1.4E+5). NS

In farrowing - treated sows had 1.3 times more clostridium (7.8E+5 vs. 6.0E+5). Treated sows increased their count from gestation at a rate that was 97% slower than that of the control group.
P ≤ 0.05

In lactation - the treated sows had 49% the level of clostridium as the control sows (4.6E+6 vs. 9.2E+6).
The treated sows increased in clostridium counts from Farrowing to lactation at a rate that was 55% slower than that of the control. NS

The rate of increase in clostridium in the fecal samples from gestation to lactation grew in the treated group at a rate that was 57% slower than that of the control group. P ≤ 0.05
All sampled pigs in the treated group had detectable B. licheniformis in their faeces compared to the control group pigs which had no detectable B. licheniformis.

Discussion
In summary the results show that B. licheniformis has the ability to reduce shedding of C. perfringens in sows which could lead to a reduction in C. perfringens related scours in baby pigs. In addition, when fed to sows in lactation, B. licheniformis can be found in the faeces of pigs nursing treated sows.

In Vitro Susceptibility of Tiamulin in Czech Isolates of Clostridium perfringens Type A

Martina Masaříková; Jiří Smola
Veterinary and Pharmaceutical Sciences Brno, Brno, Czech Republic

Introduction and objectives

Neonatal enteritis in suckling piglets caused by Clostridium perfringens Type A is an important factor influencing economic efficiency of pig operations in the Czech Republic. Because Type A Clostridium perfringens is commonly present in swine intestinal content, it often becomes the unintentional target of peroral antimicrobial at the time of therapeutic interventions. One of antimicrobial substances that is very often used in pig herds to control swine dysentery and therefore could, in our opinion, influence susceptibility in Clostridium perfringens, is tiamulin. The aim of the study was to determine the minimal inhibitory concentration (MIC) of tiamulin in Clostridium perfringens Type A isolates from suckling piglets with diarrhoea between 2001 and 2004.

Material and Methods

The set tested for susceptibility and resistance to tiamulin consisted of 213 Clostridium perfringens Type A isolates obtained from cases of diarrhoea in piglets under 7 days of age. The samples were taken at 83 different farms. The tiamulin (Novartis AG) MICs were determined using the agar dilution method with blood Wilkins-Chalgren agar in accordance with CLSI recommendations (1). As no interpretative criteria for the evaluation of MICs of Clostridium perfringens isolates to tiamulin have been defined yet, we have adopted criteria intended for porcine isolates of Brachyspira hyodysenteriae (2).

Results

2001: MICs to tiamulin obtained in 30 selected Clostridium perfringens Type A isolates ranged from 2 to >32 mg.l⁻¹. Susceptibility and intermediate susceptibility were demonstrated in 14 (46.7 %) of the isolates, 2 (6.6 %) isolates were resistant.

2002: MICs in 30 Clostridium perfringens Type A isolates ranged from 4 to >32 mg.l⁻¹. Susceptibility was demonstrated in 4 isolates (13.3 %), intermediate susceptibility in 9 (30.0 %) and resistance in 17 (56.7 %) isolates.

2003: MICs range in 30 isolates was the same as in the year 2002. Susceptibility and resistance was demonstrated in 6 (20.0 %) isolates, intermediate susceptibility in 18 (60.0 %) isolates.

2004: Susceptibility was found in 36 (29.2 %) isolates, resistance in 5 (4.1 %) isolates. The MIC values ascertained in most of the isolates 82 (966.7 %) were those corresponding to intermediate susceptibility; see Graph 1 and Table 1.

Discussion

Regardles of situation when tiamulin isn’t registered for treatment of clostridial enteritis in piglets, were MIC₉₀ surprisingly high (16 - >32 mg.l⁻¹) in monitored period, in comparison with data obtained in Canada (MIC₉₀ 1 mg.l⁻¹) (3). We believe that this unfavourable development was connected with intensive medication of pigs with tiamulin in breeding herds affected with swine dysentery (SD), because a gradual growth in tiamulin MICs was also observed in Brachyspira hyodysenteriae isolates in the same time (4). Also the decrease in MICs of tiamulin in subsequent years is probably due to the decrease in the use of tiamulin, because of clinical resistance of Brachyspira hyodysenteriae at the period of treatment.

Conclusions

Based on the results of our study, we may assume a close relationship between bacteria forming part of intestinal microflora with respect to the establishment and development of resistance to antimicrobials frequently applied in feed or in water. Even though tiamulin has not been employed in the therapy of enteric infections, isolates keep unexpected high value of resistance. Possible explanation for findings sowing increasing MICs can consists in frequent use of tiamulin in the therapy of swine dysentery. Furthermore this findings corresponds with decreased sensitivity of Brachyspira hyodysenteriae isolates in the same time.

Treatment with diclazuril 1.5% in a farm swine with history of isospora suis: effect on the daily weight, diarrhea and mortality, from birth-weaning

Ismael M. Dolso; Gabriel Di Cola; Mercedes Vazquez; Silvia Romanini; Judhit Bertone
Universidad Nacional de Río Cuarto, Río Cuarto, Argentina

Introduction

Isospora suis is the causative agent of the swine neonatal coccidiosis (1). The disease usually occurs during the second week of life and is characterized by the development of diarrhea, dehydration and loss of body condition (2, 3, 4). The study aimed to assess the effectiveness of the diclazuril on a pig farm with a history of Isospora suis and its effect on the daily gain weight, diarrhea and mortality from birth to weaning.

Materials and Methods

The experience was on a farm in 500 mothers, located south of the province of Córdoba, Argentina, with a history of Isospora since 2007. During three weeks of deliveries are weekly formed two groups of piglets, selected at random, belonging to 23 mothers each group. A total of 517 piglets at 256 (49,51 %) is given by mouth, 1 cm3 of saline (group Control C). To 261 (50,49 %) is given 2 cm3 1.5 %, (Group Treaty D) Diclazuril. Both treatments were on the second day of life. All animals were heavy individually to the 1st, 7th, 14th and weaning at 19 days. Recorded the number of animals presented diarrhea and those who died with or without diarrhea. All data were analysed and processed by the statistical programme SPPS.

Results

See the results in Table 1 and 2.

Discussion

Table 1 shows that animals treated with Diclazuril 1.5 % on the second day of life, obtained a better daily weight, while Table 2 noted that it was effective to prevent the occurrence of diarrhea caused by Isospora suis, as well to reduce mortality.

**Effect of diclazuril 1.5% on the uniformity of the litter to the weaning in a farm with Isospora suis antecedents**

*Ismael M. Dolso; Gabriel Di Cola; Mercedes Vazquez; Judhit Bertone; Silvia Romanini*

*Universidad Nacional de Río Cuarto, Río Cuarto, Argentina*

**Introduction**

Isosporosis in piglets, caused by coccidium *Isospora suis*, is recognised as a disease having a significant negative impact on the pig industry, not as a cause of high mortality, but by reducing productivity and eroding the economic returns to pig producers (1). Piglet coccidiosis has been associated with decreased nutrient absorption, impaired immunocompetence, increased susceptibility to secondary bacterial infection, uneven weight gains and uneven litters at weaning (2,3).

The training target was to evaluate the effect of Diclazuril 1.5%, in a pig farm with antecedents of *Isospora suis* on the uniformity of the litter to the weaning.

**Materials and Methods**

The experience was realised in a farm of 500 mothers, located to the south of the province of Cordoba (Argentina), with antecedents of *Isospora* from year 2007. During three weeks of childbirths two groups of pigs, selected at random, pertaining to 23 mothers were satisfied weekly each group. Of a total of 517 pigs, to 256 (49,51%) it was administered to them by oral route, 1cm³ of saline solution, (Group Control C). To 261 (50.49%) 2cm³ of Diclazuril 1.5% was administered to them, (Treated Group D). Both treatments were realised to the second day of life. All the animal were heavy in individual form to the day of birth, and the 19 days, age of weaning. All the data were analyzed and process by statistical program SPPS.

**Results**

Table 1 shows the animal birth weight distribution.

Age, not infection dose, determines the outcome of Isospora suis infections in suckling piglets

Hans-Christian Mundt1, Hanna L. Worliczek2, Soelen Siemers2, Anja Joachim2
1. Bayer Animal Health GmbH, Monheim, Germany; 2. Institute of Parasitology and Zoology, Department of Pathobiology, University of Veterinary Medicine, Vienna, Austria

Introduction
In the field, clinical presentations of neonatal isosporosis range from subclinical infection with oocyst excretion to excessive watery diarrhea with exsiccosis and unthriftiness within the same litter. Several publications on a small set of animals indicate that age is more important for the clinical outcome of isosporosis than the infection dose (Meyer et al., 1999; Martineau and de Castillo, 2000; Mundt et al., 2003). In this evaluation a larger data set from experimental studies under highly standardized conditions was analysed retrospectively.

Materials and Methods
Data from 13 trials involving 124 suckling piglets experimentally infected with Isospora suis were evaluated for the effects of infection dose and age at infection on the clinical and parasitological outcome of infection in four different models. Infections were carried out with single oral inoculations of different numbers of sporulated oocysts of I. suis per animal at different ages (days of life, d.o.l.): model 1: 1000 oocysts on the 1st d.o.l (9 piglets from 3 litters); model 2: 1000 oocysts on the 4th d.o.l (25 piglets from 11 litters); model 3: 1500 oocysts on the 4th d.o.l (40 piglets from 20 litters); model 4: 10,000 oocysts on the 4th d.o.l (50 animals from 10 litters). Weights were determined on the day of birth and in weekly intervals. Faecal consistency and quantitative oocysts excretion were evaluated for 2 weeks starting 4 days after infection (d.p.i.) as described (Mundt et al., 2006).

Results
Piglets showed typical weight depression in the second week of life during the acute phase of infection. This effect was most noticeable in model 1 (infection on the first d.o.l.) where animals only gained 2.08x their birth weight until the 22nd d.o.l., compared to 2.31 (model 2), 2.52 (model 3) and 2.38 (model 4) x the birth weight in the other groups.

This correlated with the occurrence of watery diarrhoea which was found in 37 % of the samples in the acute phase (4-11 d.p.i.) in model 2 but only 12-20 % of the samples in the other models. Oocyst excretion prevalences showed the earliest peak 5 d.p.i. in the group with the highest dose and the highest peak (100 % for 2 days) in the group infected on the first day of life. The average excretion days 5-11 d.p.i. were 41.3 % (mean OPG: 9189) in model 1, 30.0 % (mean OPG: 8545) in model 2, 39.5 % in model 3 (mean OPG: 3143), and 75.2 % (mean OPG: 26 841) in model 4.

Median oocyst excretion peaked earlier in the models with higher infection doses but reached the highest values in model 1 (early infection).

Discussion
As in previous studies, this cross-sectional analysis of a larger number of animals confirms the influence of age on the outcome of isosporosis in suckling piglets, stressing the need to control the infection at an early life phase.

Impact of piglet coccidiosis on the gut health and economic benefits of the prevention with toltrazuril

Abdulkerim Deniz; Veerle Hamaekers
Bayer Animal Health, Monheim, Germany

Introduction
Piglet coccidiosis is a parasitic disease mostly affecting young and suckling piglets in the farrowing pens. The responsible agent is Isospora suis which is very reproductive protozoa with a prepatent period of 4-6 days. It causes pasty yellowish diarrhoea, but it can also occur subclinically without any sign of disease. Isosporosis is prevalent around 74% in German, 76% in Belgium, 79% in Greek and Austrian, 90% in Polish, 56% in French (1), 75% in Japanese (2) and 70 % in Canadian pig farms (3). Coccidiosis in suckling piglet is of economic importance due to retarded growth (4,5).

Impact of isosporosis on gut health
I. suis may cause fibrinous enteritis which mainly affects the middle and posterior part of the jejunum; villous necrosis and atrophy are frequently described (6). Serious damages on the villous and gut mucosa due to coccidiosis in pigs were already detected by different scientists (6,7). Coccidiosis can run concomitantly with Clostridium perfringens, E. coli, Rota virus, Adeno virus and salmonellosis (8). Primarily coccidiosis is also predisposing factor for the contaminant diseases. Typically the disease causes significant weight gain decrease at weaning and also its impact can result in prolonged production period (slaughter age) up to 9 additional days and in high postweaning FCR (9,10). This may be seen as primary reason why the piglets have frequently bacterial infections during the course of coccidiosis (10). A mixed infection of Clostridium perfringens and I. suis caused a mortality rate of 12.1 % in the first week of life and 16.2 % up to weaning in Germany (8). This mortality rate due to mixed infection was reduced by 71% in the first week of life and 64% up to weaning by preventative treatment of 3 days old pigs with toltrazuril 5% suspension (Baycox). Prevention from the primary destructive affect of I. suis on the gut health with early toltrazuril treatment resulted in significantly reduced mortality. Similarly in an experimental study (11) the same results were reproduced. Earlier coccidiosis episode predisposed pigs for postweaning Lawsonia infections which has been detected serologically in untreated pigs aged 21 to 105 days and resulted in higher FCR (10). However, not all treatment options give optimal results as reported by Mundt et al. 2007 (7). Sulphadimidine, diclazuril and toltrazuril (20 mg/kg one shot) were used to control isosporosis in suckling piglets, but none of the treatments other than toltrazuril were able to protect gut mucosa and to prevent from weight loss.

Economic benefits of the prevention
Even in subclinical coccidiosis the weight gain of pigs can be affected significantly (5). Under subclinical coccidiosis pressure the preventative treatment with toltrazuril (Baycox 5%) resulted in €0,23 net profit per piglet at weaning. Similarly, Scala et al. 2009 (4) also stated that the early preventative treatment with toltrazuril in italian pig farm provides better returns (€10,64) than sulphonamide and trimetoprim combination (€8,57) and untreated control group (€9,72) based on the weight at weaning day 28. Not doing preventative measurements against coccidiosis has prolonged the feeding time by around 12 days (9). This statement has also been supported by McOrist et al. 2009 (10). The FCR of toltrazuril treated pigs between ages 21 to 105 was 10% significantly less than untreated pigs. Based on the increase of weaning weight (647 g) and including handling and treatment cost, Sepulveda et al. in 2008 (12) calculated a surplus of €1,09 for the toltrazuril treated pigs at weaning. The increase of weight gain up to weaning via toltrazuril prevention is presented in figure 1. Prevention from coccidiosis at early ages can also reduce the frequency of antibiotic treatments up to weaning by around 88% (13), this can be explained by the improvement of gut health due maintenance of gut mucosa integrity and low diarrhoea incidence in those pigs treated with toltrazuril.

Conclusion
Isosporosis in suckling piglets has life long affects and should not be underestimated because it has economic impacts on production parameters and can cause loss of profit in pig rearing.

Evaluation of efficacy of oral toltrazuril (Baycox 5 %®) for the improvement of post-weaning gut health in pigs in Romania

Steven McOrist1 Daniel Spiru2 Marion Ocak3 Abdulkerim Deniz4
1. University of Nottingham, Sutton Bonington, UK; 2. SMF Veterinary Services, Timisoara, Romania; 3. MD Research, Munich, Germany; 4. Bayer Health Care, Monnheim, Germany

Introduction
Isospora suis disease often occurs around the second week of life, through to the normal pig weaning age of 3-weeks-old. It is characterized by yellowish pasty diarrhoea for one to several days. Oocysts can survive outside the pig, in the farrowing area, for many months. The time for intervention in piglets with a control strategy is critical; use of a preventive drug usually take place at 3 to 4 days of age so that it can kill appropriate stages of the parasite within newly infected piglets. In the European Union, the symmetrical triazintrione toltrazuril is the only coccidiocidal registered (since 2002) specifically for the control of porcine neonatal coccidiosis in a single oral dose format of 20mg per kg bodyweight. Clinical studies of toltrazuril after weaning have not been comprehensive - pigs are only considered to show limited compensatory growth. The exact reasons for this are not clear, but could include intestinal maturity and enzymatic activity and susceptibility to further post-weaning infectious agents. The aim of this on-farm study was to evaluate the efficacy of toltrazuril (Baycox® 5% oral suspension) for the improvement of gut health in a large-scale grower-finisher pig herd.

Methods
Four-day-old matched piglets either received toltrazuril (Green, n=2,870) or placebo (Blue, n=2,812) via blinded colour-coded medications. The subsequent diarrhoea scores, growth performance, gut health and enteropathogen load in each group was monitored by blinded observations, feed and pig weighing, faecal PCR tests for Brachyspira and Lawsonia and PCV2, culture for coliforms and Clostridia, as well as Lawsonia immunofluorescence assay serology. Observations were made daily and measurements collected weekly from day 21 up to day 150 in the grower-finisher stage of farming.

Results
There was a significant drop in oocyst count in piglets around weaning in the Baycox™ treated group (p<0.01). There was markedly improved feed conversion in treated weaner-finisher pigs (2.41 cf. 2.63). Weight gains were consistently and significantly better through to day 150, see chart. Lawsonia serology results indicated a late (between day 84 and 105) and moderate on-farm exposure, which was more severe in non-treated pigs.

Discussion
These results confirm the protective effect of toltrazuril (Baycox™) for coccidiosis prior to weaning and demonstrate specific beneficial effects on gut health and feed conversion after weaning. We also found that post-weaning enteric diseases including ileitis were more severe in pigs untreated for coccidiosis. We therefore suggest there are two main reasons why the lifetime effects of small weaning weight and peri-weaning infections of coccidia are so important and detrimental. First, there is an innate anatomical issue in that smaller, gut-damaged piglets being weaned with a limited supply of mature villi units, will grow more slowly and second, there is the likelihood that pre-weaning infections can carry forward into an increased number of post-weaning infections such as ETEC, Lawsonia and Brachyspira.

In the past 5 years, novel and effective preventive programs for Lawsonia and Isospora been introduced, related to an oral live attenuated vaccine and the oral anti-coccidial medication toltrazuril (Baycox™), respectively. Unlike coccidiosis in chickens, no major vaccines have been identified for coccidiosis in pigs.
Prevalence of Coccidia in piglets in Poland in years 2003-2009

Jacek Karamon; Zygmunt Pejsak
Nat. Vet. Res. Inst in Pulawy, Pulawy, Poland

Introduction
Coccidiosis caused by Isospora suis and Eimeria spp. is one of the common diarrhoeal diseases of piglets, occurring in all countries with intensive swine production. The first clinical symptoms of this disease appear between 9 and 15 days of piglet life. The faeces are pasty at the beginning, and what is typical diarrhoeic piglets do not respond to antibiotics. The diagnosis is usually made by detecting of oocysts in faeces of the affected pigs. The reports about prevalence of piglet coccidiosis caused by I. suis demonstrate a high farm prevalence of the disease (45%-to 90%).

The objective of this study was to summarize results of routine diagnosis for piglet coccidiosis performed in our laboratory during the period from 2003 -2009.

Material and Methods
The study was carried out between 2003 and 2009, in 14 out of 16 Polish provinces. Faecal samples were taken from 2-3 weeks piglets from 3 types of farms: large (>100 sows), medium (25 to 100 sows) and small (<25 sows). In mentioned farms diarrhoea of suckling piglets at the age 8-15 days were observed in all of the examined herds, the antibiotic treatment of sick piglets gave non satisfactory results. Overall, 966 litters of suckling piglets from 132 farms and 273 mother sows, during mentioned above period, were examined. Faecal samples of 5 to 28-day-old piglets were collected directly from the rectum. Samples were taken from 3 to 5 piglets per litter and pooled. 5–10% of litters from each farm were investigated. The faeces were analyzed with the flotation method. The saturated NaCl solution sugar enriched was used. The samples were examined at 100x-400x magnification. Samples were mixed with 2.5% potassium dichromate solution and stored on Petri dishes at 25°C in order to induce the sporulation if unsporulated oocysts were present. The species of coccidia were defined based on oocysts morphology and sporulation time.

Results and Discussion
Overall, I. suis infection was found in 286 litters of sucking piglets (29.6%) from 88 farms (66.7%). The coccidia of Eimeria genus (E. debliecki, E. polita, E. suis) were detected in only 23 litters (2.4%) from 13 farms (9.8%).

Comparison of the results from different years indicated that percentage of positive farms in different periods was similar. In any period percentage of I. suis did not exceed 74% (2005) and never was lower than 58% (2008).

As shown in Tab. 1, in the large farms I. suis infection was detected the most often (91.1% of farms, 33.3% of litters), whereas in the small farms frequency of this infection was found to be twice as rare. The situation with Eimeria spp. was just the opposite - for the large and medium sized farms Eimeria spp. oocysts were very uncommon, while on the small farms these infections were found in as many as 54.5% of farms, 28.9% litters. Similar results confirming a higher occurrence of I. suis in large farms than in smaller ones were obtained in Nordic countries (1).

The examination of faecal samples collected from sows (mothers of examined piglets), yielded the following results: I. suis oocysts were found in 19 sows (7%) and Eimeria spp. (E. debliecki, E. polita, E. perminuta, E. suis, E. scabra) in 18 sows (6.6%). From 73 sows delivering I. suis infected piglets just in 12 sows (16.4%) I. suis oocysts and in as little as 4 (5.4%) Eimeria spp. oocysts were found. In the remaining 56 sows (78%) no cases of coccidian infections were detected. Small number of sows excreting coccidian oocysts and a lack of correlation between the presence of oocysts in the sows, and the I. suis infected piglets were demonstrated also by other authors (2, 3).

Study concerning coccidiosis in piglets carried out during last 7 years proved that I. suis and Eimeria spp. were quite common in piglets 2 – 3 weeks of age in all sizes of farms. It might be also stated that those intracellular parasitic species play an important role as a cause of diarrhoea in sucking piglets. The level of coccidia infections seems to be stable during evaluated period.

Prevalence of isosporidial infection in piglets with clinical signs of enteropathy

Bozidar Savic; Ivan Pavlovic; Vojin Ivetic; Milenko Zutic; Branislav Kureljusic
Scientific Veterinary Institute of Serbia, Belgrade, Serbia

Introduction
The disease caused by coccidia Isospora suis has been described as an important cause of suckling piglet diarrhea and reported from all types of farrowing facilities and under all types of management systems (2, 3). The developmental stages of Isospora suis occur both inside the host animal and outside, in the external environment. The target organ of this parasite is the small intestine, where it undergoes development within the mucosal tissue. Isospora suis can infect pigs of any age, but only causes clinical signs in piglets, usually those between the ages of 7 and 14 days. Older pigs act as carriers. The sow plays a minor or nonexistent role in the transmission of Isospora suis.

Depending on the rate of infection, the disease complexes can range from sub clinical infections to infections that include severe intestinal problems with severe lesions in the gastrointestinal tract that can result in high mortality and/or a negative impact on the factors of production (2, 4). At same time, those parasites play important role at complex of neonatal entheropathy of piglets, spread together with other enteropathogenic agents of bacterial or viral etiology contributed to the origin of diarrheas (like E.coli, C.perfrigens tip C rotaviruses, and etc.) in parallel infections in piglets to a large extent.

Reports on the presence, prevalence and epidemiology of Isospora suis have come from virtually every country in the world (4). Studies conducted in most countries have shown a high prevalence of the disease on farms (18-85%). Results of our examination are at similar range Reports on the highest occurrence of Isospora suis in relation to piglet age vary. The highest prevalence of isosporosis was reported most frequently at the piglet age of two in some cases also third week of life. During our examination most prevalence are find at 13 days of piglet age. In our study we found significant correlation between isosporosis and watery diarrhoeas because the highest isosporosis prevalence was demonstrated in piglets with watery diarrheas.

We found out total isosporosis prevalence 27.4% mostly in a litter housing system; these results document that in our conditions there are not any significant differences in the prevalence and time of occurrence of Isospora suis between different housing systems and time periods compared to the results obtained in a litterless system of piglet housing.

Impact of the pharmaceutical quality of different toltrazuril suspension formulations on the control of Isospora suis infections in piglets

Hans-Christian Mundt1 Soelen Siemers¹ Iris Heep¹ Daniel Gondol¹ Klaudia Lusky2 Abdulkerim Deniz¹
1. Bayer Animal Health GmbH, Monheim, Germany; 2. IVPT, Bernau, Germany

Introduction
Piglet coccidiosis due to infection with Isospora suis is controlled by, among other measures, a single oral treatment with Baycox® 5% suspension in the first few days of life. The product was invented and developed specifically for this purpose. Almost two decades of experience and expertise in epidemiology and control demonstrate that both coccidial infections and infections due to C. perfringens on problem farms are reliably controlled (Mundt et al., 2007; Mundt and Daugschies, 2007; Mundt et al., 2008). Generic formulations containing toltrazuril have appeared in some countries since 2002. Their pharmaceutical parameters were analyzed and compared with the reference product (approved specification of the pioneer formulation). The impact on practical clinical use is discussed.

Materials and Methods
A total of 108 generic formulations and/or different batches were analyzed for their chemical, physical and microbiological properties. Investigations were carried out with HPLC (quantity of toltrazuril, impurities and by-products, preservatives), GC, analysis of color, density, sedimentation behavior, redispersibility, particle size (microscopy and measurement of particles and crystals), pH, microbiological status. In total, 10 to 15 analyses were conducted per sample. All methods were compliant with FDA, GMP and 21 CRF Part 11 requirements. Stability testing was performed at various temperatures in compliance with the most recent VICH guidelines in a GMP and cGMP environment. The clinical impact was additionally assessed in pharmacokinetic studies carried out by way of example with some formulations in piglets (comparison with the pioneer formulation).

Results
All the formulations tested were found to deviate from the specification for the pioneer formulation. There were differences in terms of the active ingredient (impurities, content of methyltoltrazuril etc.), type and content of preservatives, particle size and distribution (some particles up to 300 μm, Figure 1), sedimentation behavior, redispersibility among others. The differences were confirmed by the pharmacokinetic behavior of the products (Cmax, AUC).

Discussion
The studies showed differences, some of them considerable, between the pharmaceutical quality of the generic formulations tested and Baycox®. Their impact in terms of bioavailability, bioequivalence, efficacy, safety/tolerability, withdrawal time, convenience and cost-benefit is discussed.

Prevalence of Isospora suis in the South of Belgium

Martine Laitat1 Veronica Ianosi1 Valery Delleur1 Frédéric Farnir1 Bertrand Losson1 Dominique Gevaert2 Claude Saegerman1
1. University of Liège, Liège, Belgium; 2. Bayer SA-NV, Animal Health Division, Diegem, Belgium

Introduction

Isospora suis is the causal agent of coccidiosis, a frequent digestive disease usually noted in 5 to 14 days old piglets. The disease is characterized by diarrhoea and growth retardation but no (or a few) mortality unless after secondary bacterial infection. It has a strong economical impact for the farmer and even more if the aetiology remains unknown, causing loss of time and money using antibiotics that will be ineffective as the pathogen is a parasite. The objective of this work was to determine the prevalence of Isospora suis and the incidence of litters affected in pig farms of the South of Belgium - Wallonia. Epidemiological data were collected in each farm and compared (Table 1) to those reported in a previous study (Leten and al., 2002) performed in the North of Belgium - Flanders.

Materials and Methods

Faeces of three to five 10-18 day old piglets per litter were collected in 58 at random selected pig farms where 10 litters were available and no toltrazuril treatment (Baycox® 50 mg/ml, Bayer) was administered. Processing of faeces (1g per sample) was performed using 7 ml of a saturated NaCl solution with 500g added glucose per litre (Henriksen and Christensen, 1992). An optical microscope 10 x 40 was used to detect oocysts. A positive diagnosis for a farm (F) or for a litter (L) was recorded when at least one (sporulated or not) oocyst was present.

Possible relation between clinical signs (diarrhoea), cleaning and disinfection of the farrowing crate and the presence of I. suis or the percentage of infected litters were tested using \( \chi^2 \) test.

Results

Table 1 presents and compares results (NS not significant) obtained in Wallonia and previously in Flanders (Leten and al., 2002).

Discussion

Isospora suis has been shown to be a common parasite in 10-18 day old piglets in the South of Belgium. Diarrhoea was not significantly correlated with the presence of the coccidia. Perhaps the not quantitative method of diagnostic used and the high frequency of diarrhoea – also due to other pathogens - in suckling piglets could explained this result. Cleaning and disinfecting the farrowing crate had no significant effect on the occurrence of the infection. These results confirm that if farm hygiene measures are important to control the infection pressure, they only reduce it. Whatever the differences between pig production and studies from both the North and South part of Belgium, similar results were obtained.

**Efficacy of Virusnip® disinfectant and Quixalud® supplement against Balantidium spp. following the treatment of sows in a pig farm in Thailand**

Woraporn Sukhumavasi1 Manop Muangyai1 Padet Tummaruk1 Metta Makhanon2 Sasivimon Talummuk2 Kai Sievert3

**Introduction**

Balantidium spp. is a ciliated binucleate protozoan parasite infecting the large intestine of mammals including pigs, primates and humans. Representative, species of Balantidium in mammals are B. suis, B. coli and B. caviae. Balantidiasis appears to be problematic mostly of developing countries in pig industry and zoonosis (1, 6). Previous report of B. coli prevalence in Thailand was 37.3% in fattening pig farms (4). In the case of preexisting pathogenic bacterial intestinal infection, Balantidium aggravates the ulcerative colitis lesion due to its hyarulonidase activity. The ciliated motile trophozoite and dormant cyst are two stages responsible for the pathogenesis and transmission, respectively. The cyst is environmentally resistant and capable of infecting the host due to its thick wall hence protecting it from desiccation and other environmental stress (5). The transmission is direct so the pigs become infected either from their sows or through contaminated water or coprophagy (6). To prevent the disease from spreading, farm sanitation and hygienic measures are important factor to control Balantidium apart from treating diarrhea pigs with antiprotozoal drug. Recent reports showed the in vitro activity of Virusnip® disinfectant to disrupt B. coli cyst wall (3) and the efficacy of Quixalud® for the treatment of diarrhea in fattening pigs caused by B. coli (2). The objective of this study is to test the activity of Virusnip®, a disinfectant composed of potassium monopersulphate (PMP), sodium dichloroisocyanurate (SDIC), sulphamic acid, water softener and surfactant, and Quixalud® (60% Halquinol), a combination of hydroxy quinoline derivatives, in reducing Balantidium spp. transmission from the sows to the nursery pigs in a pig farm as an environmental control and an antiprotozoal activity, respectively.

**Materials and Methods**

The experiments were conducted in 4 groups of 30 pregnant sows composed of control (non-treated), Virusnip® treatment, Quixalud® supplement in feed, and Virusnip®/Quixalud® combination. Virusnip® was diluted with water to the working solution at 1:200 and 1:1000 in which it was used for disinfecting the farrowing pens (a week before bringing in the full-term sows) and pregnant sows (on the due date of farrowing), respectively. 180 ppm of Quixalud® was supplemented in feed of sows between 1 week pre- and post-farrowing period. The fecal samples from the control and treated sows at 1 wk post-farrowing and their weaning piglets at 4 wk and 8 wk-old were collected and qualitatively examined for Balantidium cyst by the direct fecal smear technique. The statistical analysis was carried out by using the Chi-square test.

**Results and Discussion**

After the Virusnip® treatment, 63.0% of the sows were found positive for Balantidium cysts. Interestingly, the percentage of Balantidium-positive samples from the 4 wk-old pigs born from this group was greatly reduced to 6.7% (p<0.0001) and there was a slight increase to 9.7% after following them up until 8 wk of age. However, there was no significant difference between the last two groups (p>0.05). For the Quixalud®-treated group, the percentage of Balantidium cyst were 60.0%, 10.0% and 0% in sows, 4 wk-old pigs and 8 wk-old pigs, respectively. There were significant differences in reduction of this protozoa between sows and both groups of their offsprings (p<0.0001). For the Virusnip® and Quixalud® combination group, the percentage of cyst from sows and 4 wk-old pigs were decreased from 34.6% to 6.5% (p=0.0075). However, we found the increased percentage at 8 wk-old group up to 61.3%. The latter results need to be further evaluated other causative agents that could play a role in potentiating this findings. This study is the first to show the promising application of Virusnip® disinfectant and Quixalud® to reduce the level of Balantidium transferring from sows to nursery pigs in the farm.

2. Dept. of Obstetrics, Gynaecology and Reproduction, Faculty of Veterinary Science, Chulalongkorn University, Bangkok, Thailand;

Introduction

Balantidiasis is a disease caused by the ciliated parasitic protozoan Balantidium spp. The large intestine of several mammalian hosts including pigs serves as its niche (6, 2). Although Balantidium infection is usually asymptomatic, the trophozoite can invade the epithelium during the concurrent pathogenic bacteria infection hence worsening the disease severity of ulcerative colitis resulting in diarrhea (7, 2). Pigs acquire the cysts, an infective stage, from the contaminated water or food or from their sows via fecal-oral route (6). In Thailand, the prevalence was 37.3% in fattening pig farms and increased with age correlating to the study in Oklahoma (5, 8). Since the Balantidium cyst wall is thick thus protecting it from the environmental stress, the measures for control this pathogen are recommended composed of sanitation, hygiene and farm management to prevent the pigs from succumbing to the infection by this secondary invader (1). Based on the recent findings, Virusnip® disinfectant appeared to be effective in disrupting B. coli cyst wall in vitro (4). Also, another report showed the anti-protozoal activity of Quixalud® in treating diarrhea in fattening pigs caused by B. coli infection (3). The aim of this study is to test the activity of Virusnip® (Potassium monopersulphate) disinfectant and Quixalud® (60% Halquinol), a combination of hydroxy quinoline derivatives, in reducing the environmental contamination and infection of Balantidium spp. in the nursery pigs, respectively.

Materials and Methods

The experiments were conducted in 4 groups of 30 nursery pigs composed of non-treated control, Virusnip® treatment, Quixalud® supplement in feed, and Virusnip®/Quixalud® combination. Virusnip® was diluted with water to the working solution at 1:200 and used for disinfecting the pens of nursery pigs three times a week starting from 5 wk old until 7 wk of age. 300 ppm of Quixalud® was supplemented in feed during the period of 5 wk to 7 wk old. The control group was treated as the routine cleaning management and feeding. The fecal samples were collected before starting the experiment at 5 wk old and at the end of the treatment, 7 wk old. Direct fecal smear technique was used for qualitative examination for Balantidium cyst. The statistical analysis was performed by using the Chi-square test.

Results

Before the treatment, the percentage of Balantidium-positive pigs were similar in every group in which the percentage of control group, Quixalud®-treated group, Virusnip®-treated group and Quixalud®/Virusnip® combination was 10.0%, 13.3%, 13.8% and 16.7%, respectively (p>0.05). After the period of 2 wk-experiment, the percentage of cyst-positive pigs in control group was increased twice (20%) compared to the 5 wk old control group whereas the slight reduction of positive sow percentage was found in Quixalud®-treated and Quixalud®/Virusnip® combination group (10.0% and 6.7%, respectively) (p>0.05). For the Virusnip® treatment group, there was an insignificant increase from 13.8% to 19% (p>0.05).

Discussion

Without the treatment, the control group revealed the increase in number of Balantidium-infected nursery pigs within 2 weeks correlating to the previous findings in that the older pigs harbored higher loads of parasites (5, 8). In addition, there was a tendency in reduction of number of infected pigs after treatment with Quixalud® or Quixalud®/Virusnip® despite the non-significant differences. This study provides a possible application of both Quixalud® and Virusnip® in control Balantidium in swine farm by reducing the environmental contamination, infection as well as improving the farm biosecurity.

Modified technique for collecting and processing fecal material for diagnosing intestinal parasites in swine

Jeremy S. Pittman1 Brad J. Thacker2 Gene Shepherd3 Gil H. Myers4
1. Murphy-Brown, LLC, Waverly, VA, USA; 2. Intervet/Schering-Plough Animal Health, Desoto, KS, USA; 3. Oklahoma State University, College of Veterinary Medicine, Stillwater, OK, USA; 4. Myers Parasitology Services, Magnolia, KY, USA

Introduction

Intestinal parasites of swine are still a concern in modern swine production and cause ill thrift, reduced growth rates, decreased feed efficiency, respiratory distress and condemnations of livers at harvest.1 Fecal flotation methods for diagnosing intestinal parasites and monitoring effectiveness of deworming programs are commonly used in many areas of veterinary medicine and are easily implemented in any clinic or laboratory.2 Monitoring of swine populations for the presence of intestinal parasites using the Modified Wisconsin Sugar Centrifugal-Flotation Method is the most sensitive and accurate method for detecting parasite eggs.3 The authors herein describe and discuss the “Waverly-Modified” method of collection and processing of fecal samples for the detection of intestinal parasites in swine.

Materials and Methods

For sampling a breeding herd, a 95 (% confidence)/10 (minimum % prevalence) sampling scheme was used and 30 samples were appropriate for most sow herds. Sows were sampled post-farrowing, which has been shown in other species to be associated with a periparturient rise in egg counts.4 A fresh 2cc fecal core sample was taken from each sow, using a 10cc syringe cut at the needle hub end. A new syringe was used for each sample because of the potential high numbers of eggs in an individual sample and the “sticky” nature of parasite eggs which could cause cross sample contamination.

For growing pigs, a composite sample was prepared where one fresh 1cc sample was taken from five separate fecal piles, totalling 5cc, within a single pen. The number of composites collected per barn was based on the capacity of the barn; 10 composites from barns with up to 800 animals and 12 from barns with 800 to 1,200 animals. For barns above 1,200 animals, an additional composite was collected per 80 head up to a maximum of 24. By pen, the composite numbers provided a 95/22 sampling scheme; by animal, a 95/6 scheme.

Each core sample was then discharged into a labelled 50ml conical centrifuge tube. This tube acts as the mixing container for the first laboratory step, thereby reducing additional steps and equipment. The 50 ml tubes are returned to the laboratory, and the following steps are performed: 1) a concentrated sugar solution (0.45 kg in 354 ml water) is added to the fecal sample directly into the 50 ml tubes; 15 ml for sows, 20 ml for composites; 2) the fecal-sugar mixture is homogenized by shaking vigorously or using a wooden tongue depressor; 3) the fecal-sugar mixture is strained through a tea strainer into a 150 ml waxed paper cup; 4) the remaining liquid is pressed through the strainer using a wooden tongue depressor; 5) the strained contents are transferred into a 15 ml conical centrifuge tube; 6) the tube is centrifuged for 5 minutes at 1,000 rpm; 7) the tube is placed in a test tube rack; 8) sugar solution is again added to the tube until a slight meniscus forms; 9) a 22 X 22 mm cover slip is placed on top and allowed to sit in place for 5 minutes; and 10) the cover slip is then placed on a microscope slide. Slides are read at 40X total magnification on a binocular microscope with a movable stage. Starting at one corner of the cover slip, move in a vertical plane, counting any intestinal parasite eggs seen. When the end of the field is reached, move the field horizontally until in a new vertical plane. Continue this method for 5 total planes, allowing evaluation of the entire cover slip.

Results and Discussion

The protocol provided clean, easy to read cover slips for the accurate detection of Ascaris suum and Trichuris suis eggs in over 3,000 samples. The modifications were made by the authors to standardize sample volume, collection methods, minimize excess fecal material and consolidate steps to allow for faster processing as part of a large scale intestinal parasite survey from which the results are reported in two accompanying papers. The above modified method should allow any veterinarian or veterinary clinic to perform in-house diagnostic testing for intestinal parasites.

Introduction
Historically, internal parasites have been a source of economic loss for the swine industry, estimated at $155 million annually.1 The 2006 NAHMS survey indicated that 74.7% of breeding sites regularly gave anthelmintics.2 However, internal parasitism is a topic of little discussion or concern in many modern swine production systems. The overall prevalence of internal parasitism has likely declined with the advent of indoor rearing of swine and the application of more effective anthelmintics in parasite control programs. However, once a barn or premise is contaminated with the eggs of the key internal parasites of swine, namely Ascaris suum (Large Roundworm) and Trichuris suis (Swine Whipworm), there is continuous risk for reduced performance due to parasitism. The objective of this study was to investigate the prevalence of internal parasites in a large integrated production system.

Materials and Methods
A total of 1,197 individual sow fecal samples, from 40 sow farms within a common ownership and management structure, representing 44,050 breeding animals were collected and processed. In addition to sample collection, a questionnaire was completed for each sow farm to capture historical parasite status, current health and production parameters and facility design features to assess potential risk factors that might influence parasite burden. Sow parity and lactation age were collected for each individual sow sample. Data was analyzed by either linear or logistic regression depending on the parameter evaluated. All fecal samples were processed using a modification of the Wisconsin Sugar Centrifugation flotation technique. Each sample was read and scored based on presence and total number of parasite eggs detected (0 = no eggs; 1 = <10 eggs per coverslip; 2 = 10-49 eggs; or 3 > 50 eggs). The presence of any eggs was considered positive and a farm with at least one positive sample was considered positive.

Results
Ascaris suum was the only parasite detected. Overall, 25% of sow farms were positive, representing 12,000 breeding animals. Additional positive results by a selected subset of farm type, farm size and facility design are reported in Table 1. However, statistical analysis found no risk factors related to farm parasite status and overall sow farm health and production levels were not related to farm parasite status.

*Farm defined as: Farrow-to-finish (FTF), farrow-to-feeder pig (FTFd) or farrow-to-wean (FTW).

Discussion
The prevalence of intestinal parasites within this system was higher than anticipated prior to performing the survey. The system had quit deworming sows prior to farrowing approximately 18 months prior to this survey based on not observing any adult worms and economic considerations. Selective treatment of positive sow herds along with implementing a continuous monitoring program is planned for this production system in the future.

Prevalence of internal parasites in a production system: Part II - Finishing pigs

Jeremy S. Pittman1 Gene Shepherd2 Brad J. Thacker3 Gil H. Myers4 Charles J. Francisco3
1. Murphy-Brown, LLC, Waverly, VA, USA; 2. Oklahoma State University, College of Veterinary Medicine, Stillwater, OK, USA; 3. Intervet/Schering-Plough Animal Health, Desoto, KS, USA; 4. Myers Parasitology Services, Magnolia, KY, USA

Introduction
Historically, internal parasites have been a source of economic loss for the swine industry, estimated at $155 million annually.1 The 2006 NAHMS survey indicated that 30.6% of grow-finish sites regularly administered anthelmintics.2 The overall prevalence of internal parasitism has likely declined with the advent of indoor rearing of swine and the application of more effective anthelmintics in parasite control programs. However, once a barn or premise is contaminated with the eggs of the key internal parasites of swine, namely Ascaris suum (Large Roundworm) and Trichuris suis (Swine Whipworm), there is continuous risk for reduced performance due to parasitism. The objective of this study was to investigate the prevalence of internal parasites in a large integrated production system, while also taking into consideration the facility design and production parameters of the various farms.

Materials and Methods
A total of 1,697 composite fecal samples were collected, processed and analyzed from finishing pigs. A composite contained a pool of 5 separate fecal samples from within the same pen. The total number of composites per barn ranged from 10 to 24, depending on the capacity of the barn. The 1,697 finishing composite samples represent 153 barns (33.2% of barns) and 91 finishing sites (100% of sites). The finishing pig samples represent 124,003 finishing spaces by barn and 367,758 spaces by sites. In addition to sample collection, a questionnaire was completed for each finishing barn sampled to capture historical parasite status, current health and production parameters and facility design features to assess potential risk factors that might influence parasite burden. Data was analyzed by either linear or logistic regression depending on the parameters evaluated. All fecal samples were processed using a modification of the Wisconsin Sugar Centrifugation flotation technique. Each sample was read and scored based on presence and total number of parasite eggs detected (0 = no eggs; 1 = <10 eggs per coverslip; 2 = 10-49 eggs; or 3 > 50 eggs). The presence of any number of eggs was considered positive and a barn with at least one positive sample was considered positive.

Results
Ascaris suum was the predominant parasite detected, while Trichuris suis was found in one finishing site. Overall 31.7% of barns and 38.1% of sites were positive, representing 37,911 and 90,072 finishing spaces, respectively. Results by selected risk factors are shown in Table 1. Statistical analysis indicated that the presence of intestinal parasites was mainly influenced by floor type, waste handling system and previous detection.

Discussion
In summary the prevalence of intestinal parasites within this system was high, especially in the finishing sites. The source of infestation appeared to be the facility itself and not the sow herd of origin. Facility factors and evidence of previous infestation were strongly associated with a site’s parasite status.

1. Vetsuisse Faculty Bern, Swine Clinic, Bern, Switzerland; 2. Vetsuisse Faculty, Dept. of Clinical Veterinary Medicine, Swine Clinic, Bern, Switzerland; 3. Institute for Parasitology, Bern, Switzerland; 4. Department of Clinical Research and VPH, Bern, Switzerland

**Objective**

Porcine gastrointestinal (GI) nematodes such as *Ascaris (A.) suum*, *Trichuris (T.) suis*, gastrointestinal strongyles, *Strongyloides ransomi* and others occur worldwide and can significantly influence feed efficiency, daily weight gain, feed intake and the health status of the individual pigs as well as of the whole herd. In most Swiss finishing pig farms, deworming is not routinely performed. Recent prevalence estimates for intestinal parasites are lacking. The aims of our study were thus to exploratively assess prevalence data of porcine GI nematodes in Swiss pig farms and to identify potential risk factors for intestinal endoparasitosis.

**Materials and Methods**

The study included 110 farms: 90 conventional and 20 outdoor farms distributed all over Switzerland. A total of 2762 (conventional) and 291 (outdoor) samples was taken.

Rectal fecal samples were collected only in one weight group per farm during the farm visit. Four groups were formed: weaned with 4 weeks-40 kg (A), 41-60 kg (B), 61-80 kg (C) and > 80 kg (D). Distribution of herds was nearly equal between groups.

Fecal specimens were analyzed in pools of 5 samples for the presence of parasites by a combined sedimentation and flotation method using a 44% Zinc-Chloride solution. If a pool was positive, every single specimen out of that pool was individually retested. Farms were declared positive if one or more individual fecal samples were positive. A questionnaire was completed during a farm visit to identify potential risk factors. Statistics were performed using a multiple logistic regression model with p<0.05 and CI of 95% (NCSS 2007).

**Results**

The number of collected samples ranged from 6 to 37 in outdoor housing farms and from 4 to 58 in conventional farms. *T. suis* was the most prevalent GI nematode in conventional farms, followed by *A. suum* and gastrointestinal strongyles. Only one farm was positive for *Strongyloides* sp. (Tab. 1).

All parasites in conventional farms were found most frequently in group (D). Prevalence of *T. suis* and *A. suum* inclined continuously from group (A) to group (D). *T. suis* was common in group (A) whereas *A. suum* was very rarely present in this group (Tab. 2).

In outdoor farms, *T. suis* was the most common GI nematode found, followed by *A. suum*, gastrointestinal strongyles and *Strongyloides ransomi*. In addition *Metastrongylus* sp. eggs were detected in pigs from 6 outdoor housing farms.

**Discussion**

The study showed that GI nematodes are frequently found in outdoor and in conventional farms in Switzerland. Pigs from outdoor farms showed a higher worm burden than pigs from indoor housing. This can be explained by the higher exposure of outdoor pigs to a possibly contaminated environment. Furthermore, *T. suis* seems to be the most common GI parasite in Switzerland. Its presence in conventional herds in all age groups indicates it being a problem already in breeding as well as in fattening farms. On the other hand, the low prevalence of *A. suum* in age group (A) indicates it being a problem only in fattening herds.

*Metastrongylus* sp. infections were demonstrated for the first time in Swiss commercial outdoor pigs. Wild boars are most likely to be the source of infection. All risk factors are related to general farm management.

“Lack of visitor’s clothing”, “silage” and “no rodent control” could be identified as risk factors for a farm being positive for GI nematodes. “Lack of visitors clothing”, “dirty boots and farmer’s clothing” and “no rodent and insect control” could be identified as risk factors for an infection with *T. suis*.
Endoparasite infections and hygiene management in organic fattening herds

Albert Sundrum; Christina Werner
University of Kassel, Witzenhausen, Germany

Introduction
Studies in different European countries have revealed that infections with endoparasites are one of the most important health problems in swine herds (Roepstorff et al., 1999; Eijck & Borgsteede, 2005). In organic pig farming, the regulation (EC) No 889/2008 includes several specifications which are expected to have severe impacts on parasite infection, i.e. straw bedding, access to outdoor run, addition of roughage to the daily feed ration and no prophylactic anthelmintic medication. Organic pig farms are also characterised by heterogeneous management practices and a lack in control measures (Ebke & Sundrum, 2004; Werner et al., 2009) providing a non-assessable risk for helminth egg contamination in the environment. The aim of the study was to assess the prevalence of endoparasite infections in fattening pigs on organic swine herds and to assess effectiveness and efficiency of management measures with respect to the reduction of endoparasite infections.

Materials and Methods
The study was performed in 17 organic swine herds in Germany. An interview with the farmer was performed using a standardised questionnaire, containing closed and open-ended questions on anthelmintic treatment, cleaning and disinfectant measures, documentation of production and management data and diagnostic measures on farm-level. Furthermore, 10 faecal samples per farm, taken twice during spring and autumn, were collected from fatteners. They were examined within 12-24 h after collection for nematode egg counts per gram of faeces (EPG) and coccidian oocysts using the McMaster technique. A total number of 326 fatteners were sampled. Data were categorised to evaluate the relationship between hygiene management and parasite infection.

Results
Strongylid infections were detected in 58.8% of the herds with a mean within-farm prevalence of 30.3%. Ascaris (A.) suum and Trichuris suis eggs were detected in 21 and 9.8% of faecal samples of fatteners, respectively. Coccidia infections were diagnosed in 88% of the farms. Pigs were treated with anthelmintics (mainly flubendazol) on all farms. The hygiene management showed a high variation between the farms. Only half of the farmers performed wet cleaning in their fattening units (n=8), whereas two farmers did not clean the stables at all. 15 of the total number of 17 farmers made no use of chemical disinfectant measures versus endoparasites. However, no egg-shedding of A. suum and strongyles was detected in three of these 15 herds. Four additional herds were free of strongyles.

Discussion
Results show that farms varied to a high degree with respect to the prevalence of endoparasite infection and the implementation of hygiene measures. In contrast to expectancy, the prevalence rate of Ascaris suum infection was on a low level in comparison to other studies (Carstensen et al., 2002; Eijck & Borgsteede, 2005).

No correlation was found between hygienic procedures and the occurrence of parasite infection, confirming previous results from Roepstorff et al. (1999). Thus, those farms who use comprehensive hygiene measures are not necessarily gaining the best results with respect to parasite infection. It is concluded that farm specific control and feedback mechanism are required to minimize both endoparasite infections and efforts to control them.

Introduction

Group housing of pregnant sows is becoming more and more the norm in modern pig production. Although clearly beneficial in view of animal welfare, this poses specific challenges towards day-to-day practicalities.

It not only involves the stressful event of grouping which has to be addressed to avoid a decrease in reproductive performance (1), but it makes it also much more difficult to correctly administer routine treatments to the sows once they are grouped. Injection treatments become ‘rodeo-like’, dangerous and stressful events for both animal and man. For in-feed medication it becomes more difficult to get the dose correct as sows of different parity, condition and gestation length have different nutritional needs and it implies specific medicated feed deliveries posing additional logistic problems. Top dressing is not possible with feeding stations and becomes more difficult if sows are not individually confined during meals. This leaves the drinking water as the most convenient and least stressful medium to administer routine medication, such as deworming.

Solubenol® is a flubendazole based anthelmintic for drinking water application that recently was granted an authorization for use in pregnant sows. Flubendazole is a broad spectrum anthelmintic for pigs used for strategic deworming programs. In a target animal safety study (2), Solubenol® showed to be safe to the pregnant sow when given at multiple doses and occasions before, during and after pregnancy, indicating the absence of the risk for overdosing.

This study was performed to evaluate its safety and convenience as a routine dewormer at the therapeutic dose, in a large group of sows at different stages of pregnancy.

Materials and Methods

Four consecutive batches, each of approximately 110 sows of mixed parities and different housing system were either treated with 5 mg flubendazole per kg body weight spread over 5 consecutive days or left untreated. Sows were treated through the drinking water system in the group housed animals or individually dosed on the wet feed using a drenching gun in the individual pen housing (Table 1).

Clinical observations of the sows and their piglets, monitoring of the litter size (total, live or stillborn and mummies) and viability (mortality up to weaning and piglets weaned) were the evaluation criteria for the safety of the treatment.

</tr>
</tbody>
</table>

Results

In total, 238 sows treated with Solubenol® and 205 control sows were included. No abnormal clinical observations were present resulting from the treatment of the pregnant sows. No statistical significant differences in the way of administration or litter size were present between both groups (total born 14.2 versus 14.4), although overall, somewhat more live born piglets and less still-born piglets were present in the Solubenol® group (Table 2).

Mortality up to weaning, as well as the number of piglets weaned was comparable between groups.

Furthermore, there was no influence of the sow parity.

Discussion

From the results it is clear that the Solubenol® treatment, as a routine dewormer, is safe for use in every stage of the pregnancy. No differences in any of the parameters were detected between the results in the drinking water or wet feed treatment and the control. This renders both larger batch treatments as well as targeted individual treatments very convenient without causing additional stress to the sows.

Deworming via the drinking water system with flubendazole, both safe and efficacious

Jos Jacobs; Jan Jourquin; Lieve Goossens; Leo Van Leemput
Janssen Animal Health, Beere, Belgium

Introduction
In pig industry, disease prevention has become a pillar for good veterinary practice. Biosecurity, housing and ventilation, vaccination and routine deworming all add up to successfully achieve that goal.

Routine treatment by injections are very labor intensive and an important stress factor for both pigs and caretaker. Vaccinations are usually done at a young age when piglets are still manageable. Routine deworming however is done in older pigs which make injections troublesome. In-feed medication is a good alternative but in many cases, there are logistical and legal constraints. This leaves the drinking water as the most convenient and least stressful medium to deworm. More and more farms are equipped with a separate medicated drinking water system and dosing pumps are no longer exceptions. This offers great flexibility and the possibility of targeted treatments by the stockman. Solubenol® is a safe and efficacious flubendazole based anthelmintic for drinking water application for pigs of all ages. It is authorised at a total dose of 5 mg flubendazole per kg body weight (BW) to be administered over a 5-day period for the control of the economic most important Ascaris suum infections. Unlike levamisole, that has a narrow safety margin.

In view of reducing labor pressure, an alternative dosing schedule of the same total flubendazole dose, but administered over only 2 days was evaluated. This included two efficacy studies, a residue depletion and a target animal safety study.

Materials and Methods
The first efficacy study was run under controlled laboratory conditions (UK). It included pigs with a confirmed, naturally acquired Ascaris suum infection. They were divided in two randomised groups: one treated with Solubenol® at 2.5 mg flubendazole per kg BW on two consecutive days, the other group was left untreated. Efficacy was based on reduction in worm counts and faecal egg counts (EPG), one week after the last day of treatment.

In the second efficacy study (France) the same groups were composed but under field conditions.

In the residue depletion study, concentrations of parent flubendazole and its major metabolite were determined in edible tissues over a period of 7 days after the last administration.

The target animal safety study looked at changes in clinical, biochemical and hematological parameters after a treatment with 1, 3 and 5 times the 2.5 mg per kg BW dose over a 3-fold treatment duration.

Results
The results (Table 1) indicated that the treatment was fully effective.

<table>
<thead>

<td>0.9</td>
</tr>
<tr>
<td>p-value</td>
<td></td>
<td>0.0022</td>
<td>0.0152</td>
</tr>
</tbody>
</table>

The second efficacy study is ongoing at this moment.

One day after treatment, major total residues were found in liver and kidney; relatively low residues were quantifiable in muscle and skin/fat. Residues declined rapidly in liver and kidney and were not quantifiable in muscle and skin/fat after 3 days. The concentrations determined in the edible tissues after the 2-day treatment did not compromise the withdrawal time of 4 days as also established for the 5-day treatment.

The target animal safety study, conducted at 2.5, 7.5 and 12.5 mg/kg BW/day for 6 days did not result in any abnormal clinical observations and demonstrated no relevant changes in none of the parameters measured. This indicates that this treatment schedule has a very large safety margin. No palatability issues were noted in any of the studies using a higher day concentration of Solubenol® in the drinking water.

Discussion
From the results it is clear that a Solubenol® treatment, administered over two days while keeping the total flubendazole dose at 5 mg per kg BW, is effective, safe and does not imply a different withdrawal period. This additional dosing schedule offers more flexibility in treatment duration. Accidental overdosing if animals drink excessively or when different age groups are treated at the same time, can be avoided with flubendazole which has a very high LD50. Therefore, Solubenol® is the safer choice for routine deworming of fatteners.
Spike glycoprotein gene-based phylogenetic analysis of recent transmissible gastroenteritis virus isolates in Korea

Seong-Jun Park1 Hyoung-Joon Moon2 Hye-Kwon Kim1 Hyun-Ok Keum1 Se-Mi Rho1 Jae-Yeon Han1 Van-Giap Nguyen1 Bong-Kyun Park1

1. Department of Veterinary Virology Lab, College of Veterinary Medicine and BK21 Program for Veterinary Science, Seoul National University, Seoul, Korea; 2. Research unit, Green Cross Veterinary Products, Yongin, Korea

Introduction
Transmissible gastroenteritis virus (TGEV) has caused a devastating enteric disease with acute diarrhea, vomiting, weight loss, dehydration and high mortality and resulting in severe economical losses to the affected farms [1]. The spike glycoprotein stimulates induction of neutralizing antibodies in the host. Moreover, the spike glycoprotein has been recognized as not only a tropism but also a virulence determinant [2]. The purpose of the present study was to investigate the genetic diversity among the Korean TGEV field isolates and was to find out more prevalent TGEVs in Korea, according to sequence and spike glycoprotein gene-based phylogenetic analyses with Korean and non-Korean TGEV and PRCV reference strains.

Materials and Methods
A total of 10 porcine samples (from 5 different farms) including feces or intestinal contents had been taken from young piglets showing watery diarrhea, dehydration and high mortality. Five pairs of sense and anti-sense primers were designed based on the reference TGEV sequences and used to generate full spike glycoprotein gene of TGEV. The full spike glycoprotein gene of TGEV was amplified by RT-PCR, gel extracted and directly sequenced. Nucleotide sequence of full spike glycoprotein gene was determined and phylogenetic tree was then generated using an alignment of spike glycoprotein gene nucleotide sequences with reference TGEV and PRCV strains by applying neighbor-joining method in the MEGA 3.1 program. To assess the relative support for each clade, bootstrap values were calculated from 1000 replicate analyses.

Results
Nucleotide sequences of the full spike glycoprotein genes of 10 Korean TGEV isolates were determined and compared with one another, as well as with reference TGEV and PRCV strains. By phylogenetic analysis, all compared twenty-two viruses, including 10 Korean TGEV isolates, 11 TGEV and 1 PRCV reference strains, certainly fell into two groups at the nucleotide sequence level. One group comprised KT2, KT3, KT4, HKT2, 133, MIL65-AME, BRI70-FS, PUR46-MAD, NEB72, TOY56 and HOL87 and 8 Korean TGEV isolates. Another group consisted of TFI83 and 2 Korean TGEV isolates.

Discussion
By spike glycoprotein gene-based phylogenetic analysis, all Korean TGEV isolates were divided into two groups. It was suggested that recent, many Korean TGEV field isolates are closely related to the group including KT2, KT3, KT4, HKT2, 133, MIL65-AME, BRI70-FS, PUR46-MAD, NEB72, TOY56 and HOL87 rather than to the group including TFI83. It is notable that recently more prevalent TGEVs in Korea are especially close to the NEB72, respiratory Purdue type TGEV.

Novel vaccine against swine transmissible gastroenteritis using Salmonella choleraesuis as a live vector

Weidong Chai; Qiqai He; Fei Song; Kun Zhang; Lili Xu

College of Veterinary Medicine, Huazhong Agricultural University, Wuhan, China

Introduction
Swine transmissible gastroenteritis (TGE) is a highly contagious enteric disease in piglets causing high mortality rate of up to 100% and resulting in severe economical losses to the affected farms. The currently commercial available vaccines could provide only partial protection, and this emphasizes the importance of developing a new vaccine to prevent this disease. The mucosal immunity is required for protection. Salmonella has been proved as good vector that stimulates mucosal immunity. How to enhance expression of main antigen is a crucial strategy. Site A and site D in the spike protein (S) of transmissible gastroenteritis virus are the main inducer of neutralizing antibodies while Site A is a major B cell epitope. Peptide N321, which is located on the nucleoprotein (N), defines a functional T helper epitope eliciting T cells capable of collaborating with B cells specific for different proteins of TGEV(1).

Material and Methods
Antigen site A, site D and antigen site N321 of TGEV were combined by two Linker ((GGGGS)4 as a fusion peptide (SLN). By using SalI and XhoI site, two copies of SLN (2SLN) were constructed. Non-resistance expressing plasmids pYA-SLN and pYA-2SLN were constructed, respectively. The two plasmids were electrotransformated into Salmonella choleraesuis C500 competent cells to construct the recombinant Salmonella strains C500 (pYA-SLN) and C500 (pYA-2SLN) respectively. We evaluated the immunogenicity and protective capacity of the recombinant Salmonella strains through a vaccination and challenge trial in mice. Furthermore, field trail of the recombinant vaccine was applied in a farm which was being affected by TGE which was confirmed by our in-house RT-PCR in Jan. 2009 and the mortality rate was around 60%.

Result
We successfully constructed the recombinant Salmonella choleraesuis strains C500 containing plasmid pYA-SLN and pYA-2SLN, respectively, in which the gene integrated could be highly expressed. Both of the recombinant Salmonella strain induced the immunized mice a high titer of serum IgG and gut mucus secreted IgA against the antigens of Salmonella and SLN-protein. A higher titer of IgG and IgA could be induced in mice vaccinated with recombinant salmonella choleraesuis containing pYA-2SLN than that containing pYA-SLN, indicating that a peptide antigen displaying repeating copies of SLN is a more potent inducer of TGEV-neutralizing antibodies than SLN alone. Furthermore, IgG subclasses, among which the IgG2a titer is higher than IgG1, were induced in mice immunized by Salmonella choleraesuis harboring pYA-2SLN. The sIgA could also be detected in mice four week after vaccination and peak at six week. The primary result of field trail showed that by oral administration, no new cases were observed, and about 99% piglets recovered from diarrhea between 48-72 hours after oral administration of the new vaccine.

Discussion
Due to the mucosal immunity is important factor in the protective mechanism of swine TGE which inactivated vaccine always lack. In this work, we used Salmonellas choleraesuis as a live vaccine to express main antigen protein of TGEV. The three epitopes domains were combined, cloned and integrated the genes into non-resistance expressing plasmid, non-resistance recombinant Salmonella strains were successfully constructed and efficiently expressing the fragments integrated in. Furthermore, we evaluated the immunogenicity and protective capacity of the recombinant Salmonella strains using a vaccination and challenge trial both in mice and in piglets. These results indicated that the recombinant C500(pYA-2SLN) vaccine showed the potential live vaccine against Swine transmissible gastroenteritis

Genetic diversity of porcine rotaviruses in selected Korean pig farms, 2009
Shienyoung Kang1 Yunkyung Song1,2 Seonghee Kim2 Kyoungki Lee2 Changil Yeo2 Chaewun Bae2 Osoo Lee2 Choikyu Park2
1. Chungbuk National University, Cheongju, Korea; 2. National Veterinary Research and Quarantine Service, Chungang-ro, Anyang, Korea

Introduction
Rotaviruses(RV) are important causes of diarrheal disease in animals and humans and a common cause of gastroenteritis in sucking and postweaning pigs (1). Based on viral protein(VP) 6, major component of the inner capsid, RV are divided into seven distinct groups, A to G. Among them, group(G) A, B, C and E RV have been detected in pigs. GARV are the most commonly associated with diarrhea in pigs (1). GCRV were first detected in pigs in 1980 and have been identified as the causes of diarrhea in sucking and newly weaned piglets. In Korea, GARV and GCRV have been detected in pigs with diarrhea (2). GARV are classified into G and P types based on the specificity of two outer capsid protein VP7(glycoprotein) and VP4(protease-sensitive protein), respectively (1). The examination of the diversity and prevalence of G and P types is important to survey the contemporary circulating strains.

Materials and Methods
Eighty nine intestinal or fecal specimens were obtained from 42 pig farms in Korea between January and July 2009. All specimens were examined by reverse transcription-polymerase chain reaction(RT-PCR) using group-specific primers for detection of GARV, GBRV and GCRV (2, 3). Positive samples for GARV were subjected to G genotyping by RT-PCR using type-specific primers (4). The RT-PCR products of VP6 of GCRV and VP7 amplicons from samples positive for G9 RV were sequenced and analyzed.

Results
Of 89 samples from 42 pig farms, 40 from 22 pig farms and 40 from 21 pig farms were positive for GARV and GCRV, respectively. No samples showed positive for GBRV. Twenty-three out of 40 GARV-positive samples were genotyped by RT-PCR. The G genotypes of 23 samples were determined as follows; three samples were G3, six were G5, nine were G9, three were G3+G5, one was G3+G9 and another one was G3+G5+G9. The identity of the partial nucleotide(nt) sequence of the VP6 gene from 20 porcine GCRV detected in this study was 87-99% and that of the amino acid(aa) was 92-100%. By the phylogenetic analysis of the partial VP6 gene of 20 GCRV detected in this study and reference strains of human, bovine and porcine GCRV, it was found that 19 Korean GCRV belonged to the porcine lineage and one didn’t belong any porcine, bovine and human lineages. By the phylogenetic analysis of VP7 gene of G9 RV, four amplicons were shown to belong to lineage VI and sublineage b(VIb) and two amplicons were Vlc according to the novel nomenclature for G9 RV (6 lineages with 11 sublineages) (5).

Discussion
This study indicated that GCRV(50.3%) and GARV(52.3%) were widespread in Korean pig farms. Genetic analysis of partial VP6 gene of GCRV showed that most GCRV belonged to the porcine lineage. However, relatively short nucleotide sequences of GCRV VP6 gene were analyzed due to the direct sequencing of detected amplicons. For further detailed genetic sequence analysis, the comparison of the extended or whole nucleotide sequence of GCRV VP6 gene will be necessary. The determination of G genotypes showed that G3, G5 and G9 types were prevalent in Korean pig farms examined in this study. To define the more detailed diversity of circulating RV, P typing is absolutely needed. Phylogenetic analysis of VP7 gene of G9 RV indicated that seven isolates were close to the porcine G9 RV rather than human G9 RV. For further study, it is necessary to isolate the circulating porcine RV and characterize them genetically and serologically and develop the vaccine by the selection of the most prevalent and effective strains.

Prevalence of rotavirus and coronavirus in piglet production herds in the Czech Republic

Linda Czanderlova; Marek Zizlavsky; Dita Kellnerova; Marcela Gambova; Svetlana Odehnalova; Jiri Odehnal
Sevaron Counselling, Brno, Czech Republic

Introduction
Pre-weaning diarrhoea in pigs is a complex problem involving a large number of causative agents. Multiple enteric infections can occur, often in association with non-infectious factors. Viruses can play an important role by modifying the intestinal mucosa and thus predisposing secondary infections (1). Group A rotaviruses have been detected most frequently in swine. Rotaviruses and TGE and PED coronaviruses are important swine pathogens in nearly all countries with an intensive pig production. The significance of rotavirus and coronavirus infections is frequently underestimated in practice and these viruses are not often included in the differential diagnostics of diarrhoeal diseases in suckling piglets.

The aim of this study is to report the data of identification of rotavirus group A and TGE a PED coronaviruses in suckling piglets with diarrhoea in the Czech Republic.

Materials and Methods
The study included in total 98 pool samples of faeces taken from 53 pig production herds in the territory of the Czech Republic in the year 2008 and 2009. The samples were taken from suckling piglets with clinical manifestations of diarrhoea at the age from 2 to 28 days. All samples were tested for the presence of rotavirus group A, TGE coronavirus and PED coronavirus. Commercial immunochromatographic tests Rota Ag test kit and TGE/PED Ag test kit (Bionote) were used to prove these viruses in laboratory.

Results
Of 98 faeces samples included in the study, the presence of rotaviruses and/or coronaviruses was detected in 66 samples (67.3%). The capture of rotaviruses and coronaviruses in the year 2008 and 2009 is presented in Table 1. TGE coronavirus was diagnosed most frequently (51 positive laboratory diagnoses). PED coronavirus was detected in 41 cases, rotavirus was diagnosed less frequently (30 positive laboratory diagnoses). Monoinfections were detected only in 25 cases (37.8% of all positive laboratory diagnoses), mixed infections with various combinations of rotaviruses and coronaviruses were diagnosed in the remaining cases (see Table 2). The combination of TGE and PED coronaviruses was found to have the highest prevalence, followed by TGE monoinfection and combined infection of rotavirus, TGE and PED coronavirus.

Discussion
The acquired results indicate that the problem of viral diseases of digestive system in suckling piglets is still topical in the Czech Republic. These results and observations from farm audits suggest that environmental conditions and husbandry practices (poor disinfection) may be predisposing suckling piglets to viral intestinal infection. Although the infections related to rotavirus and coronaviruses have an enzootic course in pig herds in the Czech Republic, they lead to atrophy and degeneration of enterocytes and aggravate the course of intercurrent infections (e.g. C. perfringens type A, C. difficile, ETEC).

When solving these viral infections in practice, vaccination of breeding stock sows before delivery, either by a commercial vaccine containing ETEC and the rotavirus group A, or by an autogenous vaccine with ETEC, rotavirus group A and TGE and PED coronaviruses proved good.

Interspecies transmission of goat rotavirus to swine

Min-A Hwang; Jung-Ah Lee; Seung-Yong Park; Chang-Sun Song; In-Sooh Choi; Joong-Bok Lee
Konkuk University College of Veterinary Medicine, Seoul, Korea

Introduction
Rotavirus A, the major cause of gastroenteritis in children and animals, is interspecies pathogen. The notion of interspecies transmission between porcine and human(1), porcine and equine(2), and porcine and bovine(3) was reported. Transmissibility between porcine and goat was not reported up to date. An attempt was carried out to support the evidence that rotavirus A isolated from different species may infect others by demonstrating that goat rotavirus may infect pigs.

Material and Methods
Inoculum was 1ml of 10^4 TCID50 caprine rotavirus, GRV G3P[5] that was isolated from fecal specimen of 3-month-old goat(4). GRV was orally administered to the 3-day-old piglets which were raised with replacement milk after cesarean section (GRV n=6, mock n=3). For six days, clinical sign was monitored by scoring diarrhea level (0=normal, 1=mild, 2=moderate, 3=severe). In order to confirm fecal shedding and to see if GRV is disseminated to other organs besides conventional infection site of rotavirus, fecal samples were sampled daily and then ileum, liver, brain and lung tissue were collected by the end of experiment period. NSP4 gene of rotavirus was amplified by nested PCR to confirm viral infection. In addition, mRNAs from spleens were collected to profile mRNAs for innate immunity and pro-inflammatory cytokines. Quantitative analysis using reverse transcription real-time PCR using SYBR® green reagent was conducted.

Result
Mild diarrhea began at day 1 post inoculation (PID 1) and got worse day by day till PID 3. The severe diarrhea peaked at PID 4 and reached flat for 24 hours. The PCR detection rate of PID 4 and 5 were significantly higher than the others (Fig 1).

Fig. 1. The mean diarrhea score (line) and density of PCR products (bar).

As shown in Table 1, PCR products of GRV appeared at 50% of ileum, liver, lung, and brain, respectively. It is interesting that one of infected piglet did not shed, but spread virus to all of the tested tissue.

Discussion
This study directly support the possibility of interspecies transmission. Cytokine analysis also showed that GRV strain may evoke innate immunity to provide antiviral activity. In an attempt to control co-circulation of rotavirus infection in animal and/or human population, to understand mechanism by which transmission of interspecies occurs is important.

In GRV infected piglet, mRNAs of both type I and II interferon (IFN-α, γ, respectively) were elevated in parallel with increase of mRNAs for IFN–inducible antiviral molecules, OAS and PKR. mRNAs of TNF-α and IL-4 increased, while those of IL-6, 8, 10 decreased slightly (Fig. 2).

Development and validation of a quantitative PCR for the detection of *Actinobacillus suis*

Maria J. Clavijo; Simone Oliveira

*University of Minnesota, Saint Paul, MN, USA*

**Introduction**

*Actinobacillus suis* is an emerging pathogen considered to be a new threat for swine production. The isolation of this pathogen from tissues submitted to the University of Minnesota Veterinary Diagnostic Laboratory (MVDL) increased considerably in the past three years. In 2006, a 16s rRNA gel-based PCR was developed and since then requests for *A. suis* PCR testing have raised significantly.1 This tool has been highly employed in protocols attempting to eradicate *A. suis*. However, complete elimination of the pathogen has not yet been achieved.2,3 Limitations of this gel-based PCR include the non-specific amplification of *A. equuli* and the lack of bacterial quantification. Therefore, a more sensitive and specific quantitative diagnostic tool is needed to improve eradication protocols. The objective of this study was to develop and validate a sensitive and specific quantitative PCR assay for the detection of *Actinobacillus suis* in clinical samples.

**Materials and Methods**

Forward and Reverse primers and a TaqMan probe specific for the amplification and detection of an *A. suis* housekeeping gene involved in thiophene oxidation (*Thdf*) were designed using the Primer 3 Software. Quantitative PCR conditions were optimized utilizing an ATCC *A. suis* reference strain. This strain was also utilized to evaluate the analytical sensitivity of the quantitative PCR by testing 10-fold dilutions of extracted DNA. The analytical specificity was evaluated by testing 29 unrelated bacterial species frequently isolated from swine in addition to *A. equuli*, which generated non-specific amplifications with the gel-based 16S rRNA PCR. The stability of the targeted gene sequence among *A. suis* field isolates was evaluated by testing 70 different isolates representing 12 genotypes circulating among U.S swine herds.

**Results**

The newly developed quantitative PCR detected a minimum of 3.5 x 101 CFU/ml, compared to 7.2 x 102 CFU/ml detected by the 16S rRNA gel-based PCR test. The *Thdf* quantitative PCR was highly specific, detecting exclusively *A. suis* isolates. There was no non-specific amplification of *A. equuli* DNA, as previous observed with the gel-based PCR. The new quantitative PCR amplified the *Thdf* gene from all 70 *A. suis* field isolates tested, indicating that this housekeeping gene is highly conserved among different strains circulating in U.S swine herds.

**Discussion**

We have developed a more sensitive and specific quantitative PCR for detection of *A. suis* in clinical samples. This new test will allow swine veterinarians to perform a more comprehensive comparison of different control and eradication protocols. All attempts to eradicate *A. suis* from endemically infected populations have failed so far. In most of these cases, *A. suis* was not detected at weaning following intensive antibiotic treatments, but was detected at the end of the nursery using the gel-based PCR. The new quantitative PCR, which is more sensitive and specific than the previous gel-based PCR, will allow a better characterization of prevalence at weaning. Quantification of *A. suis* in tonsil swabs will also provide a more detailed characterization of treatment effect, and will allow swine veterinarians to evaluate the cost-benefit of each protocol. We expect the new *A. suis* quantitative PCR to be an important aid in *A. suis* control and eradication.

Preliminary study of Actinobacillus suis colonization in upper and lower respiratory tract in naturally infected animals

Marina Sibila; Eva Huerta; Llorenç Grau-Roma; Virginia Aragón; Joaquim Segales
Centre de Recerca en Sanitat Anima (CReSA), Bellaterra, Spain

Introduction
Actinobacillus suis (A. suis) is considered an early colonizer of the upper respiratory tract, which may also cause fatal cases of septicaemia in young piglets. A. suis infection has been also described in adult animals with fever, inappetence and erysela-like skin lesions (1). However, in high-health farms this pathogen has been linked as well to different pathological conditions including arthritis, pneumonia, enteritis, meningitis, abortion and endocarditis in pigs at different ages (2). Besides, A. suis infection can cause very similar lesions to those of Actinobacillus pleuropneumoniae (App). In fact, both pathogens share some virulent factors including Apx toxins, urease, and iron-regulated outer membrane proteins. Moreover, distinction of A. suis isolates from App biotype II ones can be difficult if it is not confirmed biochemically or by molecular biology techniques. This high similarity between both pathogens may sometimes lead to erroneous diagnosis (2).

Little information on the A. suis prevalence in animals of different ages and clinical conditions is nowadays available. Therefore, the goal of the present study was to gain insight into A. suis prevalence in upper and lower respiratory tract samples from pigs with different clinical conditions.

Material and Methods
Forty seven pigs were included in this study. From these, 34 pigs (from 6 to 18 weeks of age) were submitted for necropsy to the Pathology Diagnostic Veterinary Service at the Veterinary School of Barcelona (Spain) with different clinical signs (mainly, growth retardation, digestive and respiratory problems). The remaining pigs were 13 6-week-old healthy pigs. The following samples were collected from each animal: nasal swab (NS), tonsillar swab (TS), tonsillar brush (TB), tonsil tissue (T), bronchial swab (BS) and lung (L). TB was not taken in 9 of the 47 animals. Lung was always taken from the accessory lobe, independently on the presence or absence of lesion.

DNA from swabs and tissues was extracted using commercial kits and processed according to the manufacturer’s instructions. In order to differentiate between A. suis and App, samples were tested with two PCRs. One to detect the Apx IV gene (3), present exclusively in all App serotypes, and another to detect the Apx II gene (4), present in A. suis and in most of App serotypes. The Apx IV PCR was done in a singleplex mode in all samples but when ambiguous results were obtained the nested PCR was performed (5).

Results
Apx II and IV toxin genes were detected in a number of animals showing different clinical signs. Positivity was found in samples from the upper (NS, TS, TB and T), but not in those from lower respiratory tract (BS and L). On the other hand, all tested samples from healthy animals were PCR negative to both toxins. Apx II was more frequently detected (15 out of 47 [32%]) than Apx IV (9 out of 47 [19%]). In both cases, the number of PCR positive samples per animal varied from one (mainly TS) up to 3 (TS, TB and T or NS). From the 47 tested animals, 31 (66%) were negative to both Apx II and IV PCRs in all the tested samples. Nine (19%) out of 47 pigs were PCR positive to both Apx II and IV at least in one sample. Finally, 6 (13%) animals were positive only to Apx II PCR while only 1 (2%) was positive exclusively to Apx IV.

Discussion
Detection of Apx II in absence of Apx IV amplification in some samples would indicate A. suis infection in such animals. These preliminary results suggest that A. suis detection in upper respiratory tract by means of direct PCR is feasible and relatively frequent in animals of different ages and showing different clinical conditions. The best sample to be tested by direct PCR resulted to be the TS or TB.

The concomitant detection of both toxins in some animals together with the existence of an animal in which only Apx IV was found, indicated the presence of different App serotypes in the samples.

More studies will be useful to assess the role and prevalence of A. suis in porcine respiratory pathologies.

Detection of *Haemophilus parasuis* requires strategic diagnostic

Rose-Leah Austin-Busse¹ Andrea Ladinig² Joachim Spergser³ Mathias Ritzmann² Karl Heinritzi¹ Andreas Palzer¹

1. Clinic for Swine, Veterinary Faculty Ludwig-Maximilians University Munich, Munich, Germany; 2. Clinic for Swine, Veterinary University Vienna, Vienna, Austria; 3. Institute of Bacteriology, Mycology and Hygiene Veterinary University, Vienna, Austria

**Introduction**

*Haemophilus parasuis* (HPS) is the etiological agent of porcine polyserositis and arthritis (Glässer’s disease). Despite the increased prevalence and severity of Glässer’s disease in recent years (1), diagnosis of Glässer’s disease is still a challenging task. Not only is the isolation and cultivation of the bacteria tedious due to its fastidious nature, but routine diagnostic methods are hampered by the heterogenic nature of HPS and its commensal status in the upper respiratory tract of healthy pigs (2). The aim of this study was to evaluate the detection of HPS by PCR and bacterial culture (BC) in different materials taken from weaned piglets that were experimentally infected with HPS serovar 5.

**Materials and Methods**

36 piglets, approximately 3 weeks old, were obtained from a commercial farrowing farm which had no previous history of porcine reproductive and respiratory syndrome virus (PRRSV). Also, the animals were *Mycoplasma hyorhinis* PCR negative and *Haemophilus parasuis* serologically negative. Piglets were housed in two separate units in a biosafety level 3 facility. After an acclimatization period of 17 days, 27 piglets were infected intratracheally with 5 x 10^8 colony-forming units (CFU) of HPS serovar 5. The remaining 9 animals served as control animals and received phosphate-buffered saline (PBS) instead. The study was terminated 15 days after infection. Dry swabs of the serosal surfaces (pleura, pericardium, and peritoneum) and the brain, synovia and cerebrospinal fluid (CF), and joint capsule were taken for PCR (3) analysis from each animal either at study termination or at removal. Furthermore, swabs from the serosal surface were investigated for bacterial examination.

**Results**

Results of the PCR and BC of the infected pigs are illustrated in Table 1. All sample materials from the control animals were negative by PCR analysis and BC. A total of 12 infected pigs died or were euthanized due to humane reasons within 10 days after infection. HPS was more frequently isolated in samples from these animals than animals that died at study termination. The sample material and method with the highest HPS detection was the PCR analysis of serosal swabs. HPS genome was detected by PCR in the joint capsule of 5 animals, however, the synovia fluid from these animals were HPS negative. Similarly, the synovia samples from four animals were PCR positive but the corresponding joint capsules from these animals were negative. Also, HPS genome was more frequently detected in the cerebrospinal fluid than the brain swab by PCR testing. At study termination, HPS genome was detected predominantly in the synovia fluid; all other sample materials were negative by PCR analysis and BC.

**Discussion and Conclusion**

In the current experiment, 12 pigs died within 10 days after infection. This study confirms the findings of Kielstein and Rapp-Gabrielson (4) who classified serovar 5 as very pathogenic, capable of eliciting death within 4 days. Although this study was conducted with a relatively small number of animals, differences in HPS detection were found, particularly after comparing PCR and culture results between animals that died acutely or at study termination. Turni et al. (2) noted that sample material tends to yield differing results depending on if samples were obtained after a subacute, acute or chronic infection.

Based on the results from this study, conclusive HPS detection is best achieved by examining samples from various sites using both PCR and BC. Furthermore, HPS detection is more successful in sample material from animals which are in the acute phase of infection. In this study, HPS genome was only detected in the synovia fluid when animals were chronically infected. Also, PCR testing of CF was more successful at detecting HPS genome than a brain swab. Further investigations are necessary to confirm these results.

*Table 1: Results of PCR and bacteriological examination of samples from pigs infected with HPS serovar 5*
Introduction
Matrix-assisted laser desorption ionisation-time of flight mass spectrometry (MALDI-TOF-MS) in combination with dedicated analysis software is a reliable method for the identification of microorganisms (1).

The analysis software incorporates functionalities for the processing of mass spectra as well as for identification. Identification of bacteria is achieved by comparison of generated mass spectra with reference spectra stored in a ready to use database which contains the characteristic spectra information of species and subspecies. However, Haemophilus parasuis spectrum was not present.

We present here, the generation of a new reference pattern for H. parasuis and its use for a rapid identification of H. parasuis strains in a clinical approach as an alternative to time-consuming and expensive routine methods.

Materials and Methods
The bacterial strains used to evaluate the H. parasuis reference mass spectra were recovered from clinical diagnosis. They were identified using traditional biochemical tests (4) and PCR (3).

These bacterial strains were H. parasuis (29), A. pleuropneumoniae (1), Actinobacillus taxon C (1), Actinobacillus minor (6), B. bronchiseptica (1) and P. multocida (1).

Bacterial strains were grown over night on different media and under diverse culture conditions according to the microorganisms.

To establish a reference mass spectrum for H. parasuis, the well known and identify reference strain CIP 105098 was used (CIP : Pasteur Institute collection). A good average was achieved by the measurement of 24 spectra of the reference strain. The software automatically generated the peak lists from the whole set of the 24 spectra and extracted the typical peaks which were present in all the spectra to established the H. parasuis reference spectrum. This spectrum was added to the library.

Direct “cell smear”, a simple method applicable to many bacteria, was used. Small amounts of biological material (single colony) were smeared directly as a thin film onto a Maldi target. One microliter of chemical matrix was deposited and allowed to dry down.

The samples were analysed in a Bruker Microflex (LT) Maldi-Tof Mass Spectrometer.

The MALDI BioTyper™ software was used to process raw spectra. Identification of the bacterial strains was performed by comparison with the library of reference spectra from Bruker and our H. parasuis reference spectrum. A matching score based on identified masses and their intensity correlation was generated and used for ranking of results.

Results
Traditional identification of H. parasuis is based on colony morphology, Gram staining, NAD requirement and biochemical testing (4). However, those techniques remain time consuming and labor intensive procedures. H. parasuis identification strain from clinical samples processing needs, at least, 3 days.

Starting from a few biological material, mass spectra could be observed for each bacterial isolate tested. Results were known in a few minutes.

In total, Maldi Tof MS identified 29 of the 29 isolates H. parasuis (100%), concordant with traditional bacterial methods and PCR. The remaining tested bacteria were identified at the species or genus level, but not as H. parasuis. Since the validation of the H. parasuis reference spectrum, numerous strains have been identified using this new method.

Discussion
These results show that it’s easy to create a new reference mass spectrum for H. parasuis which is nowadays used for routine and rapid identification in our laboratory. Now, H. parasuis is identified within 24 h rather than the 72 h or more needed for traditional bacteriological methods. Furthermore, samples preparation and analysis do not exceed traditional methods cost.

Thus, Maldi Tof MS offers a good alternative to traditional laboratory methods in veterinary and environmental diagnostics (2). The speed and minimal sample preparation make it well suitable for routine use. Prerequisite is the establishment of high quality spectra libraries.

A further field of application is the potential of lineage typing, analysis of taxonomic relationships.

Serotyping of Haemophilus parasuis isolates from German pigs

Katrin Strutzberg-Minder1 Jan Boehmer1 David Goldstein1 Herve Le Galludec2 Matthias Homuth1
1. IVD GmbH Innovative Veterinary Diagnostics, Hannover, Germany; 2. Fort Dodge Animal Health, GM Naarden, Netherlands

Introduction
Haemophilus parasuis is the cause of Glässer’s disease (porcine polyserositis and arthritis) and other clinical disorders in pigs, but it can also be isolated from the upper respiratory tracts of healthy pigs.

Fifteen serotypes of Hps, defined by an immunodiffusion or agar gel precipitation test with heat-stable antigens, have been described by (1), and it has been shown that there is an association between serotype and the degree of virulence (2). A new indirect hemagglutination (IHA) test for serotyping of Hps isolates has also been developed and evaluated (3). The latest published data on the prevalence of Hps serotypes in Germany are from 1998 (4).

Material and Methods
The IHA test was performed according to the method of (3). Antisera against all 15 serotype-specific reference strains were prepared as described (1) with some modifications.

A total of 96 strains isolated from German pig herds with clinical problems were typed by IHA, most of them with the objective of making a herd-specific vaccine. No precise data were available on the source tissue of the isolates and on clinical symptoms.

Results
The most prevalent Hps serotype was 1 (n = 18), followed by serotypes 2 (n = 16), 13 (n = 13), 4 (n = 12), and 5 (n = 9) (Fig. 1). Less prevalent were the serotypes 12 (n = 5), 7 (n = 4), 9 (n = 2), 11 (n = 1) and 14 (n = 1). No Hps isolate was identified as serotype 3, 6, 8, 10 or 15. In all, 15 of the Hps isolates showed no reaction with any of the 15 serotype-specific antisera and were thus not typeable (s. Fig. 1: n.t.).

Discussion
The most frequent serotypes 1, 2, 13, 4 and 5 (73.8%) are associated with a moderate to severe degree of virulence (2). Our data support the assumption that these isolates were involved in the clinical problems of the herds. The IHA test for serotyping Hps isolates is thus a useful tool for evaluating whether an isolate can be expected to have a clinical impact.

The IHA test was originally developed as a new method for serotyping of Hps and was evaluated by determining the prevalence Hps in North America. More than 90% of the field strains of Hps were found to be typeable by IHA, including those exhibiting cross-reactivity in immunodiffusion which fails to identify approximately 30% of field isolates of Hps (3). In our study, 15 (15.6%) field isolates could not be identified with any serotype, although 84.4% of the isolates were typeable. Since genotyping is not strictly correlated with serotyping and virulence is associated with serotype, there is still a need for antigen-based typing. Furthermore, despite great progress in genotyping techniques, antigenic characterization of prevalent strains of Hps is still essential for the development of effective vaccines and serodiagnostic tests and for epidemiological analysis.

A Modified Multi-Locus Sequence Typing (MLST) Scheme for *Haemophilus parasuis*

Karen B. Register; Michael A. Mullins; Darrell O. Bayles
USDA/ARS/National Animal Disease Center, Ames, IA, USA

**Introduction**

*Haemophilus parasuis* is the etiologic agent of Glässer's disease and pneumonia in swine. Phenotypic classification systems are of assistance in epidemiologic studies but molecular methods provide numerous distinct advantages. An MLST scheme proposed by others appears promising (4). However, recently acquired genome data (3,5) reveal the primers used, based on sequences of other bacteria, are not optimal for *H. parasuis*. Furthermore, several different PCR mixes and cycling programs are required for amplification of all targets. Here we report modifications to enhance and simplify the original method, thereby facilitating data acquisition and increasing accuracy. The modified MLST was applied to a group of 35 diverse *H. parasuis* isolates and the results compared with those obtained using the original method.

**Materials and Methods**

Thirty-five genetically distinct strains of *H. parasuis*, including the 15 serovar reference strains, were evaluated by the original (4) and modified MLST methods. Amplicon sequences were trimmed, concatenated and used to construct Neighbor-Joining trees as reported (2). Target-specific alignments used to guide primer redesign included genome sequences of four *H. parasuis* strains (3,5). Vector NTI Advance was used for sequence editing and analysis and to assist in primer design.

**Results and Discussion**

Alignments of genome sequences from 7 target genes, *atpD, infB, mdh, rpoB, 6pgd, g3pd* and *frdB*, were examined for variability and quality of match within the original primer-binding regions (see Fig. 1 for an example). Ten of the 14 originally recommended primers (4) were redesigned to eliminate mismatches and avoid regions of high sequence heterogeneity.

To simplify the method for end users, we standardized the Tm of all primers and identified a universal PCR mix and set of cycling conditions that resulted in robust and reproducible amplification of all targets.

The number and percentage of variable positions within the dataset obtained using our modifications (240 of 3154 positions; 7.6%) is slightly less than for the original method (408 of 3806 positions; 10.7%) but the grouping of strains in major clusters is nearly identical (Fig. 2). Analysis of *H. parasuis* genomes indicates some MLST targets are in close proximity along the chromosome (e.g., *6pgd* and *frdB* are separated by ~10Kb), in opposition to general guidelines for MLST (1). Nonetheless, the discriminatory power of the scheme proposed here suggests it is a highly useful phylogenetic and epidemiologic tool.

Phylogenetic Analysis of Dutch and Belgian *Haemophilus Parasuis* Isolates Using ERIC-PCR

Remco Dijkman¹ Gerard J. Wellenberg¹ Tom Duinhof¹ Harold M.J.F. van der Heijden¹ Refke Peerboom¹ Alex Olvera² Cora Miry³ Anja Rothkamp¹ Eric. van Esch¹

1. Animal Health Service, Deventer, Netherlands; 2. Centre de Recerca en Sanitat Animal (CReSA), Barcelona, Spain; 3. Animal Health Care Flanders, Torhout, Belgium

**Introduction**

*Haemophilus parasuis* (*H. parasuis*), a ubiquitous bacterium in the upper respiratory tract of swine, is the causative agent of Glässer’s disease. To date, more than 15 *H. parasuis* serotypes have been described and isolates with the same serotype can be very heterogeneous in virulence (1).

Several attempts have been made to improve the differentiation of field isolates both on phenotypic and genotypic level. In this study, the Enterobacterial Repetitive Intergenic Consensus-PCR (ERIC-PCR) for fingerprinting of field isolates has been used to identify separate lineages in Dutch and Belgian *H. parasuis* isolates. ERIC-PCR lineages were compared with serotyping results.

**Materials and Methods**

From October 2007 until September 2009, 89 *H. parasuis* isolates have been collected from pigs which were presented at the Dutch Animal Health Service for postmortem examinations. Typical growth on chocolate (+NAD) agar plates, satellite growth without hemolysis on blood agar plates using *Staphylococcus aureus* nurse strain and a negative CAMP test were used for the identification of *H. parasuis*. Ten *H. parasuis* reference strains and 11 Belgian field isolates were examined too. The serotypes were determined at the IVD GmbH (Gesellschaft für Innovative Veterinärdiagnostik, Germany) using type-specific antisera. ERIC-PCR was performed as described by Rafi ee et al (2). PCR products were visualized on a 2% agarose gel. Gel images were analyzed using the BioNumerics software package (Applied Maths NV, Sint-Martens-Latem, Belgium).

**Results**

Serotyping revealed in general the serotypes 1 (n=14), 2 (n=12), 4 (n=29) and 13 (n=18), whereas serotype 5 was serotyped 8 times.

ERIC-PCR gel images of the 100 isolates were analyzed by the BioNumerics software. Similarities were determined using Pearson correlation and clustered using the UPGMA algorithm (Figure 1). ERIC-PCR revealed a very heterogeneous pattern. No clear correlations between serotypes and ERIC-PCR lineages were found.

**Discussion**

Different *H. parasuis* serotypes and ERIC-PCR lineages were found in Dutch and Belgian isolates. The overall correlation between serotype and ERIC-PCR analyses was low. Isolates with different ERIC-PCR patterns were found within the same serotype. Other techniques and further analyses of these isolates in correlation with clinical and pathological findings will be used to identify more virulent isolates and to separate these from low virulent isolates.

Phylogenetic Analysis of Dutch and Belgian *Haemophilus Parasuis* Isolates Using HSP60 Sequence Typing

Gerard J. Wellenberg1 Remco Dijkman1 Tom Duinhof1 Harold M.J.F. van der Heijden1 Refke Peerboom1 Alex Olvera2 Cora Miry3 Anja Rothkamp1 Eric. van Esch1

1. Animal Health Service, Deventer, Netherlands; 2. Centre de Recerca en Sanitat Animal (CReSA), Barcelona, Spain; 3. Animal Health Care Flanders, Torhout, Belgium

Introduction

*Haemophilus parasuis* (*H. parasuis*) is the etiological agent of Glässer's disease. Glässer's disease is characterized by serofibrinous and fibrinopurulent polyserositis, arthritis, meningitis which can also lead to acute death, especially in piglets. *H. parasuis* can also be isolated from lungs.

At this moment, 15 different serotypes are described (1). Certain serotypes may be associated with virulence but the link between serotype and virulence is often inconclusive. Several attempts have been made to improve the differentiation of field isolates both on a phenotypic and a genotypic level. Partial sequencing of the heat shock protein 60 gene (*hsp60* gene) proved to be a reliable marker for epidemiological studies of *H. parasuis* and showed that the analysis of its sequence is superior to other fingerprinting techniques (2). The objective of this study was to identify lineages of Dutch and Belgian *H. parasuis* isolates. These isolates, including 10 *H. parasuis* reference strains, were subjected to serotyping and *hsp60* sequence analysis.

Materials and Methods

From October 2007 until September 2009, 134 *H. parasuis* isolates were collected from pigs which were submitted to the Dutch Animal Health Services for postmortem examinations. Typical growth on chocolate (+NAD) agar plates, satellite growth without hemolysis on blood agar plates using *Staphylococcus aureus* nurse strain and a negative CAMP test were used for the identification of *H. parasuis*. Ten reference strains and 11 Belgian field isolates were examined too.

The serotypes were determined at the IVD GmbH (Gesellschaft für Innovative Veterinärdiagnostik, Germany) using type-specific antisera. The *hsp60* universal PCR was performed as described by Goh et al. (3). PCR products were sequenced and sequence data was aligned and analyzed using the BioNumerics software package (Applied Maths NV, Sint-Martens-Latem, Belgium).

Results

Serotyping revealed in general the serotypes 1 (*n*=14), 2 (*n*=12), 4 (*n*=29) and 13 (*n*=18), whereas serotype 5 was serotyped 8 times.

*hsp60* partial sequences (498 bp) of 145 isolates were aligned, and parsimony trees (using 200 bootstrap simulations) were constructed (Figure 1). Variations were detected at 116 nucleotide positions and pair-wise similarities using Pearson correlation ranged from 86 to 100%. In total, 56 different sequence types (STs) were detected. Using 99% sequence similarity, as threshold for group separation, 4 separate clusters (I, II, III and IV) could be distinguished. When comparing STs with serotyping data no strong correlation was observed, except for a possible correlation between cluster I and serotype 5.

Discussion

Different *H. parasuis* serotypes and *hsp60* lineages were found after analysis of the 145 *H. parasuis* isolates. The overall correlation between the two methods, serotyping and *hsp60* sequence analysis, was low, except for serotype 5. A possible association between cluster I and *H. parasuis* serotype 5 and/or higher virulence will be examined furthermore based on the recorded clinical symptoms and pathological lesions.

Identification of a novel immunogenic and species-specific protein in *Haemophilus parasuis*

Nubia R. Macedo; Simone Oliveira

University of Minnesota, Saint Paul, MN, USA

**Introduction**

*Haemophilus parasuis* continues to be one of the most important causes of nursery mortality in modern swine production. One of the main challenges in *H. parasuis* control is the lack of a reliable serological test to characterize the development of antibodies in sows and piglets. This information is critical to understand herd immunity and to identify the best timing for vaccination. In this study we have identified a highly immunogenic and species-specific protein in *H. parasuis*. This protein is a strong candidate for the development of a *H. parasuis*-specific ELISA test and of a universal subunit vaccine.1,2

**Material and Methods**

Twenty pigs involved in an *H. parasuis* outbreak were selected based on clinical signs (fever > 105 F, respiratory distress, lameness, CNS signs) for necropsy and *H. parasuis* isolation (n=10) or for antibiotic treatment to produce convalescent sera (n=10). Whole cell proteins obtained from *H. parasuis* isolates recovered from diseased pigs were probed with convalescent serum using Western blot. An immunodominant protein observed in all *H. parasuis* outbreak strains and 13 reference strains was identified and sequenced. Specificity of the highly immunogenic protein was tested by doing Western blot analysis using whole cell proteins obtained from 10 additional bacterial species commonly isolated from swine tissues, including *Actinobacillus porcinus*, *A. indolicus*, *A. minor*, *A. pleuropneumoniae*, *A. suis*, *Streptococcus suis*, *Bordetella bronchiseptica*, *Pasteurella multocida*, *Escherichia coli*, and *Salmonella choleraesuis*. Precolostrum serum obtained from a 1 day-old piglet was used as a negative control in all Western blots.

**Relevant results and discussion**

The convalescent sera obtained from pigs that survived the *H. parasuis* outbreak recognized a wide range (27 kDa – 77 kDa) of whole cell proteins in both outbreak and reference strains. One single band with an estimated molecular weight of 52 kDa was clearly immunodominant and it was observed in all *H. parasuis* strains tested. This protein was not identified in any of the unrelated bacterial species, indicating that it was specifically expressed by *H. parasuis*. Precolostrum swine serum also failed to detect this protein in all isolates tested. The 52 kDa immunodominant protein was identified by sequencing as an oligopeptide permease ABC transporter membrane protein in *H. parasuis* (OppA). This protein has now been cloned and expressed in *E. coli* (Figure 1). We have identified a novel immunogenic and species-specific protein in *Haemophilus parasuis*. This protein will now be utilized to develop a *H. parasuis*-specific ELISA test and will be evaluated as a potential universal subunit vaccine.

Simultaneous infection by serotypes 4 and 12 of *Haemophilus parasuis* in a swine herd: a clinical case

Andrea Luppi1 Giuseppe Iodice2 Luigi Franchi3 Paolo Bonilauri1 Giuseppe Merialdi4 Marianna Merenda5 Michele Dottori1

The clinical expression of *Haemophilus parasuis* (HPS) in pigs is well described since many years, in the form of polyserositis and arthritis (Glässer's disease) (4). Of the 15 known serovars, strains belonging to serovars 1,5,10,12,13,14 have been shown to be highly virulent, serovars 2,4 and 15 moderately virulent, serovar 8 mild virulent while serovars 3,6,7,9 and 11 avirulent (3). The purpose of this paper is to report a clinical case where 2 different pathogenic serotypes of HPS were isolated.

Materials and Methods

This clinical case took place between April and May 2009. The farm was a farrow-to-feed unit with 500 sows. The piglets were vaccinated against PCV2 and *Mycoplasma hyopneumoniae* at 3 and 5 weeks respectively. The clinical symptoms of disease started at 7 weeks of age and the mortality rate increased at 12 weeks of age reaching over 10% in some batches. The symptoms observed were: loss of appetite, swollen joints, lameness, dyspnoea, cough, sometimes nervous signs and sudden death. Seven dead piglets were submitted for necropsy to the Istituto Zooprofilattico Sperimentale Lombardia and Emilia Romagna (IZSLER), laboratory of Reggio Emilia, following routine methods. From dead piglets several samples of affected organs were collected. Bacteriological cultures were performed using Gassner agar, nutrient agar and blood agar added with nicotinamide adenine dinucleotide (NAD). *H.parasuis* PCR was performed from pathological samples (fibrinous lesions in the lung and pericardium) collected and stored at -20°C (4). From six live piglets in the affected age groups, blood samples were collected and examined for antibodies against PRRSV (indirect ELISA IDEXX), against PCV2 (competitive ELISA IZSLER-Brescia) and for the presence of PCV2 and PRRSV using a rt-PCR and a real time PCR respectively (2,5). The strains of *H.parasuis* isolated were serotyped using the agar gel immunodiffusion test and by indirect haemagglutination (1). Phenotypic methods were used to identify other bacteria isolated.

Results

The gross lesions observed were: arthritis in the carpal and tarsal joints with fibrinous content, fibrino-purulent pneumonia, pericarditis and peritonitis with fibrin trends over the abdominal organs in four pigs. Two of these showed also pleuropneumonia. Catarrhal bronchopneumonia without other lesions was observed in two pigs, while no lesions were observed in one pig. Two serovars of *H.parasuis* were isolated from diseased pigs. Two strains isolated from pigs with systemic disease (polyserositis) were serotyped as serovar 4, while another strain isolated from a pig with bronchopneumonia was serotyped as serovar 12. Two strains of *Actinobacillus pleuropneumoniae* biovar 2 serovar 7 and biovar 1 serovar 9 were isolated from the two lungs with pleuropneumonia respectively. PCR results confirmed bacteriological findings and also demonstrate the presence of *H.parasuis* in two cases of polyserositis in which this pathogen was not isolated by culture. All sera samples showed antibodies against PRRSV (S/P values ranging between 1 and 2,5) and also antibodies against PCV2. Positive PRRSV rt-PCR (European strain) was observed in a pool of three sera, while all sera resulted PCV2 real time PCR negative.

Discussion

The results agreed with the classification of Kielstein and Rapp-Gabrielson (1992), in which the serovar 12 has been shown to be highly virulent (generally isolated from pigs without polyserositis), while serovar 4 moderately virulent (generally isolated from pigs with polyserositis). However, the connection between serovar isolated and gross lesions observed can be influenced by several factors (host factors, vaccinations and other bacterial and viral diseases). In this work *H.parasuis* coexisted with other pathogens like *A.pleuropneumoniae* and PRRSV. The results of this work showed the importance of isolates serotyping, mainly if the vaccination is used for the disease protection.

Characterization of field isolates of Haemophilus parasuis from Colombian swine farms

Paula C. Manrique Ramirez1 Jose D. Mogollon2 Ricardo J. Piñeros Duque3 Ivonne I. Hernández3 María A. Rincon Monroy3
1. Pontificia Universidad Javeriana, Bogota, Colombia; 2. Universidad Nacional de Colombia, Bogota, Colombia; 3. Instituto Colombiano Agropecuario ICA, Bogota, Colombia

Introduction

Haemophilus parasuis (Hp) is an important commensal opportunistic respiratory pathogen of swine. These organisms can potentially invade the host and cause systemic infection characterized by fibrinous poliserositis, arthritis and meningitis. Hp usually in our country affects young pigs after 7 weeks of age in the nursery. Some serovars of Hp seem to be more virulent than other, but so far no true virulence factors have been identified.

A tentative diagnosis can often be made on the basis of history, clinical signs and gross lesion observed during necropsy. Isolation and culture of this microorganism is considered the gold standard. To control this disease the characterization of the strains associated with systemic disease is required. The goals of this study were (i) to isolate Hps from intensive swine affected herds (ii) to apply the ERIC – PCR technique to detect the genetic diversity among the isolated strains.

Materials and Methods

Samples were collected from eleven commercial farrow-to-finish pig farms located in three different raising regions. The farms had a previous history of Glasser’s disease outbreak in nursery piglets.

Clinical samples (joints, pericardium, pleural and abdominal fluid swabs, lungs and spleen) were examined by isolation. Routine biochemical tests to identify H. parasuis were performed, although final identification was achieved by PCR [1,2]. Additionally, to characterize the Haemophilus parasuis isolates ERIC-PCR was done as described. [3,4].

Results and Discussion

Haemophilus parasuis was recovered in pure culture from sick piglets (joint, pericardium, pleural cavity, abdominal fluid and from some lungs). The DNA patterns (fingerprints) of the Hps strains were distributed in four clusters, indicated heterogeneity between herds (Figure1). Additionally, the isolates obtained from the respiratory tract didn't differ from those collected from systemic sites. The Hp strains obtained were not serotyped because of the lack of this type of reagents.

The isolates F-R2 and F-S3 had the same ERIC-PCR profile, because they were the only two strains isolated from the same herd, even through they were collected in different dates. Despite of these preliminary results the information obtained with this procedure may be useful to understand the epidemiology in the Colombian swine farms and to suggest control measures using autogenous vaccines.

---

**Introduction**

Clinical and diagnostic evidence have suggested that porcine respiratory diseases are caused by an association of several viral and bacterial infections. The clinical symptoms like fever, a slower growth and a worse feed conversion lead to increasing economic losses. The aim of this study was to describe the serological and temporally course of a H. parasuis infection on three farms. Furthermore the influence of other agents, like PRRSV, PCV2 and M. hyorhinis onto the course of H. parasuis infection was proved.

**Material and Methods**

The study was conducted on three breeding farms and their finishing units. Clinical examination (based on a score system for body condition, gastrointestinal tract, respiratory tract and lameness) and blood sampling were performed in two-week intervals between 1st and 11th and in four-week intervals between 14th and 22nd week of life. Also the sows were sampled in the 1st week after farrowing. The samples were analysed via ELISA for antibodies against H. parasuis, M. hyorhinis, PCV2 and PRRSV.

**Results**

A significant correlation between the antibodies of the sows and their piglets was found for all agents in the 1st week of life. In the 1st week of life, identical antibody values for H. parasuis were measured in the sows and piglets. The PRRSV and PCV2 antibody values of the piglets were even higher at this time. The decrease of antibody values in the following week of life depended on the specific agent and the basic antibody value of the piglet in the 1st week of life. If in the first week of life the antibody value was very high, the decrease was prolonged. In the three farms no uniform seroconversion time for the four examined agents could be determined. The highest antibody values could be detected in one pig during the 14th to 22nd week of life:

On farm 1 25% of the pigs got seropositive for all four agents and 75% for three agents (H. parasuis, PRRSV, PCV2). Farm 2 was PRRSV negative and there 52% of the pigs got seropositive for all three, 29% for two (5% H. parasuis and PCV2, 24% M. hyorhinis and PCV2) and 19% for only one (PCV2) agent. On farm 3 55% of the pigs became seropositive for all four agents, 35% for three (M. hyorhinis, PRRSV, PCV2) and 10% for two (PRRSV and PCV2) of the tested agents.

On farm 2 the H. parasuis antibody values increased between the 7th and the 9th week of life and on farm 1 and 3 in week 11. The first seropositive pigs were detected on all farms until the 14th week of life. The H. parasuis seroprevalence on farm 1 was 90% in the 18th and 100% in the 22nd week of life. At the same time the seroprevalence for H. parasuis on farm 2 was 50% and on farm 3 45%.

Discussion

The present study demonstrates the difficulty of the interpretation of serological profiles and indicates that an appropriate interpretation of the serological profile can only be done when the clinical signs are also taken into consideration. A specific serological profile on every single farm for each relevant agent should be provided.

The time point of infection with the four examined agents was different on the three farms, but the study showed that the incidence of multiple infections increased during the finishing period. On farm 2 and 3 a simultaneous seroconversion time in the 9th and 11th week of life was detected for H. parasuis, M. hyorhinis and PCV2. The association between H. parasuis and PCV2 in the 18th week of life was significant, which is an evidence for a simultaneous infection time with those two agents on the respective farms. Also on farm 1 a simultaneous seroconversion for PRRSV and PCV2 in the 18th week of life could be observed, but the association was not significant.

Interaction between H. parasuis, M. hyorhinis and PCV2 is possible and between PRRSV and PCV2 even more likely. High antibody values in sows are the basic requirement for a good passive immunity of the piglets in the first weeks of life and the maternal immunity against H. parasuis, PRRSV and PCV2 could be improved by sow vaccination.

Efficacy of Porcilis®Glässer vaccination of sows to control H.parasuis serotype 15 infection in young piglets

Albert Finestra1, Rut Menjon1, Jesus M. Bollo1, Jesus V. Lopez1, Marta Jimenez1
1. Intervet Schering Plough Animal Health, Alcobendas (Madrid), Spain; 2. Veterinary Practitioner, Les Borges Blanques, Lleida, Spain

Introduction

For many years, Glässer’s disease has been considered of only minor importance, mainly seen at the end of the weaning or the beginning of the finishing periods. More recently, its incidence has increased, and the disease is frequently observed during the first weeks of life.

The efficacy of commercial vaccines has been controversial: some have proved very successful (1), while others have appeared to be lacking. Various causes have been proposed, such as inappropriate vaccination program, lack of cross-protection between serotypes and deficient immune response (2). The aim of this study was to show that sow vaccination with Porcilis® Glässer is an effective tool in the control of H.parasuis infection in young piglets, even against a heterologous challenge. Porcilis® Glässer is a vaccine based on an inactivated whole cell concentrate of Haemophilus parasuis serotype 5, strain 4800, mixed with dl- α-tocopherol acetate as adjuvant.

Materials and Methods

This study was performed in an 1100-sow herd, managed on a three site production system in the north-east of Spain. From January 2009, a high incidence of arthritis had been observed in young piglets. It was first seen in piglets of 10 days old and, although no mortality was recorded during the suckling period, clinical signs increased at the start of weaning, leading to >7% mortality. The presence of H. parasuis was confirmed from the results of bacteriological examinations of synovial fluid and lungs of affected but untreated piglets. An indirect hemagglutination test revealed the pathogen to be H.parasuis serotype 15.

The piglets were treated with 0.2ml long-acting ceftiofur at 5 days of age, and then vaccinated at 3 weeks of age with a polyvalent inactivated vaccine available on the Spanish market, which included a H.parasuis bacterin, and some management improvements were implemented.

Clinical signs were still being observed in May 2009, and weaning mortality remained above 6%. Consequently, the treatment regime was abandoned completely in favour of vaccinating the sows with two doses of Porcilis® Glässer, between 7 and 6 weeks, and again between 3 and 2 weeks, before farrowing.

Clinical signs and mortality were recorded over a 5 month period for litters born from vaccinated sows, and were compared with the same parameters prior to the Porcilis® Glässer vaccination program. Statistical analysis was performed using the Pearson's chi-square test and Fisher's exact test.

Results

No negative effects were observed on the health status of the vaccinated sows or their progeny. The clinical signs of Glässer’s disease were clearly reduced in both sucking pigs and weaners. In sucking pigs incidence of arthritis moved from 15% to 1% in piglets born from vaccinated sows. There was a statistically significant reduction in mortality rates (p<0.001) after weaning (Table 1).

Table 1. Mean monthly mortality during weaning period of piglets born to vaccinated and unvaccinated sows.

Discussion

This study showed that the vaccination of sows with Porcilis® Glässer is a safe and efficacious treatment which can prevent Glässer’s disease in young piglets.

These data obtained from field conditions confirmed previous laboratory results demonstrating that sow vaccination with Porcilis® Glässer increased H.parasuis colostral antibody levels, and that the transmission of these MDA could protect piglets up to 6 weeks of age (3).

The efficacy of Porcilis® Glässer has been shown previously against homologous and heterologous serotypes 1, 5, 12, 13 and 14 (4). The study reported here proves that Porcilis® Glässer can also provide effective immunity against a heterologous challenge with H.parasuis serotype 15.

Introduction and Objectives
The goal of our study was to evaluate the in vitro sensitivity pattern for Streptococcus suis strains isolated from pigs showing neurological clinical signs in porcine farms from Venezuela.

Materials and Methods
A total of 9 strains of Streptococcus suis were isolated from brain tissue samples from 41 suspected cases coming from farms with histories of neurological signs in 5 to 12 week-old piglets between January 2005 and December 2008. For the purpose of this study, the piglet heads were transported to our laboratory where they were dissected under sterile conditions and samples were collected in selective media (blood agar) and then incubated in a microaerophilic environment at 37 Celsius for 48 hours. Colonies were identified considering their morphology and biochemical properties (Quinn, P.J. et al en 1994). An antibiogram from the isolated strains was done through the method of Kirby-Bauer (NCCLS, 1990, MA-A4). The antibiotics assessed in this study were enrofloxacin, norfloxacin, gentamicin, neomycin, sulfamethoxazole-trimethoprim, ceftiofur, amoxicillin, florfenicol, tetracyclin, lincomycin and penicillin. The interpretation of the antibiogram was performed according to the NCCLS (National Committee for Clinical Laboratory Standards) standards (2).

Results
The Streptococcus suis strains isolated in this study had the highest percentage of resistance to lincomycin, gentamicin, tetracycline, neomycin, florfenicol and sulfamethoxazole-trimethoprim and to a lesser degree to enrofloxacin and amoxicillin. One hundred percent (100%) of the strains assessed were sensitive to penicillin. Likewise, it was observed that 100% of the evaluated strains had moderate sensitivity to norfloxacin. Finally, 100% of the strains in this study were resistant to lincomycin. The results are summarized in table 1.

Table 1. Percentage of sensitivity to antibiotics of Streptococcus suis strains isolated from January 2005 to December 2008.

Discussion and Conclusions
In our study, a high percentage of Streptococcus suis strains were resistant to Sulfa-Trimethoprim. Our results differ from those published by Tarradas M.C. in 1994 (3) who suggested the use of this drug as an alternative for Streptococcus suis control. Likewise, our results show a high percentage (44.4%) of resistance to Amoxicillin which also differs from other studies (Ristow, et al., 2008) (4) which have shown less than 1% resistance to this drug. Finally, we observed a high proportion of strains resistant to lincomycin, tetracyclin, gentamycin, sulfa-trimethoprim and sensitive to Penicillin as was shown in previous studies in Venezuela (Pineda, et al; 1996) (5). Based on our in vitro data, penicillin and ceftiofur appear to be the antibiotics of choice against Streptococcus suis infections in these farms; however, most previous studies show the highest susceptibility of this bacteria to amoxicillin when compared to penicillin. During the last years there has been wide spread use of amoxicillin in pre-initiation and initiation food in Venezuela which could explain an increase in resistant strains to this antibiotic. During this study, a total of 41 cases were assessed during a 4 year period and only in 9 of these, strains of Streptococcus suis were isolated. The low number of isolated strains is probably the consequence of the wide spread use of antibiotics in the food in farms in our country, which is a limitation for our study.

Maternal immunity to *Streptococcus dysgalactiae* subsp. *equisimilis* and incidence of lameness in piglets

Mate Zoric; Maria Persson; Per Wallgren
National Veterinary Institute, Uppsala, Sweden

**Introduction**

Lameness is one of the most important animal welfare issues in suckling piglets and about every 10th piglet could be expected to be treated with antimicrobials because of lameness before being weaned (1). Despite this, lameness is only diagnosed in about every second litter, and the treatment incidence varies from one to all piglets in affected litters. Consequently, an effect of the sow could be expected. *Streptococcus dysgalactiae* subsp. *equisimilis* (SE) is commonly associated to arthritis in piglets and the aim of this study was to scrutinise the maternal protection to that microbe.

**Materials & Methods**

Three indirect ELISA-systems detecting antibodies to SE were designed by using sonicated field strains of SE isolated from piglets diagnosed with arthritis in three herds. The three ELISA systems were used to define the levels of serum antibodies to SE in three day old piglets from these herds in a cross-over model. Each serum was diluted 1/100 in PBS-T and analysed with respect to presence of antibodies to SE by all three ELISA systems. In addition, colostrum from sows that had been collected from sows in the three herds at the day of farrowing were analysed for presence of antibodies to SE in whey diluted 1/50 in PBS-T employing the same ELISA systems. Finally, the amounts of antibodies to SE in colostral whey of the 93 sows in herd C were related to the incidence of lameness in the offspring. Also parity number and litter size were compared to the incidence of lameness in the offspring.

**Results**

As seen in Figure 1, the amounts of serum antibodies varied somewhat due to herd and to antigen used in the tests. However, the optical density values were fairly constant in samples regardless of antigen used. In contrast, the levels of antibodies in colostral whey clearly differed between herds, but was again fairly nondependent of antigen preparation used. The standard deviation of the OD-values in colostral whey indicated a large variation between sows, and the levels of antibodies to SE, as well as litter size and party number were compared with the incidence of lameness in the offspring (Fig. 2).

**Discussion & Conclusions**

The results obtained indicate that an indirect ELISA-system detecting antibodies to SE based on a field isolate from one herd could be used also in other herds. However, mean OD-values in piglets appear to be fairly equal between herds, and if the target is to identify piglets at risk each individual sample must be assessed individually. We therefore paid attention to the levels of antibodies in colostral whey, with the aim of identifying litters at risk. Indeed, lameness were more rarely diagnosed in sows with high levels of colostral antibodies to SE (p=0.06 to 0.08). However, also litter size and parity numbers influenced the incidence of lameness (1), and it is striking that the only litter with 6 piglets treated for lameness included 16 piglets and emanated from a sow with low levels of antibodies to SE (OD-value 0.70). The results obtained indicate that high levels of colostral antibodies to SE can have a potential to decrease the incidence of lameness in piglets, and this ought to be further scrutinised.

A highly virulent *Streptococcus suis* serotype 33 strain as a cause of acute sepsis in pigs

Marcelo Gottschalk\(^1\) Charles Surprenant\(^2\) Marie-Pier Lecours\(^3\) Marycruz Dominguez Punaro\(^3\) Sonia Lacouture\(^3\)

1. Faculté de médecine vétérinaire, GREMIP and CRIP, Université de Montréal, St-Hyacinthe, QC, Canada; 2. F. Ménard Inc., Ange Gardien, QC, Canada; 3. Université de Montréal, St-Hyacinthe, QC, Canada

**Introduction**

*Streptococcus suis* is one of the most important swine pathogens worldwide. It can cause septicemia, meningitis and other infections\(^1\). There are 35 serotypes described, with serotype 2 considered as the most virulent and the most frequent type isolated from diseased pigs in Eurasia. However, its prevalence in North America is lower, and some other serotypes are also implicated in clinical disease\(^2,3\). *S. suis*, especially serotype 2, has been pointed out as an emerging zoonotic agent. Recently, many streptococcal toxic shock like-syndrome (STSS) human cases with high mortality have been described\(^1\). This syndrome is characterized by a short incubation time, an exaggerated inflammatory response with massive organ failure and mortality. Serotype 33 is not a common serotype, and it represents less than 1% of *S. suis* strains recovered from diseased animals in Canada\(^2\). In the present study, we report an atypical strain of *S. suis* serotype 33 responsible for a STSS cases in pigs.

**Materials and Methods**

Herd: The affected herd is a multisite production system, with a sow herd of 1000 animals. Weaning is carried out at 18 days of age. Nurseries are operated All in All out per building. The herd is actively infected with PRRSV.

Health problems in nursery: Acute infections of PRRSV in the sow herd lead to abortion problems and weak piglets at weaning. During the first 2 weeks post weaning (PW), piglets presented different respiratory and intestinal clinical signs, accompanied by typical cases of septicemia and meningitis caused by *S. suis*. Response to antibiotic treatment (penicillin, amoxicillin or ceftriofur) was good. During weeks 3 to 6 PW, the clinical picture changed, with a relatively high proportion of animals presenting typical signs of a STSS, such as sudden death with septic shock, multi-organ failure, ventral edema with weak response to antibiotic treatments.

Laboratory methods: *S. suis* isolation/serotyping were carried out as described\(^2\). In some experiments (comparison purposes), the reference strain of *S. suis* serotype 33 and a well characterized virulent strain of serotype 2 were used. Cytokine measurements in sera were performed by ELISA. Genotyping was performed by ERIC-PCR. Virulence was evaluated using a well standardized mouse model, with a dose of 5 X 10\(^7\) C.F.U./mouse\(^4\).

**Results**

Bacteriology: Two different serotypes of *S. suis* were present: a) a serotype 4, usually isolated from meningitis cases (1-2 weeks PW); b) a serotype 33, responsible for most STSS cases (weeks 3-6 PW). Both strains were equally susceptible to the antibiotic used.

Cytokine levels in swine sera: Sera from STSS caused by serotype 33 affected animals presented in general higher levels of IL-6, IL-12 and IL-8 than healthy animals.

Genotyping: A single clone of serotype 33 was responsible for the STSS cases in the farm. The strain was genetically different from the reference strain.

**Figure 1. Virulence in a mouse model of infection**

**Discussion**

- *S. suis* is able to induce a STSS in pigs, similar to that observed in humans in Asia, with high concentrations of pro-inflammatory cytokines in serum of affected animals.
- An atypical highly virulent strain of serotype 33 (genotypically different from the reference strain) was responsible for such cases, which hardly respond to antibiotic treatment.
- Serotypes different from serotype 2 may cause important disease in North American herds, especially when an active PRRSV infection is present.

Capsular polysaccharide modulates *Streptococcus suis* interactions with swine dendritic cells

Marcelo Gottschalk1 Marie-Pier Lecours2 Mariela Segura2 Mathieu Houde2 Charles Surprenant3 Tufaria Mussa4 Maria Montoya4
1. Faculté de médecine vétérinaire, GREMIP and CRIP, Université de Montréal, St-Hyacinthe, QC, Canada; 2. Université de Montréal, St-Hyacinthe, QC, Canada; 3. F. Ménard Inc., Ange Gardien, QC, Canada; 4. CReSA, Universitat Autonoma de Barcelona, Bellaterra, Barcelona, Spain

**Introduction**

*Streptococcus suis* is a major swine pathogen and a zoonotic agent causing mainly meningitis and septicemia. Serotype 2 is considered the most virulent and the most frequently type isolated from both pigs and humans1. Mechanisms involved in the host innate and adaptive immune responses toward *S. suis* as well as the mechanisms used by *S. suis* to subvert these responses are unknown. The capsular polysaccharide (CPS) is the only proven critical virulence factor1. Dendritic cells are powerful antigen presenting cells that initiate the immune response against pathogens, and interactions between DCs and pathogens can strongly influence the outcome of a disease. DCs capture and process the antigens, and then migrate to the adjacent lymphoid organs where they activate T cells. In the present study, we used porcine bone marrow-derived DCs (bmDCs) to investigate the capacity of *S. suis* to interact with DCs and to induce their maturation and activation.

**Materials and Methods**

Bacterial strains: *S. suis* serotype 2 virulent strain 31533, originally isolated from a case of porcine meningitis, and its isogenic CPS-negative mutant B218 were used.

**Generation of bmDCs:** Bone marrow was removed from femurs of 7 week-old SPF piglets. Cells were obtained and characterized by morphology and appropriate receptors by FACS2.

**Phagocytosis assay and intracellular survival:** Bacteria were either not opsonized or pre-opsonized with complete normal serum. Phagocytosis was left to proceed for different incubation times before antibiotics were added into the wells for 1h to kill extracellular bacteria. Cells were then washed and lysed to determine viable intracellular bacteria. The intracellular survival of *S. suis* was performed in a similar manner, but antibiotics were added for a period times up to 6h. Cells were processed as described above.

**Microscopy analysis:** The interactions between *S. suis* and bmDCs were analyzed by scanning electron microscopy (SEM). Internalization of *S. suis* by bmDCs was confirmed by confocal microscopy.

**Cytokine measurement and expression of co-stimulatory molecules:** Levels of IL-6, IL-8, IL-12 and TNF-α in cell culture supernatants following *S. suis* stimulation were measured by ELISA. The expression of MHC-II and CD80/86 were analyzed by FACS.

**Results**

In vitro interactions: *S. suis* interacts with bmDCs. This interaction is modulated by the CPS, as shown by SEM.

**Phagocytosis:** The CPS interferes with the uptake of *S. suis* by bmDCs (Fig.1). Once internalized, both strains are equally destroyed.

**Fig 1:** Interactions between *S. suis* strain 31533 and its non-encapsulated mutant with bmDCs as observed by confocal microscopy. White arrows show bacteria.

Cytokines and co-stimulatory molecules: *S. suis* triggers the release of IL-6, IL-8, IL-12 and TNF-α as well as the expression of MHC-II and CD80/86 by bmDCs. However, the CPS-negative mutant induced higher levels of cytokine production and co-stimulatory molecule expression by bmDCs than the wild-type strain.

**Discussion**

• *S. suis* interacts with bmDCs, which results in an activation of these cells.

• The CPS highly interferes with *S. suis* internalization by and activation of bmDCs, as previously shown with other professional phagocytes1.

• This reduced level of antigen uptake/activation due to CPS might lead to a reduced host immune response.

Distribution of *Streptococcus suis* capsular types isolated from diseased pigs in 2008 and 2009 in Canada

Marcelo Gottschalk¹ Sonia Lacouture¹ Laetitia Bonifait² Daniel Grenier²

1. Faculté de médecine vétérinaire, GREMIP and CRIP, Université de Montréal, St-Hyacinthe, QC, Canada;
2. Faculté de médecine dentaire, Université Laval, Québec, QC, Canada

**Introduction**

*Streptococcus suis* is an important pathogen of swine causing meningitis, sudden death, septicemia, endocarditis, and pneumonia. The distribution of different serotypes varies depending on the geographical origin of the strains. As a reference laboratory, we routinely perform serotyping of *S. suis* isolates recovered in Québec (and sometimes in other provinces of Canada) from tissue samples of diseased pigs. Exceptionally, samples from other animal species are also received. Serotype determination remains a valuable tool used by veterinary practitioners and diagnosticians, to understand the epidemiology of a particular outbreak or to increase the possibility of success of a vaccination program within a herd. The present communication presents the distribution of the serotypes isolated in 2008 and 2009 in Canada.

**Materials and Methods**

Isolates: Animals from which these isolates have been obtained presented a variety of clinical signs, as for example, nervous signs, sudden death, arthritis, and/or respiratory problems. All but two *S. suis* strains were recovered from pigs. Although it is not possible to determine whether *S. suis* was the sole causative agent of the pathological condition, it was isolated in pure culture or in a significant number to be considered involved in the pathology observed. One strain was isolated from milk from a cow presenting mastitis and one strain was isolated from a human case of meningitis.

Laboratory analysis: Serotyping was carried out by using the co-agglutination test with reference antisera. All reagents for serotyping are prepared in our laboratory according to a described procedure. Serotype 2 strains were tested for the proposed virulence markers muramidase-released protein (MRP), extracellular factor (EF) and suilysin (Sly) by PCR and/or red blood cell lysis and/or immunoblotting. Non-typable (NT) or autoagglutinating (AA) isolates were confirmed to belong to the *Streptococcus suis* species using a well described specific PCR. Representative NT and AA isolates were tested for the presence of a capsule using electron microscopy and polycationic ferritin labelling.

**Results**

Distribution of capsular types of *S. suis* in 2008 and 2009.

* non-typable or autoagglutinating isolates

- Most NT/AA isolates (including a bovine isolate) were confirmed to be *S. suis* by a species-specific PCR.
- Three representative NT/AA isolates were shown to be non-encapsulated by electron microscopy.
- The human strain was shown to be a serotype 14.
- Most serotype 2 strains are MRP+/-, EF- and Sly-.

**Discussion**

- The distribution of the most common serotypes in 2008/2009 is comparable with that from previous years.
- The prevalence of serotype 2 is much lower than that from European countries.
- The first serotype 14 isolate recovered from human in North America was identified.
- Most NT/AA isolates recovered from diseased pigs were shown to belong to the *S. suis* species.
- Many of these NT/AA isolates are non-encapsulated, indicating that they are probably not “new serotypes”: it is possible that they belong to known serotypes before they lost the capacity to express capsule.

Preliminary report on the characterization of pathological lesions and serotype of Streptococcus suis infection in Serbia

Bozidar Savic; Oliver Radanovic; Milenko Zutic; Ivan Pavlovic; Vojin Ivetic
Scientific Veterinary Institute of Serbia, Belgrade, Serbia

Introduction

Streptococcal disease is a worldwide problem in the swine industry. Among Streptococci, serogroups which are considered pathogenic in pigs belonged to Lancefield group D, E, C and occasionally other groups. In most parts of the world, Streptococcus suis (S. suis) is the predominant agent of Streptococcal infection, which is associated with a variety of diseases including meningitis, septicemia, arthritis, endocarditis and pneumonia (1). Thirty-three serotypes (types 1–31, 33, and 1/2) have been described based on capsular polysaccharides; polysaccharides, with serotype 2 being most commonly associated with diseases in pigs and humans, and also the most frequently reported serotype worldwide (2,3). The objectives of this study were to determine the anatomic distribution and pathologic conditions associated with S. suis infection and prevalence of S. suis strains isolated in pigs from Serbia.

Materials and Methods

The pigs were from 15 conventional farrow-to-finish pig farms which were submitted to the Pathology Department of the Veterinary Institute during 2008 - 2009. Over 600 pigs of different ages were necropsied including: 337 suckling piglets, 179 nursing piglets, 107 grower/finisher pigs and 4 aborted foetuses. The samples for bacteriology were obtained from corresponding lesions and different tissues including: joint, brain, heart, lung abscesses and blood as well as 39 samples of milk, 27 vaginal swabs from clinical cases of mastitis and endometritis and 38 tonsils swabs from slaughtered pigs. The samples were cultured on Columbia blood agar base and base for blood agar (M 144-Hi Media) containing 5% defibrinated ovine blood. The plates were incubated at 37°C for 48 hours. Bacterial isolates were identified by biochemical tests and commercial kits (Api Strep.) and for Lancefield classifications, Slidex Strepto Kit (Biomerieux ref. 58 810)). Serotyping of S. suis was carried out by a coagglutination test, using commercial specific sera against serotype 1–10 (Statens Seruminstitut, Copenhagen, Denmark).

Results

Pathomorphological finding in suckling, nursing and grower/finisher pigs and clinical conditions in sows associated with S. suis infections as well as total number of examined and number of positive isolates of S. suis according to site of isolation and clinical material were presented in table 1. Distribution of serotypes of S. suis isolated from corresponding lesions and clinical material obtained from sows were presented in table 2.

Discussion

Overall, meningoencephalitis, septicemia and arthritis, otitis interna with encephalitis endocarditis and periarticular abscesses and pneumonia, appeared to be most frequent pathomorphological finding in suckling, nursing and grower/finisher pigs respectively and mastitis and endometritis are the most frequent clinical conditions in sows associated with streptococcal infections of pigs from Serbia. These findings are in concordance with described lesions in swine from other European countries (4), however, encephalitis and periarticular abscesses are most frequent pathological conditions in suckling and nursing piglets and seems to be main lesions of Streptococcal infections in Serbia in 2008 and 2009.

From the distribution of S. suis strains in corresponding lesions, serotype 2 was the most frequently isolated strain, which is at this time main causal agent of Streptococcal diseases in Serbia. In addition, serotype 1⁄2 was also highly prevalent, and some generally acknowledged invasive serotypes in European countries such as 9, 3 and 7 (2,4) were much less encountered in our study.

Acknowledgments

This work was funded by Serbian Ministry of Science and Technological Development, project number TP: 20110.

Case study on a project to eradicate Streptococcus suis serotype 2 from a breeding herd

Grace Webster1 Karen Degenstein2 David Woofall4 Brian Hunt3 Jennifer Thacker1 Jill R. Thomson1
1. Scottish Agricultural College, Edinburgh, UK; 2. Meadows Veterinary Centre, Old Meldrum, UK; 3. Royal (Dick) School of Veterinary Studies, Edinburgh, UK; 4. Vion Food Scotland Ltd, Banff, UK; 5. Veterinary Laboratories Agency, Bury St Edmunds, UK

Introduction

Streptococcus suis serotype 2 infection in pig herds has significant health, economic and zoonotic implications (1, 2, 3) and therefore, disease freedom is essential for specific pathogen-free breeding pyramids. Starting new herds with caesarian-derived piglets is recognized to be the most successful method of achieving disease freedom but it is costly, slow and labour-intensive. Disease eradication from established herds has been attempted by antimicrobial treatment (4) and medicated-early-weaning programmes (5). However, the success rate has been generally poor, and attributed to subclinical carriage of infection in tonsil crypts resulting in failure to detect and eliminate carriers (6). This paper describes a programme that aimed to eliminate S. suis serotype 2 from a nucleus herd through assiduous testing of pigs and removal of carriers, medication, vaccination and herd relocation.

Materials and Methods

The herd: A 400-sow herd with valuable genetics, in an isolated location and area of low pig density.

Strategy: Initially all sows were tested twice and any positives were culled, remaining sows were vaccinated twice (interval 4 weeks) with Porcilis Strep suis (Intervet-Schering Plough Ltd), then all received in-feed medication with potentiated penicillin for 6 weeks and were moved to a clean unit. However the herd continued to have evidence of S. suis serotype 2 infection, therefore the plan was amended, to create a clean, pure, nucleus herd from the progeny. All piglets received the above vaccine at 14 and 28 days of age and moved to 4 separate sites at weaning. All pigs in all batches were tested 4 times at a maximum of 6 week intervals from 10 weeks of age onwards, and any batch with a positive result was culled in its entirety. From the batches that were negative after the first 2 tests gilts were selected and moved into isolation for 8 weeks and were then moved to a further clean site to start the new herd.

Testing: Initially this was by culture and immuno-fluorescent antibody test on tonsil swabs and vaginal swabs from individual sows, and tonsil swabs from piglets. Testing then changed to PCR (7) on tonsil swabs and scrapings from growing pigs. Tonsil swabs and scrapings were collected from the palatine tonsils, applying as much pressure to the tonsils as possible. Mucus samples collected by scraper were transferred to swabs before submission to the laboratory.

Results

10 of the 400 sows were culled due to being positive on initial testing. Of the remaining 390 sows that moved to the clean site 4 were culled following subsequent testing. 9 batches of weaners in groups of 80-100 were tested and of those 4 groups were culled as positive. 5 batches comprising a total of 450 pigs were negative on two occasions. The selected gilts (approx 180) tested negative for a further two successive tests and were retained to form the new herd. These gilts have been bred and are due to farrow in the coming weeks. To date they have remained disease-free.

Discussion

Repeating the same testing schedule on the first crop of piglets should provide an indication of the initial success of the programme. However, long term monitoring for both the agent and any clinical signs of infection will be needed before concluding whether the methods used were genuinely successful. If successful, the key factors are considered to be effective sampling and testing methods that allow detection and elimination of pigs that remain carriers despite vaccination and medication. Use of the tonsil scrapers allow more pressure to be exerted on the tonsil surface and better expression of mucus from the tonsil crypts. The change to PCR testing detected some positive animals that had previously tested negative by swabbing the tonsil surface and hence, aided the elimination of carriers. Establishing a practical and successful means of eradicating S. suis serotype 2 from breeding herds without total depopulation or using caesarian-derived methods of piglet retrieval will be a valuable resource for companies undertaking radical health improvement programmes in the future.

Development of immunohistochemistry for detection of Brucella suis type-2 in formalin-fixed tissues from pigs

Zeljko Mihaljevic; Dinko Novosel; Zoran Lipej
Croatian Veterinary Institute, Zagreb, Croatia

Introduction
The aim of this study is to develop an immunohistochemical method for detection Brucella suis type 2 and to compare this method with PCR detection and bacteriological isolation.

Material and Methods
Testis samples obtained from 10 naturally infected pigs that were PCR and bacteriologically positive to Brucella suis type 2 were analyzed by immunohistochemistry (IHC). Demonstration of Brucella suis type 2 in formalin-fixed, paraffin-embedded tissues was performed using polyclonal antibodies and positive samples kindly provided by Dr. Silvio Spicic (Croatian Veterinary Institute, Zagreb, Croatia). Testis tissue from clinically healthy pigs and PCR and bacteriologically negative tissue samples served as negative controls. Briefly, 5 μm cuts were placed on silanized slides, section was deparaffinized in xilen and rehydrated through different grades of ethanol. Endogenous peroxidase was blocked with 3% H2O2 in 0.5M/0.15M Tris/NaCl (TBS). Slides were pretreated with Proteinase K (Dako ® ) 3 min. on room temperature according manufacture instruction. Non-specific reaction was blocked with incubation 1 hour in 5% normal goat serum. Primary antibody was diluted 1/500 in 2% normal goat serum in TBS and incubated over night at +4°C. Anti-mouse secondary antibody marked with labeling polymer (Dako Envision) was incubated according with manufacture instruction. For visualization is used DAB chromogen, slides were counterstained with Mayer’s hematoxylin and then were dehydrated and mounted with DPX.

Results
In testis of PCR and bacteriologically positive pigs Brucella suis type 2 was found in all diseased animals. In their testis samples large amounts of Brucella suis type 2 antigen were concentrated in the cells of the inflammatory foci. All samples from healthy animals were IHC negative.

Discussion
An optimized IHC protocol was developed for the detection of Brucella suis type 2 in formalin-fixed, paraffin-embedded tissues and its results were compared with those determined by PCR and bacteriological isolation. The results obtained show that the use of IHC test is a reliable detection method. In the present study observed infection pattern is consistent with similar studies. When only formalin-fixed tissues are available, IHC would be useful diagnostic methods for the detection of Brucella suis type 2. The high specificity of IHC test for Brucella suis type 2 could be used in experimental studies of disease in pigs.

Effect of Erysipelothrix rhusiopathiae bacterial cell lysate on immunogenecity of swine erysipelas killed vaccine

Hyun Jang; Kyung-sil Kim; Min-su Park; Min-su Park
Komipharm International Co. LTD, Gyeonggi-do, Korea

Introduction
Swine erysipelas may occur as an acute septicemic disease or chronic disease typically characterized by endocarditis and polyarthritis. Previous research shows the protective antibodies were elected against 64-66 kDa and 40 kDa protein of the membrane component in E. rhusiopathiae. Mice immunized with the purified 64-66 kDa proteins from E. rhusiopathiae were protected against challenge by the virulent strain. The 66-64 kDa protein appears to be most immunogenic when complexed with glycolipid. This may be due to an adjuvant effect of polysaccharide antigens. Therefore cell homogenate of E. rhusiopathiae was very important component for effective vaccine development. In this study the effect of E. rhusiopathiae bacterial cell homogenate to the efficacy of the swine erysipelas killed vaccine was tested by challenge test using highly virulent E. rhusiopathiae T2 strain and also we will determined which was the major antigen in cell homogenate using western blotting methods.

Materials and Methods
The bacterial strain E. rhusiopathiae SE9 was used in this experiment. The initial culture was grown on solid BHI agar media containing 5 % sheep blood. Bacterial cell number was expanded in the flask culture using semi defined and complex media. Measuring the optical density at 600 nm monitored bacterial cell growth. The concentrated bacterial cells were homogenized using high-pressure homogenizer and cell breakage determined by measuring viable cell count. Trial vaccines were made with inactivated cell homogenate, whole bacterial cell and mixture of the inactivated cell homogenate and whole cell bacterial cell. Immunoblotting, SDS-PAGE and ELISA assay were performed following general methods. Efficacy test of trial vaccines was performed by mouse challenge test. using E. rhusiopathiae T2 strain.

Results
Antibodies to a 66-64kDa and 34 kDa proteins released from the cell surface have been shown to be involved in protective immunity. The efficacy of the vaccine using the bacterial cell homogenate was better than vaccine using the bacterial whole cell. 66-64kDa and 34 kDa proteins on the E. rhusiopathiae SE9 are major antigen of the immune response in mouse

Discussion
The results of this study provide important information for the development of safe and efficacious vaccine development. 66-64kDa and 34 kDa proteins on the E. rhusiopathiae can act as an important antigen of the vaccine protectivity. In addition, 66-64kDa and 34 kDa proteins can be used as a protein partner for glycolipid conjugate vaccine production.

Analysis of the surface protective antigen (Spa) patterns of Erysipelothrix spp. isolates in tissues, environmental samples and vaccine strains obtained from vaccinated farms experiencing acute erysipelas outbreaks in the Midwest

Joseph Bender; Huigang Shen; Tanja Opriessnig
Iowa State University, Ames, IA, USA

Introduction

Erysipelothrix spp. isolates are divided into four groups (E. rhusiopathiae, E. tonsillarum, E. sp. strain 1, E. sp. strain 2) and 28 serotypes (1a, 1b, 2-26, N) (6) Diagnostic investigations of U.S. field cases have indicated that E. rhusiopathiae serovar 1a is typically the cause of acute septicemic erysipelas and serovar 2 is most common in subacute and chronic cases of swine erysipelas. All other known serovars are thought to have low levels of virulence for swine (6). Currently available commercial attenuated-live vaccines against swine erysipelas are based on serovar 1a (3). Swine practitioners often rely on serotyping results to determine if a vaccine will be cross-protective. Recently, the surface protective antigen (Spa) protein of Erysipelothrix spp. was characterized and shown to be highly immunogenic (2). Moreover, it was found that Erysipelothrix spp. isolates typically harbor one of three known Spa proteins (Spa A, Spa B, Spa C). There appears to be cross-protection between isolates within the same Spa type but not between Spa types (4). The objective of this study was to characterize the Spa types present in Erysipelothrix spp. isolates involved in suspected vaccine breaks.

Materials and Methods

Eighteen tissue samples and 126 environmental samples were collected from six farms in the Midwest experiencing erysipelas outbreaks in vaccinated animals. In addition, autogenous and commercially available modified-live erysipelas vaccines that were used on the farms were included in the analysis. Tissue specimens were also included from cases submitted to the Iowa State University Diagnostic Laboratory where swine erysipelas was suspected (1). Enrichment broth-based isolation was used for detection of Erysipelothrix spp. (1). Further characterization was done by serotyping of the isolates (1). In addition, a novel multiplex real-time PCR method for simultaneous detection of Spa A, B1, B2, and C was used which was previously validated using 28 Erysipelothrix spp. reference strains (5).

Results

Erysipelothrix spp. was isolated from tissue samples obtained from all six farms which were investigated and included serovars 1a, 2, 10, and 21. Environmental samples were positive for Erysipelothrix spp on each farm; however in two farms the serovar identified from the tissues did not correlate with serovars found in environmental samples. Spa PCR results on 109 selected tissue and environmental isolates indicated that isolates identified as E. rhusiopathiae serovar 1a, 2, 6, 9, 10, 11, and 21 all were positive for Spa A, while isolates identified as E. tonsillarum serovars 7 and 10 were negative for Spa A, B1, B2, and C. E. sp. strain 1 (serovar 13) was also identified on one of the six farms (negative for all Spa A, B1, B2, and C). All vaccines tested were found to be E. rhusiopathiae serovar 1a and were positive for Spa A.

Discussion

Previously investigations have shown Spa proteins to be highly immunogenic as antibodies are formed against these cell surface proteins (2,4). Current literature reports that each Erysipelothrix spp. serovar is specific to a particular Spa protein based on analysis of reference strains (4). Results of this study indicate that variability exists between Spa proteins and serovars, this conclusion is supported by the fact that the U.S. field isolates investigated during this study differed in Spa type when compared to the Spa types reported for the reference strains. Currently available attenuated live vaccines in the US are based on E. rhusiopathiae serovar 1a, and contain Spa A. Studies have shown that there is cross protection within the same Spa type; however, minimal cross protection exists between Spa types. In the current study, the Spa type identified in the vaccinated strains was not always identical to the Spa type identified in the tissue and environmental samples. Further investigation is warranted to explore the cross protection provided between Spa types under field conditions.

References

Erysipelas is a contagious infectious disease of pigs caused by the bacterium Erisipelothrix rhusiopathiae. The Swine Erysipelas is an actual disease, as reported Schwartz (AASV 2002) with the increase of cases at the University of Iowa, with economic impact in the herd losses may include loss of death (1%) - $ 2.50dls/hembra; treatment cost $ 1/hembra; abortion (4%) - $ 5dls/hembra for a total of $ 10dls/hembra. Also in the growth stage - complete the death loss (3%) - $ 2.50dls; treatment cost $ 1dls; retarded (3%) - $ 1.25dls for a total of $ 4.75dls/animal. The cost of an outbreak can be high, and this does not include effects on carcass quality, or forfeitures. In 2008, in traces of Sonora, Queretaro and Mexico City for the confiscation of channels because of erysipelas (personal communication) has been frequent.

Sierra (2006) reports that Erysipelas is the second most isolated bacteria in the presence of PRRS in farms of Guanajuato, Jalisco, Michoacan and Perea (2006) reports that 90% of animals tested in the State of Mexico are positive Erysipelas, Huerta (2006-2008) reported 80% incidence of seropositivity in Sonora. According to remarks by Dr. Calderon (personal communication) 75% of the farms of La Piedad and Tepatitlán have subclinical Erysipelas.

Materials and Methods
The aim of this study was to monitor the serological to 5 piglets before and after application of a live vaccine and see if through the Elisa test (kit for the detection and / or quantification of specific antibodies Erisipelotrix rhusiopathiae INGENASA pig serum) we identified a serological response at 30 and 60 days after vaccination. The piglets are from a farm of 1,100 stomachs located in the State of Puebla, stable PRRS virus and by late last year introduced Erysipelas problems and proceeded to vaccinate the herd and piglets savanna around week 7 of age. 5 piglets were selected at random, were identified individually and they took blood samples at day 1 (before vaccination) and 30 and 60 days after vaccination, sera were sent to Diagnostic Laboratory IASA, obtaining the following results.

Graphically this is the result.

Discussion
3 / 5 piglets showed a decrease in the immune response during the 2nd bleeding and 5 / 5 piglets have a greater serological response and uniform prior to vaccination. We believe that using the Elisa test for the detection and / or quantification of specific antibodies in swine serum Erisipelotrix rhusiopathiae (INGENASA) can be used to measure the response post vaccination, but this work must be replicated again to set specific parameters post-vaccination response, since this kit is designed to identify negative animals, suspicious and positive in the presence of erysipelas in the field, which we know will change the immune response towards each individual and the degree of infection present. For the third bleeding, we can see that there is a similar response in 5 cases. It is noteworthy that farm animals had clinical symptoms of Erysipelas and after vaccination this extint.

**Usability of quantification of interferon-gamma production after in vitro stimulation with Mycobacterium-specific antigen in diagnosis of mycobacterial infection in pigs: a limited field study**

Martin Faldyna; Eduard Gopfert; Hana Kudlackova; Marija Kaevska; Iva Slana; Ivo Pavlik  
Veterinary Research Institute, Brno, Czech Republic

**Introduction and Objectives**

At present, there is no doubt that Th1-type immune response is crucial for the control of mycobacterial infections [1,2]. Interferon-gamma (IFN-γ) is a key cytokine produced by Th1 lymphocytes. It plays a role in modulation of immune response associated with activation of macrophages [3]. Th1-type immune response is also associated with the 4th type of hypersensitivity. This fact has been used in intravital diagnosis of mycobacterial infections using intradermal administration of a specific antigen.

In the 1990, Wood and coworkers showed that quantification of IFN-γ produced by lymphocytes after in vitro stimulation with a specific antigen is a useful tool for detection of tuberculosis in cattle [4, 5]. A similar test is used also in human medicine [6].

At the 20th IPVS Congress, we showed that IFN-γ release detection after in vitro stimulation could be used in pigs experimentally infected with M. avium subsp. avium and hominissuis (MAA and MAH), with the latter having weaker production [7]. The aim of the present study was to ascertain whether the test is useful for individual diagnosis of naturally infected pigs.

**Materials and Methods**

Sixty-one clinically healthy pigs, aged 4-5 months, utilized in feeding experiments at the Veterinary Research Institute were used in the study.

One month before slaughter, samples of heparinised blood were taken from the pigs. The samples were in vitro stimulated for 20 hours with M. avium - specific antigen. Produced IFN-γ was quantified using available ELISA kit (BioSource International, Inc., USA) in accordance with manufacturer’s recommendations.

Simultaneously, intradermal administration of antigen designed for such a type of test (Avitubal, Bioveta na Hane, Czech Republic, containing 28000 IU of M. avium antigen) was performed. Based on manufacturer’s recommendation, local lesions were evaluated 48 hours after administration.

In a slaughterhouse, carcasses were inspected and tuberculous lesions were evaluated by microbiological methods (Ziehl-Neelsen staining, culture examinations, qPCR).

**Results**

No animals were positive to intradermal tests, i.e. no local reaction at the site of injection exceeded 2 cm in diameter 48 hours after administration.

Lymphocytes of 3 animals produced detectable amounts of IFN-γ, i.e. more than 18 pg/ml. Two of these 3 animals were bacteriologically proven to be infected with MAH. On the other hand, one pig infected with M. xenopi was not able to produce a detectable amount of IFN-γ.

**Conclusions**

Our results indicated that detection of IFN-γ production after in vitro stimulation with Mycobacterium-specific antigen could be used in diagnosis of mycobacterial infections in naturally infected pigs. It should be noted, however, that much lower amounts of IFN-γ were produced by naturally infected pigs than by experimentally infected ones [7].

Testing immunogenicity of Mycoplasma hyosynoviae vaccine candidates; Induction of antibodies and IFNγ response

Klara T. Lauritsen; Ulla Riber; Jens Nielsen; Jeanne T. Jakobsen; Gregers Jungersen
National veterinary Institute, Technical University of Denmark, Copenhagen, Denmark

Introduction

*Mycoplasma hyosynoviae* (Mhs) is a significant cause of acute arthritis in swine above 10 weeks of age. No effective prophylaxis is available. Therefore attempts are made to develop a vaccine candidate with potential to protect against arthritis caused by Mhs. First step is screening of the immunogenic effect of Mhs antigen in combination with various adjuvants. Earlier studies of the infection have shown that antibodies can provide a certain degree of protection against the infection (Lauritsen et al., 2006), but a cell-mediated immune response has also been shown to play a significant role in protection (Lauritsen, 2005).

Materials and Methods

The four vaccine candidates tested, were based on the same formalin fixed Mhs, but combined with various EMULSIGEN oil-in-water adjuvant formulations (MVP Laboratories). One dose contained 300 μg antigen in aqueous solution and adjuvant was added to 20% of the total volume. Eleven pigs at 12-weeks of age (one litter, from *Mycoplasma* free herd) were administered the primary vaccination i.m. (EMULSIGEN-D: 3 pigs, EMULSIGEN: 2 pigs, EMULSIGEN-BCL: 3 pigs and EMULSIGEN-P: 3 pigs). Revaccination was carried out with identical boosters after three weeks. Another three weeks later the pigs were killed.

Mhs-specific IgG in serum was measured by ELISA (Nielsen et al. 2005). IFNγ measurements were included as an indicator of the ability of the vaccines to induce a cellular immune response. Mhs specific IFNγ response was measured by ELISA (Riber & Jungersen 2007) in supernatants from stimulated heparin-stabilised blood.

Results and Discussion

When measuring Mhs-specific IgG in serum, all pigs seroconverted from day 24 to 28 after first vaccination (i.e. day 3 and 7 after boost). Plateau was reached 7 to 14 days after boost, OD values ranging from 0.5 to 1.75. Measurement of IFNγ in supernatants from whole blood cultures stimulated with Mhs antigen showed that all groups had pigs that reacted to vaccination with a very high IFNγ response. All pigs had IFNγ measurements reaching beyond 500 pg/ml, in some pigs beyond 4000 pg/ml (Figure 1). The negative control samples (PBS stimulated samples) did not exceed an IFNγ level of 102 pg/ml. However, no group of pigs had consistently higher IFNγ level than the others.

Figure 1. Mycoplasma hyosynoviae-specific IFNγ response. Type of vaccine used is indicated for each pig; Square; EMULSIGEN-D, Triangle; EMULSIGEN-BCL, Stippled line; EMULSIGEN, Line; EMULSIGEN-P

Earlier attempts to develop a vaccine against Mhs have focused on the serological response (Ross, 1978; Feenstra et al., 1994). Our experiment, however, focuses on the use of adjuvants that are reported to favour cell mediated immune response, while still giving rise to an antibody response. The investigation is a part of a larger initial screening for vaccine candidates against Mhs. Thus more candidates are to be tested, and finally a promising candidate, with ability to induce both serological end cell-mediated immune response, will be tested in challenge experiments.

**Introduction**

*Mycoplasma hyosynoviae* (Mhs) causes arthritis in swine. Since an effective immunoprophylaxis against the disease is not available, the aim of this project was to attempt to develop one.

**Materials and Methods**

Twenty-six Mhs-free cross-bred pigs (3 litters) from an infected herd were isolated from 3 1/2 weeks of age. A vaccine containing formalin inactivated Mhs (strain M60, 300 μg/dose) with EMULSIGEN-BCL® (MVP Laboratories) as adjuvant was administered to 13 pigs at 7 and 10 weeks of age. 13 placebo pigs received adjuvant in saline. Intranasal challenge infection with Mhs was given 3 weeks after boost. 14-21 days after this, the pigs were autopsied.

Mhs-specific IgG in serum was measured by ELISA (Nielsen et al. 2005). IFN-γ measurements were included as an indicator of the ability of the vaccines to induce a Mhs-specific cellular immune response. Mhs specific IFN-γ response was measured by ELISA (Riber & Jungersen 2007) in supernatants from stimulated heparin-stabilised blood.

**Results and Discussion**

Three pigs in the placebo group and one in the vaccine group developed lameness after inoculation. Eight vaccinated and 10 placebo pigs had pathological changes in joints at autopsy. Primarily mild changes were seen. One day before inoculation a significantly higher level of IFN-γ was measured in supernatants of antigen stimulated full blood in the vaccinated group compared to the placebo group. On day 6 after inoculation the placebo group had a significantly higher IFN-γ level when compared to the vaccinated group. Compared to placebo pigs, all vaccinated pigs had a more potent response in Mhs specific IgG in serum after challenge, with a more rapid onset and higher levels reached before autopsy (Fig 1). The latter results show that the vaccinated pigs have been primed to mount a more rapid specific antibody response when encountering the infection. Presence of different levels of maternally derived antibodies in the three litters did not seem to interfere with this priming effect (Figure 1).

In order to be able to conclude anything on the protective effect of the vaccine against clinical disease, larger experimental groups are needed.

Novel vaccine against Mycoplasma hyosynoviae: The immunogenic effect of iscom-based vaccines in swine

Klara T. Lauritsen1 Annette V. Heydenreich2 Ulla Riber1 Jeanne T. Jakobsen1 Nikolai Kirkby2 Gregers Jungersen1
1. National veterinary Institute, Technical University of Denmark, Copenhagen, Denmark;
2. Rigshospitalet, Dept. for Clinical Microbiology, Copenhagen, Denmark

Introduction
Arthritis in swine is frequently caused by Mycoplasma hyosynoviae (Mhs). For the development of an effective vaccine, we investigated the immunogenic effect of three vaccine preparations with the ISCOM adjuvant Posintro™ from Nordic Vaccine.

Materials and Methods
Vaccine A consisted of formalin fixed whole-cells Mhs (300 μg/dose) mixed with Posintro. Vaccine B consisted of Deoxycholate extracted lipoproteins from Mhs organisms (DOC-antigen, 300 μg/dose) in Posintro and finally Vaccine C consisted of DOC antigen (50 μg/dose) in Posintro. Each vaccine-group contained three pigs. Vaccinations (i.m.) were performed at 12 and 15 weeks of age. Three weeks after the last dose the pigs were autopsied. The presence of specific IgG in serum was measured during the experiment. Furthermore secretion of the cytokines IFN γ and IL-12p40 by stimulated blood cells was measured. IFN γ was measured in supernatants of whole-blood cultured with Mhs-antigen whereas IL-12p40 was measured in supernatants from stimulated peripheral blood mononuclear cells. The latter two measures were included to describe the cell-mediated immune response (CMI).

Results and Discussion
Vaccine B induced a high level of specific serum IgG in all animals 1 week after boost. Vaccine C gave a variable response after boost, with two pigs seroconverting, while no response was seen by vaccine A. All pigs secreted IFN γ after primary vaccination followed by an increased production after booster vaccination (Fig 1). The CMI response was highest with vaccine B when compared to responses induced by vaccine A and C at one (P<0.01) and two (P<0.001) weeks after boost. IL-12p40 levels in the supernatants corresponded with the IFN γ responses. At autopsy only vague signs of tissue damage could be seen, and only in pigs that received A and C.

Clearly, Posintro™ Mhs-vaccines possess the potency to raise a high level of both a cellular and a humoral immune response. Whether the induced immune response prevents clinical disease after infection should be measured in a challenge study.
Detection of Mycoplasma suis in healthy pig populations

Erin Strait; Nyssa Levy; Cassandra Roe; Alejandro Ramirez
Iowa State University, Ames, IA, USA

Introduction
Mycoplasma suis (formerly Eperythrozoon suis) is a blood-borne bacterial pathogen and causative agent of immune-mediated hemolytic anemia in pigs. Once infected, animals become lifelong carriers, causing a variety of signs that have been reported to include reproductive failure, hypoglycemia, general unthriftiness, increased susceptibility to secondary infections, and even acute death1. Good diagnostics for this agent are currently lacking, and because of this, the true prevalence and significance of this disease is unknown. This organism is not able to be cultured in the laboratory, and until recently, diagnosis of M. suis was primarily by acridine-orange staining of red blood cells; however, recent studies have shown this method to have limited sensitivity2. Recently, an intracellular strain of M. suis was identified that was unable to be detected by this staining method. An ELISA test has been described, but is not commercially available. This highlights the need for a rapid and sensitive test such as real-time PCR. A real-time PCR assay targeting the msg1 gene has been recently described, but can only be performed on a single instrument that is not widely used, thus limiting its application3. The main objective of this study was to develop a real-time PCR based on the msg1 assay that could be performed on a wide range of instruments and facilitate diagnosis of M. suis. In addition, a sampling of normal pig populations of various ages was performed to begin to assess the prevalence of this organism in US swine herds.

Materials and Methods
Blood samples were collected in EDTA and/or heparin tubes from apparently healthy pigs in 4 age groups, each from different herds: 3-day old piglets (n=13), 12-18 week old pigs (n=17), 6-24 month old boars (n=23) and sows at time of slaughter (n=42). Additionally, meat juices (n=50) were obtained from muscle samples taken at the time of slaughter at 10 unique sites in 3 different states and processed at the Iowa State University Veterinary Diagnostic Laboratory- Meats Laboratory. DNA was extracted by spin column (Qiagen QiAmp DNA mini kit) and/or magnetic bead-based protocol (Ambion Mag-Max kit).

Results
We determined that extracting blood samples by the spin column method is the most sensitive protocol for positive detection of M. suis by real-time PCR. Positive samples were found within each sample group at various rates between 2-28.6%, except for the 3-day old piglets which were all negative. EDTA-blood samples from PCR-positive (n=10) and PCR-negative (n=15) pigs were submitted for complete blood count analysis. While not statistically significant due to low sample number, a trend for lower clinical blood values in PCR-positive samples was observed (Table 1).

Discussion
Results of this study suggest that the presence and impact of M. suis in otherwise healthy pigs may be currently underappreciated. Further testing of both apparently healthy and clinically-affected animals will be necessary to determine the true prevalence and significance M. suis-induced disease in today’s swine industry.

Introduction

African swine fever (ASF) is a highly contagious hemorrhagic disease of domestic pigs. The disease was reported for the first time in Kenya in the 1920s, and actually remains endemic in Sardinia and in East and Southern Africa, producing important economical losses in the pig industry (1). The recent outbreak in Georgia last 2007, and its extension to some Russian counties, has increased the chances for the ASFV to be extended to European and Asian countries. Due to the absence of vaccines available against this disease, ASF control is based on efficient diagnostic and the slaughter of infected animals.

The aim of the present work was to develop an optimized in situ hybridization (ISH) protocol to detect ASF virus genome in formalin-fixed paraffin-embedded tissues.

Material and Methods

Animal samples. Tissue samples including liver, spleen, kidney, lung, and gastro-hepatic lymph node were obtained from experimentally infected animals using Ba71L and E75L virulent ASFV isolates.

ISH method. Three different digoxigenin (DIG) labeled probe approaches were used: a pool of DIG-oligonucleotide probes complementary to ASFV sequences, a 18.5kb SalI fragment (SD probe) of the genomic Ba71V DNA, and the total E75 viral DNA (CG probe). Two different proteolytic treatments were also tested: proteinase K and pepsine digestion.

Combined ISH and immunohistochemistry (IHC): in order to verify the presence of ASFV DNA in the nucleus of lymphocytic-like cells, a double ISH-IHC protocol was performed in different tissues. T-lymphocytes were first identified by IHC using a polyclonal anti-human CD3 antibody (Dako). ISH was next performed using the CG probe after proteinase K digestion.

Results

Positive specific ASFV signal was obtained in most of ASFV-infected tissues tested either using SD or CG probes. Nonetheless, no signal was detected using the DIG-oligonucleotide probes.

While the SD probe was able to detect the presence of ASFV DNA only in Ba71L infected tissues, the CG probe hybridized with both E75L and Ba71L infected tissues. Proteinase K treatment resulted more efficient than pepsin digestion, yielding a better tissue integrity and a lower background.

Discussion

Regarding ISH staining distribution, intranuclear and perinuclear positive signal was mainly found in cells of the monocyte-macrophage cell lineage. Positive staining was also found in other cell types, including endothelial cells, hepatocytes, neutrophils, and T-lymphocytes (double staining performed).

References

African swine fever (ASF) is one of the most complex and lethal disease of swine. The disease transmission involves domestic pigs, wildboars, warthogs and bushpigs. ASFV usually induces unapparent infection in a variety African wildboar population. Soft ticks (Ornithodoros spp) act as reservoir and biological transmission vectors.

ASF is endemic in the majority of sub-Saharan Africa. Within EU, it is confined to Sardinia. On June 2007, ASF was notified in the Caucasus region, in Georgia. It was associated to a new isolate, related to p72 genotype II, circulating in East Africa. Since then, ASF progressed to neighbouring countries Armenia, Azerbaijan and Russian Federation, reaching the near border with Ukraine, and, on October 2009, jumping to St Petersburg in north-western Russia, in the Baltic Sea. Current situation of ASF threatens the EU countries, Eastern Europe, the Black Sea basin countries and - in the worst case scenario – central Asia and even China, which has the largest pig population in the world.

There is no vaccine available and control strategies are based on rapid laboratory diagnosis. But, are we ready to combat with ASF? Would current diagnostic techniques be sensitive enough taking into consideration the new circulating viruses?

From 2000 to date, reliable, specific, and fast PCR tools have been developed and validated for virus detection. They have been shown to be highly sensitive for the detection of the new current circulating isolates in Europe and Africa.

However, serological surveillance studies performed in East Africa among 2000-2009, have shown low seroprevalence with, in contrast, a high incidence of virus in domestic pigs. This could be related to genome variability of antigenic ASF proteins in Eastern African isolates, the more variable and genotypically distant. To what extent current serological diagnostic techniques might be missing some of these new variants?

To study these questions, different ASFV were selected on the basis of genome variability criteria and date collection. Particular emphasis was placed to those belonging to p72 genotype X, the most variable, and p72 genotype II, current European circulating genotype. After successfully adapted to grow in COS cells, new soluble cytoplasmic antigens were used in indirect ELISA tests for initial standardization. To evaluate the capability and competence of these new tests with regards to the formal ASF serological tests, a comparative study is carrying out using a wide panel of serum comprising: i) experimental sera from "in vivo" experiments with East Africa and Caucasus ASFV circulating isolates ii) field sera from East-West Africa and Sardinia from 2004 to 2009. The preliminary results using the new p72 genotype X-based antigen indicate correlation to those using OIE serological tests and INGEZIM PPA.K3 Compac®. It's important to highlight the results achieved analysing negative serum samples from "apparently healthy" virus-positive pigs from East Africa. The capability of new others ASFV antigens from Africa and Caucasus to be used in ASF serological tests is under evaluation.

Theses results together with those obtained from in vivo experiments at CISA-INIA with recent isolates from East Africa and Caucasus regions, could be the first approach demonstrating the capability of the formal diagnostic techniques to perform a serological diagnosis with high sensitivity, specificity and confidence, adapted to current epidemiological situations.

Introduction

African swine fever (ASF) is a lethal, hemorrhagic disease of domestic pigs for which animal slaughter and area quarantine are the only methods of control. Since first description of ASF in Kenya in 1921, the disease was maintained in African until the initial export in 1957 to Lisbon spreading between 1957 to 1990 throughout Europe and America. Currently ASF is present in Sardinia, in Caucasus Republics and in most than twenty Sub-Saharan Africa countries, where ASFV can infect hosts through either a domestic cycle or a sylvatic cycle involving warthogs and bushpigs as well as ticks of the genus Ornithodoros.

In 2006, ASF broke out among commercial pigs in Kenya-Uganda border and spread in 2007 to Central Kenya around the city of Nairobi, after an apparent absence from the entire country since 2001. The outbreaks were traced to movements of domestic pigs and were not linked to warthogs or bushpigs. However, Kenya has had several outbreaks caused by regular reemergence of ASFV since its first description in 1921. These outbreaks could be result primarily from direct contact between infected domestic pigs with tick-involvement. In addition, experimental evidence suggests that pigs can exceptionally become infected from eating infected warthog tissues playing an important role in the transmission of the disease in the country. We report the first extensive study to investigate the role of sylvatic cycle involving warthogs, O. porcinus porcinus ticks and domestic pigs in the epidemiology of ASF in Kenya.

Materials and Methods

Samples from 83 ASF asymptomatic domestic pigs, 51 warthogs and a total of 1,576 Ornithodorus porcinus porcinus ticks from 26 independent warthog's burrow were collected from area of interface between domestic and wild pigs in Central Kenya, where ASF had been reported. Their infection status with ASFV was determined using combined p72-based PCRs, restriction analyses and virus isolation. In addition, sera from wild suids and domestic pigs were tested for anti-ASF antibodies using OIE serological prescribed methods. Different ASFV isolates were selected for genotyping purposes using a combination of full length p54-gene and p32-gene sequencing [1, 2], partial p72-gene sequencing [3], and analysis of tetrameric amino acid repeat regions within the variable region of the B602L gene (CVR) [4].

Results

The presence of ASFV was determined in 62 of 285 (22%) O. porcinus pools, 3 of 51 (3.22%) warthogs serum samples and 41 of 83 (49%) domestic pigs serum samples. Interestingly, no seropositive response was found in any domestic pig in contrast with the warthog's results where all of them were seropositives. Twenty O. porcinus, twelve domestic pigs and three warthog ASFV isolates were selected for genotyping. Phylogenetic analysis indicated that the ASFV isolates obtained in this study from ticks and healthy domestic pigs clustered in a sylvatic cycle P72 genotype X, whose range encompasses viruses from Rwanda, Burundi, Tanzania and Kenya, whereas ASFV isolates collected from warthogs were placed into p72 genotype IX related to recent domestic pig outbreaks occurred in Kenya in 2007.

Discussion

The detection and characterization of ASFV in warthogs, ticks and domestic pigs in this study verifies and expand on the first report of the relevance of vertebrate and invertebrate hosts in the transmission and maintenance of ASF following disease outbreaks in Kenya. Together these results signal the possible establishment of domestic pig-warthog and domestic pig-tick cycle transmission playing an important role in the maintenance and possible reemergence of future outbreaks of the disease in Kenya. This highlights the complex epidemiological situation in Eastern African countries which complicate control of the disease in these regions and emphasize the requirement for improved regulation and monitoring of domestic pig as well as a most effectiveness control by preventing contact between domestic pigs and wild suids and their ticks.

**Immunogenicity of commercial vaccines for the control of Porcine Rubulavirus causing Blue Eye Disease**

Francisco Quezada-Monroy; Ruben Echeveste-Garcia de Alba; Bernardo Lozano-Dubernard; David Sarfati-Mizrahi; Ernesto Soto-Priante; Horacio Lara-Puente

*Laboratorio Avi-Mex, S.A de C. V., Mexico City, DF, Mexico*

**Introduction**

Porcine Rubulavirus is the causal agent of Blue Eye Disease (BED). This is an endemic disease of the central area of Mexico, been the only country reporting the disease (Stephano *et al.*, 1981). The objective of this study was to analyze the capacity of commercial vaccines to stimulate the pig immune system to produce neutralizing antibodies.

**Material and Method**

3 weeks-old SPF piglets were divided in 2 groups. The first group with a commercial inactivated vaccine A (n= 16) and the second group with a commercial inactivated vaccine B (n =16). Both groups were vaccinated at days 0 and 14 of the experiment with a dose of 2.0 mL. Blood samples were taken on days 0, 14, 21 and 28 post vaccinations (PV). Antibody detection was done by means of Virus Neutralization (VN) test, with two-fold dilutions in a 12 wells plaque. A positive result was considered when the sample reached a titer equal or higher than 1:16 (Ramirez *et al.*, 1996).

**Results**

Twelve animals died due to causes not related to the trial. Group A started with 13 pigs and group B with 7.

For vaccine A, sero-conversion was first detected on day 14 PV (76.92%), and by day 28 PV all animals were positive, as shown in graph 1.

For vaccine B, sero-conversion was first detected on day 28 PV (28.57%), as shown in graph 1.

**Discussion and Conclusions**

Vaccine A showed a better capacity to stimulate the immune system of SPF pigs (antibody level was 1:128 at day 14, reaching 1:2048 on day 28). Vaccine B showed a lower capacity to stimulate the immune system of SPF pigs (at day 28 antibody level varied from 1:16 to 1:256). Statistical differences were detected among both groups at days 14, 21 and 28 using a T test (P=0.05).

Serological response differences found for both commercial inactivated vaccines can be due to several factors such as the seed used, viral titer before inactivation, quantity and quality of antigen, inactivation process, production process and type of adjuvant, among others.

**Graph 1.** Comparative neutralizing antibody levels induced by 2 applications of two commercial inactivated Blue Eye Disease vaccines.

**Bibliography**

Introduction

A controversy in Veterinary Medicine in reference to the existence of cross reaction or cross immunity exists, the fact that this phenomenon can affect the vaccination and diagnose processes. A classical example is Newcastle disease virus, any vaccine strain protects against any pathogenic isolate, independently of the homology percentage and is equally employed in laboratory tests. In pigs PRRS virus (1), which can or can’t protect against different isolates when employed as a vaccine. In a negative sense we find Bovine Viral Diarrhea (BVD) and Classical Swine Fever (CSF)(2), since the presence of BVD antibodies can yield a false positive result for CSF. The objective of this study was to acknowledge cross reactions that exists between antibody levels detected in serum of challenged animals and confronted with isolates of homologous and heterologous Blue Eye Disease (BED) isolates.

Material and Method

Nine SPF 8 weeks old pigs were employed distributed as follows: Group A (n=3), Group B (n=3) and Group C (n=3). The animals were challenged with isolates of BED virus, from 1999 (virus A), 2000 (virus B) and 2006 (virus C). Challenge dose was $10^{5.0}$ TCID 50%/mL administered 1.0 mL/IM and 1.0 mL/IN. Blood samples were taken from 0 days post challenge (dpc) and up to 36 dpc, with intervals of 4 days. Virus sero neutralization test (VSN) was employed with serial double dilutions starting at 1:2 and up to 1:4096; a positive result was considered with a titer of 1:16. For such test all 3 virus (A, B and C) were employed as test antigens (Ag) for the virus employed in the challenge (An antigen homologous to each challenge isolate) and also a 4th virus isolated in 1992 (virus D) (heterologous antigen for all the challenge isolates).

Results

At days 0 and 4 post challenge (PC) all animals remained negative. At day 8 PC group A became positive to Ag A and D but remained negative to B and C; Group B became positive to Ag A, B and D but negative to C; Group C became positive to Ag A and D but negative to B and C. At days 12 and 16 animals form group A were negative to antigen C but positive to A, B and groups A and C, became positive to all 4 Ag used with mid to low titers. From day 20 to 36 all animals became positive to all four Ag with mid to high titers (see table 1). It was noticeable that challenge virus C was less antigenic than the other 2 towards the 4 tested Ag. It is also noticeable that using Ag D a higher titer of antibodies was reached, even in comparison with homologous reactions.

Discussion

Cross reaction is given in function to characteristic or antigenic distance between the virus that produces immunity and the employed virus, for the case, in VSN. For this study the cross reaction was from low to negative intensity at 8 days PC, the antibodies of the 3 challenged groups being able to detect A and D antigens but in low titers, 1:20 and 1:30 respectively. As days PC passed the antibody levels became mid to high, antibodies from all 3 challenged groups identified all 4 Ag. Antibodies had higher affinity to A and D from day 8 PC and posterior samplings. The cross reaction can be linked to the viral capacity to stimulate high antibody titers as observed with Ag C, the less antigenic.

**Potency of a Blue Eye Disease commercial vaccine against 3 different viral challenges (Lung lesions)**

Horacio Lara-Puente; Bernardo Lozano-Dubernard; David Sarfati-Mizrahi; Ernesto Soto-Priante; Francisco Quezada-Monroy; Ruben Echeveste-Garcia de Alba

*Laboratorio Avi-Mex, S. de C. V., Mexico City, DF, Mexico*

**Introduction**

Blue Eye Disease (BED) was observed in the 80’s in farms around La Piedad, Michoacan, Mexico. Affecting pigs of different ages. Lung damage caused by the virus is of capital importance since the loss of pulmonary capacity repercussions in productive parameters and days to market, impacts medication costs and pigs become carriers of the disease in the farm and the geographical zone (ISU 2006 and Hernandez et al 2004). The objective was to determine the lung lesion percentage produced by 3 different isolates of BED and to evaluate the protective response of a vaccine by reduction of lung lesions against these 3 genetically different viruses.

**Material and Method**

Virus: 3 isolates collected in Mexico between 1980 and 2007. Animals: 28 SPF pigs between 5 and 6 weeks of age distributed in 7 groups, 4 piglets each, Negative Control (NC), Positive control Challenged with A virus (PCCAV), Positive Control challenged with B virus (PCCBV), Positive Control Challenged with C virus (PCCCV), Vaccinated Challenged with A virus (VCAV), Vaccinated challenged with B virus (VCBV) and Vaccinated Challenged with C virus (VCCV). All groups were maintained with strict biosecurity measures, with daily monitoring of rectal temperature and clinical signs. Blood samples were drawn at day 0 and repeated every 7 days. On day 0 pigs were vaccinated with 2.0 mL/IM of a commercial vaccine against BED, repeating at day 17. Challenge was performed 15 days post vaccination (pv) using 3 viral isolates (A, B, and C) with a genetic homology of 100%, 99.7% and 97.6% respectively, using 1.0 mL/IM and 1.0 mL/IN at 10⁵.⁰ CCID 50% mL. At day 18 pc all animals were sacrificed and necropsied, lung lesions were evaluated and blood was collected. Lung lesions were valorated by the planimetry method described by Ciprian et al. 1988. An ANOVA test and Tukey’s test was done to the collected data.

**Results**

Lung lesions on pig groups PCCAV, PCCBV and PCCCV reached an average of 6.9%, 8.0% and 2.2% respectively. On groups VCAV, VCBV and VCCV this average lowered to 1.5%, 3.6% and 0.3% that is a reduction of a least 55% (Table 1, Graph 1).

Different literals indicate statistical differences (P ≤0.05).

**Discussion/Conclusions**

The commercial BED vaccine clearly showed effectively lung lesions reduction and protected independently to genetic differences of the challenge virus. No statistical difference was found between lesion reduction and viral genotype employed in challenge, however it was found between challenged pigs and vaccinated challenged pigs (P ≤0.05).

**Clinical response in SPF pigs challenged with isolates of Porcine Rubulavirus (Blue Eye Disease)**

Ruben Echeveste-Garcia de Alba; Bernardo Lozano-Dubernard; David Sarfati-Mizrahi; Ernesto Soto-Priante; Francisco Quezada-Monroy; Horacio Lara-Puente

*Laboratorio Avi-Mex, S. A. de C. V., Mexico City, DF, Mexico*

**Introduction**

Porcine Rubulavirus affect swine and produces nervous signs and high mortality in 2 to 5 days-old piglets. It also produces reproductive failures. Affected sows increase the wean to service and repetitions rate, it also increases the number of stillbirths and mummies; in males, libido and semen quality are affected due to a permanent damage to testicular structures. In affected animals, regardless to their age, corneal opacity (blue eye) can be observed around 30 days post-infection in about 10% of the herd. The most important macroscopic lesion observed in pigs of all ages is pneumonia (consolidation zones) affecting the ventral region of the cranial lobes. Such clinical sign depends on the age, immunological status, production system and concomitant infections present (Stephano et al., 2002). The objective of this study was to acknowledge the behavior of 3 Porcine Rubulavirus isolates in relation to days with fever and percentage of macroscopic lung lesions in order to correlate fever with lung damage.

**Material and Method**

Eight weeks old SPF pigs (Avifarma, SA de CV, Mexico) were divided in 3 groups and challenged with different BED isolates. Group A (n= 3) challenged with isolate A (1999); Group B (n= 3) challenged with isolate B (2000), and Group C (n= 3) challenged with isolate C (2006). Challenge with any of all isolates was done with a $10^{5.0}$ TCID50% administered by intramuscular and intranasal routes (1 mL each). Rectal temperature and clinical signs were monitored daily. At day 18 post challenge (PC), one pig from each group was humanely sacrificed in order to evaluate lung lesions. At the end of the experiment on day 36 PC, all pigs were humanely euthanized and lung lesions were evaluated. Lung lesions score was performed according to the planimetry method described by Ciprian et al. (1988). The correlation between fever and lung lesion was analyzed.

**Results**

Among the 3 viral isolates employed, virus B showed the highest number of days with fever (24) and also the highest percentage of lung lesion (8%), compared with the other 2 viruses employed (see graph 1), which indicates a direct correlation among fever and lung damage. Pigs also had a fever peak at day 3–5 PC in all 3 groups.

**Discussion**

A direct correlation between days with fever and lung lesions was detected, the higher the numbers of days with with fever the higher the percentage of lesions. Pigs had a higher immune response towards virus A and B than to C. This is coincident with field observations regarding clinical signs. Apparently signology and clinical lesions differ towards what was described in the initial reports of the disease in 1980. The lung damage and days with fever induced by Rubulavirus or any other pathogen has a lot of impact in pigs, due to the loss of lung capacity and appetite loss, which in time repercussions in productive parameters as daily gain, alimentary conversion and in consequence days to market, and also negatively impacts medication costs in order to control secondary pathogens.

Impact in days with fever after the employment of a commercial
Blue Eye Disease vaccine against 3 viral challenges

Francisco Quezada-Monroy; Ruben Echeveste-Garcia de Alba
Laboratorio Avi-Mex, S. A. de C. V., Mexico City, DF, Mexico

Introduction
Blue Eye Disease (BED), was originally described in Mexico in the 80's. Besides the lesions produced by the viral replication it is important to consider fever as a generator of productive losses since an animal during this process eats very little or nothing at all, situation that repercussions in its productive efficiency and also converts them into easy targets for other pathogens (Hernández, et al, 2004). The objective of this research was to evaluate the impact of the use of a BED commercial vaccine in days with fever in animals challenged with 3 genetically different BEDv isolates.

Material and Method
Virus: 3 BED isolates, obtained during 1999 – 2006 (Quezada, et al, 2008). Animals: Twenty eight SPF, 5 – 6 weeks old pigs, distributed in 7 groups of 4 pigs each: (NC) Negative Control, Positive control Challenged with A virus (CA), Positive Control challenged with B virus (CB), Positive Control Challenged with C virus (CC), Vaccinated Challenged with A virus (VCAV), Vaccinated challenged with B virus (VCBV) and Vaccinated Challenged with C virus (VCCV). All groups were maintained in strict biosecurity measures, with daily monitoring of rectal temperature and clinical signs. For temperature monitoring infrared thermometers (Dottori UR 100), were employed, reading the temperature on the neck area posterior to the ear of the pigs. In order to determine presence or absence of fever the average daily temperature of NC was employed, we determined a group average and Standard deviation (SD) was calculated, we added twice this value to the obtained average, all data above this rank was considered as fever. On day 0 they were vaccinated with 2.0 mL/IM of a commercial BED vaccine, repeating it 17 after; challenge was done 15 after revaccination, using 3 different isolates (A, B and C) with a genetic homology of 100, 99.7 and 97.6% respectively, using 1.0 mL/IM and 1.0 mL/IN at 10^6.0 TCID_{50}/ml. At day 36 post challenge all animals were sacrificed, and necropsied.

Results
None of the NC group had fever or clinical signs at all. The per se effect of the vaccination on the pigs was minimal and was detected as fever 1 days PV that spontaneously receded without any other effect. On vaccinated/challenged groups with isolates A, B or C (VCAV, VCBV and VCCV) between 1 and 3 days with fever were detected (Table 1), on non vaccinated/challenged groups (CA, CB and CC) had between 15 to 24 days with fever (Graph 1).

Conclusions
Clinical manifestations of viral infection on SPF pigs were less severe than expected. It is probable that secondary infections in commercial pigs and other unfavorable environmental farm conditions become a factor in the clinical onset of the disease along with the pigs age. The decrease of the disease’s impact in the field by employing a commercial vaccine is shown not only in the adverse effects of the infection but with a reduction of at least 80% of days with fever after challenge, which in turns manifests as a considerable improvement in the herd.

Non cited Bibliography
Porcine Rubulavirus Infection, Iowa State University, Institute for international cooperation in animal biologics. 2006.
Introduction
Currently the diagnostic for Porcine Rubulavirus by antibody detection is done through different serologic tests such as Immunoperoxidase, ELISA, Virus Sero Neutralization (VSN) and Hemmaglutination Inhibition (HI) test. HI has been widely employed for Blue Eye Disease (BED) diagnostics and seroepidemiology due to its easiness of implementation and that the results are repeatable, reproducible, and of low cost, when compared to other tests (Gonzalez, 2002). The objective of this study was to compare the results obtained by HI tests using 2 different isolates of Porcine Rubulavirus.

Materials and Methods
Samples: 144 field sera.
Virus: two different isolates of different origin were employed.
Hemmaglutination Inhibition test (HI): All samples were inactivated at 56° C for 30 minutes. Then adsorbed as follows: 100 μl of serum, 50 μl kaolin and 50 μl of 5% bovine erythrocytes resting all night. Once adsorbed, double serum dilutions were employed from 1:4 and up to 1:512, 8 HAU were added incubating 30 minutes at room temperature, once finished bovine erythrocytes at 0.5% were added. Sample was considered positive when they showed a titer equal or higher to 1:16 (Ramirez, 1996).

Results
Using Virus A we detected 91 positive and 53 negatives sera; virus B detected 85 positive and 59 negative sera (Table 1). It was noticeable that in 80.56% of the samples there were no differences in the dilutions or only one difference, with 2 differences 13.19% and with 3 or more 6.25% (Table 2). To know if there were differences among results, a T student test was performed and did not found statistical differences among the results employing both viruses (p= 0.01)

Discussion
In this study there were samples which did not completely agreed in their results using both viruses, 6.25% of the samples had 3 or more dilution differences, this may be due to the percentage of false positive and false negative inherent to the HI test (Hernandez, 1992).

We did not found any statistical difference employing both isolates at the moment of the report of the results of the HI test, It has been said that result differences may exist in the test results using different viruses (Sanchez, 2004), but our results agree with the theory that there are no antigenic variations among the different isolates of Porcine Rubulavirus.

Real time PCR diagnosis of Blue Eye disease

Alvarado I. Arcelia1 Cuevas R. Sandra1 Colmenares V. German1 A. A. Blomstron1,2 Garcia F. Arturo1 Mejia S. Pedro1 M. M. Berg2

1. INFAP-CENID-Microbiologia Animal, México, DF, Mexico; 2. Upsala Sweden University, Suecia, Sweden

Introduction
Currently, Blue Eye Disease represents a barrier for the exportation of swine; it is a disease that affects pigs at different ages, although 2 to 15 day old piglets are the most susceptible. Most notable symptoms are changes in behavior, nervous alterations, respiratory failure, and reproductive alterations in dams and sires and in some cases corneal opacity of one or both eyes.

The objective of this study was the development of a sensitive and specific enough diagnostic method that could to detect pigs persistently infected with the porcine Rubulavirus (PoRV-LPMV) that is the causal agent of this disease.

Materials and Methods
This method was developed and standardized for the detection of the gene fragment that codifies for the porcine Rubulavirus phosphoprotein, in tissue and blood samples. To read it, the assay was adapted to a Light Cycler 1.5 system. For standardizing this technique a plasmid developed in the University of Agriculture of Sweden was used, which is formed by a 1384 base pairs of gene fragment that codifies for the PoRV-LPMV phosphoprotein. Serial decimal dilutions were performed with this plasmid to establish the sensitivity of the assay and then the assay was tested on samples from naturally and experimentally infected animals in order to validate it.

Results
Results obtained showed an assay sensitivity of 10 copies for detecting the positive plasmid control. Assay conditions were established according to the protocol corresponding to the Light Cycler TaqMan Master, whereby the presence of porcine Rubulavirus was established. The assay has 1.98% efficiency according to the Light Cycler Instrument 1.5 equipment system.

Discussion and Conclusions
Real time PCR technique is efficient for detecting with high sensitivity animals that carry the porcine Rubulavirus since it is possible to carry out the diagnosis with up to a minimum of 10 phosphoprotein gene copies. Technology developed may be transferrable to national diagnostic laboratories.

Introduction

Porcine rubulavirus (PoRV) is the etiological agent of blue eye disease (BED) of pigs that has been endemic in Mexico (Kirkland & Stephano, 2006). The clinical signs are age-dependent. Orchitis, epididymitis and decrease of seminal quality are presented in boars, eventually leading to infertility (Ramirez-Mendoza et al., 1997; Solís et al., 2007). Viral RNA persistence has been documented in the central nervous system, lymph nodes and reproductive tract (Wiman et al., 1998; Cuevas et al., 2009) but not detected in semen and viral isolation not is record in persistent infection status in boars. The aim of the present work was to detect persistent PoRV in semen and reproductive tract of experimentally infected boars.

Materials and Methods

Nine 12-month-old York * Landrace boars were obtained from a PoRV free farm. Boars were inoculated by intranasal instillation with 5 ml 105 TCID50/ml of strain PAC-3 Jalisco/1992 (Ramirez-Mendoza et al., 1997) and kept for 142 day post inoculation (dpi). Serum and semen samples were collected twice per week. Antibody response was evaluated by haemagglutination inhibition (HI) and virus neutralization (VN) test. Boars were killed at 10, 16 and 20 weeks post inoculation (pi) and testicle and epididymis were collected. For PoRV RNA detection in serum and semen samples, RT-PCR was performed and amplified 375bp of N gene. For viral isolation, semen and reproductive tissues were used and cultured in MDCK cell line in order to be stained by an indirect immunofluorescence assay.

Results

PoRV infection caused clinical signs in day 5 pi, testicular swelling and pathological changes in epididymis were observed as well as the spermatic concentration that was significantly decreased. At necropsy three boars showed testicular and epididymal lesions. All boars seroconvert, HI and VN antibodies were detected in the second week pi, showing a high titer until the end of the experiment (Fig. 1). Viral isolation and PoRV RNA results showed in table 1.

*Tissues from one boar killed. †Tissues from four boars killed.

Discussion

The nine boars exhibited testicular changes and negative effects in seminal quality. Antibody response in persistent status was demonstrated. These results were consistent with previous experiments (Ramirez-Mendoza et al., 1997; Hernandez et al., 1998; Cuevas et al., 2009). Viral isolation is a novel report in persistent status, though other researchers only detected viral RNA in epididymis in long time of infection and PoRV in semen in acute infection (Solís et al., 2007; Cuevas et al., 2009). Thus, these results confirm that PoRV RNA persists in semen and the virus is present in genital organs during prolonged periods of infection.

Introduction

Blue eye disease in pigs is an emerging and endemic disease in México. The causal agent is porcine rubulavirus a paramyxovirus isolated for first time in La Piedad, Michoacan (Kirkland & Stephano, 2006). Humoral immune response in clinic phase has been identified by conventional test, such haemagglutination inhibition (HI), virus neutralization (VN) and indirect fluorescent antibodies (IFA) (McNeilly et al., 1997; Hernández et al., 1998) and persistent stage of infection with ELISA specific HN antibodies (Cuevas et al., 2009). Quantification of antibody response in persistent infection has not been investigated. The objective of this study was evaluated the humoral immune response in clinical and persistent experimental PoRV infection.

Materials and Methods

202 serum samples were collected from pigs experimental infected (24 sera preinfection and 178 posinfection), analyzing two weeks pre and 20 pi.

Haemagglutination inhibition (HI) and virus neutralization (VN) test were carried according to previous standard procedures (Ramírez-Mendoza et al., 1996; Hernández et al., 1998) with next modifications for HI, 8 and 16 haemagglutination units were used with 1:8 and 0 cut point, respectively. For VN 0.5% chicken and bovine erythrocytes were used for measurement haemagglutination limit, all assays were performed in MDCK line cells. Immunoperoxidase monolayer assay was performed in MDCK cell line infected with PoRV at 0.01 MOI. Indirect fluorescent antibodies test was developed in same cell line, goat anti swine IgG conjugated with fluorescein isothiocyanate was used. All sera were placed in double serial dilutions. The results were analyzed with SPSS 10.0 statistical package.

Discussion

The humoral immune response begins in the first week post-infection and it maintained high titers for prolonged periods in the persistent phase of infection. Cuevas et al. (2009), it has been reported that animals retaining seropositivity during the persistent phase of infection, but was not quantified with standard methods. The results correspond to previously report by Hernández et al. (1998), which analyzed the humoral immune response by HI and VN in the clinical phase of disease. The results of the IPMA and IFA demonstrate the utility of fixed and inactivated antigens in the development of serological diagnostic tests.

Introduction
Classical swine fever (CSF) is an economically important swine disease worldwide. The glycoprotein E2 of classical swine fever virus (CSFV) is capable of inducing the production of neutralizing antibodies in the host (1). A CSF subunit marker vaccine has been developed which contains the E2 produced in insect cell by the recombinant baculovirus expression system (2). Recently, we have constructed a recombinant E2 protein using the yeast Pichia pastoris secreted expression system, and the yeast-expressed E2 protein (yE2) is able to induce a protective immune response against CSFV infection (3). The aim of this study was to determine the optimal dose of yE2 vaccine for conferring full protection against CSF.

Materials and Methods
Twelve 6-week-old specified pathogen-free (SPF) piglets were randomly allotted to three yE2 vaccine groups and a control group. Concentrated secreted product from the recombinant E2-expressing yeast (yE2) was used for vaccine preparation without further purification steps. Each pig was immunized at 6- and 9-week-old respectively intramuscularly in the pig's neck with 2 ml vaccine containing 200, 300, or 400 μg yE2 (yE2/200, yE2/300, and yE2/400 vaccine groups respectively) or normal saline (control group) in a 1:1 water-in-oil emulsion with the adjuvant IMS 1113 (SEPPIC). The pigs at 12-week-old were challenged intramuscularly via the neck with a 1*10⁵ TCID₅₀ dose of virulent CSFV strain. Serum samples were tested for their neutralizing activities by serum neutralization test. Neutralizing titers were expressed as the reciprocal of the highest dilution that cause complete neutralization.

Results
All yE2 vaccine groups including yE2/200, yE2/300, and yE2/400 mounted anamnestic response after booster vaccination with the average neutralizing antibody titers of 64, 928, and 2683 respectively. Neutralizing antibody titers of yE2 vaccine groups increased dramatically after challenge infection (Fig. 1).

The control pigs developed an acute febrile response after challenge infection and had to be euthanized because of severe clinical symptoms by the post-infection day 10. None of the yE2/300 and yE2/400 pigs became febrile (Fig. 2). All yE2-vaccinate pigs survived after challenge without any apparent clinical symptoms and post-mortem evaluation at 14 days post challenge revealed no evidence of CSFV infection.

Discussion
All of three doses of yE2 vaccine could induce protective immune response against CSFV infection. The optimal dose of yE2 was recommended to be 300 μg of total secreted protein. The E2 constituted 5-10% of total secreted protein (300 μg) which is equivalent to 15-30 μg of E2 in one dose of yE2 vaccine. Yeast-expressed E2 recombinant protein (yE2) represents an alternative subunit E2 marker vaccine candidate with advantages of easy manipulation and low cost.

Gross and histopathological scoring systems to evaluate Classical Swine Fever virus infections

Francisco J. Salguero; Helen E. Everett; Alejandro Nunez; Trevor Drew; Helen Crooke
VLA-Weybridge, Addlestone, UK

Introduction

Classical swine fever (CSF) virus infections cause large economic losses in the pork industry and have profound social and welfare consequences. CSF has been reported in many countries throughout America, Asia and Europe in the recent years. Control strategies are based on stamping out as well as vaccination. Clinical and pathological diagnoses have proven to be very important in the early steps of an outbreak. However, many clinical signs and gross lesions cannot be differentiated from other porcine diseases. The characterization of CSF virus infections by different isolates is key to identify the common and unique features associated with infection. Few clinical and very few and basic post mortem gross scoring systems have been applied to these characterization experiments. In this paper we describe two detailed scoring systems, gross and histopathological, and their use in experimental infections with two genetically diverse CSF virus strains.

Material and Methods

Two different animal experiments were carried out. Six 10 week-old pigs were inoculated by the intranasal route with $10^5$ TCID$_{50}$ of the corresponding isolate (UK2000/7.1 and CBR/93) and housed with 3 animals used as “in contact” sentinels, while 2 animals were housed separately as non inoculated negative controls. Clinical signs were monitored daily and animals were euthanized at 18-21 dpi. Post mortem examination was carried out following standard procedures and any observed lesion was recorded. 21 parameters were used for the gross pathology scoring system: body condition, skin and subcutis, tonsils, fluid in body cavities, spleen, kidney, ileum (and ileocaecal valve), caecum and colon, brain and meninges, respiratory system, eight lymph nodes (precrural, inguinal superficial, mandibular, lateral retropharyngeal, medial retropharyngeal, prescapular, ventral cervical superficial and ileocaecal), urinary bladder, thymus and conjunctiva. Scores from 0 (normal) to 3 (severe) were given to observed lesions for each parameter (e.g. hemorrhages, thymic atrophy, etc.)

Samples from tonsils, spleen, kidney, ileocaecal valve, colon, encephalon, lung, thymus, pancreas, liver, bone marrow and the eight lymph nodes were fixed in buffered formalin and embedded in paraffin wax. 4 μm sections were stained with H&E for histopathological examination. 33 parameters were used for the histopathological scoring system and the severity of lesions was also recorded from 0 (no lesion) to 3 (severe). Data from both scoring systems were analysed by Kruskal–Wallis non-parametric mean comparison test and differences were considered significant for P < 0.05(*)..

Results

Results are summarized in figure 1 (A, B; gross pathology) (C, D; histopathology). Boxes represents percentile 25 to 75; whiskers represents maximum and minimum values; lines represent medians. No statistical differences were found between UK2000/7.1 and CBR/93 inoculated or UK2000/7.1 and CBR/93 in contact animals. Significant differences were observed between the 3 groups (inoculated, in-contact and control) within the same experiment.

Discussion

The extended gross and histopathological scoring systems described here have proven to be a valuable tool for systematic comparison and assessment of pathological findings related to CSF infection.

**IFN-gamma immunodetection in tissues from pigs vaccinated (C-strain) and challenged with Classical swine fever virus (UK 2000 7.1)**

Francisco J. Salguero; Helen E. Everett; Simon P. Graham; Felicity Haines; Olubukola Sosan; Helen Johns; Alejandro Nunez; Trevor Drew; Helen Crooke

VLA-Weybridge, Addlestone, UK

**Introduction**

Classical Swine Fever (CSF) is a viral haemorrhagic disease caused by Pestivirus within the Flaviviridae family. The disease is characterized by haemorrhages and lymphopenia, and the main target cell for the virus is the monocyte-macrophage. The attenuated C-strain is an effective vaccine, widely used in many countries but its use within the EU has been hindered by limitations in differentiating vaccinated from infected animals by serology. To investigate mechanisms behind the effective protection afforded by this vaccine, we have studied the immunohistochemical detection of IFN-gamma within lymphoid tissues of pigs vaccinated and challenged with CSF virus.

**Material and Methods**

Groups of six, ten-week old pigs were vaccinated (V) with the Reimser C-strain vaccine by intramuscular route 5, 3 or 1 day/s prior to intranasal challenge (Ch) with UK2000/7.1 CSF virus strain. Four unvaccinated pigs were also challenged to control for infection (C+). In all cases, challenged animals were re-introduced to unvaccinated, “in-contact” (IC) animals twenty-four hours post-challenge. Animals were monitored twice daily and blood samples were taken to assess viremia (RT-PCR). Animals were euthanized and gross and histopathological scores were calculated as described (see poster presented by this group). At necropsy, medial retropharyngeal lymph node, tonsil and spleen were also collected and fixed with Bouin’s solution for immunohistochemical detection of IFNgamma (R&D Systems Inc.) by means of a modified ABC technique.

**Results**

Unvaccinated animals developed clinical signs, viraemia and transmitted the virus to “in contact” animals within 14 days of inoculation. Animals vaccinated 5 days prior to challenge were completely protected. Five of the 6 animals vaccinated 3 days prior to challenge had only few clinical signs and pathological changes while half of the animals vaccinated 1 day prior to challenge were protected to some extent. Results of gross pathology and histopathology are summarized in Figures 1 & 2 respectively.

Immunohistochemical detection of IFN-gamma displayed high levels in animals vaccinated 5 days prior to challenge, mostly in lymph node medulla, interfollicular areas of the tonsils and splenic red pulp. IFN-gamma-expressing cells were reduced in numbers in all the other groups. The level of IFN-gamma expression in animals showing some degree of protection was higher than those not protected within the group vaccinate 1 day prior challenge.

**Discussion**

C-strain vaccination provides good protection against CSF virus infection by 5 days post vaccination and this protection is correlated with IFN-gamma expression in lymphoid tissues. These results support the hypothesis that the presence of high levels of IFN-gamma secreting cells provide a cell mediated mechanisms that are able to control CSF virus infection.

Comparison of PCR methods for detection of classical swine fever virus and other pestiviruses

Katarzyna Podgórska; Katarzyna Kamieniecka; Zygmunt Pejsak; Tomasz Stadejek
National Veterinary Research Institute, Pulawy, Poland

Introduction
Classical swine fever virus (CSFV) is an etiological agent of an economically important notifiable pig disease - classical swine fever (CSF). Other viruses belonging to the same Pestivirus genus, border disease virus (BDV) and bovine viral diarrhoea virus (BVDV) types 1 and 2 are also able to infect pigs, sometimes causing lesions resembling infection with a low-virulent CSFV strain (1). Therefore, discrimination of these infections is important from epidemiological point of view.

The aim of the study was to compare the usefulness of PCR methods for CSFV detection and differentiation from other pestiviruses.

Materials and Methods
Viruses. Strains representing all species within Pestivirus genus were propagated in cell cultures and included into the study: CSFV (strain Alfort/187 of genotype 1 and field strain 1795/94 of genotype 2), BVDV 1 (NADL), BVDV 2 (Short) and BDV (Moredun).

RNA extraction and reverse transcription. RNA was extracted using Total RNA Prep Plus kit (A&A Biotechnology) and eluted in 100 μl of RNase-free water. Next, cDNA was synthesized using MMLV reverse transcriptase as described elsewhere (4). Tenfold dilutions of cDNA's were aliquoted and stored at -70°C.

PCR methods. Two Real-Time methods and conventional one-tube nested RT-PCR were applied for specific detection of CSFV. TaqMan I method was performed according to previously described protocol (2). In TaqMan II assay csfv 6 and csfv 7 primers designed by Uttenthal et al. (7) and CSFV specific probe (Stadejek et al., unpublished) were used. Nested PCR was based on Katz et al. (3) with later modifications (5) including immobilization of the inner primers pair in tube caps.

Additionally two pan-pestivirus specific methods, Real-Time SYBR Green I (6) and gel-based one-tube nested RT-PCR (8) with further modifications (5) were included into the study.

All PCR reactions were performed in triplicates. Real-Time PCR reactions were run on Stratagene Mx3005P system using Quantitect PCR Probe or SYBR Green I kits (Qiagen). CSFV-specific nested RT-PCR amplified fragment of genome encoding E2/NS2. All other assays were designed based on 5'UTR genome region.

Results
The highest sensitivity in detection of CSFV was observed using TaqMan I method. Similar results were obtained by CSFV-specific nested RT-PCR. These methods allowed detection of the virus in examined samples containing 101 and 102 TCID50/ml of Alfort/178 respectively.

Both pan-pestivirus specific methods were less sensitive in detection of CSFV. The virus was detected in samples containing 105 and 103 TCID50/ml using SYBR Green I and nested PCR method respectively. Only the nested RT-PCR method detected BDV strain. Moreover, the sensitivity of this test for BVDV detection was 2 or 4 logs higher (depending on the strain) compared to SYBR Green I method.

Discussion
In this study sensitivity and specificity of 3 methods specific for CSFV and 2 methods specific for all pestiviruses was compared. The results confirmed that both, conventional and Real-Time PCR methods, are useful for detection of CSFV and discriminating from other pestiviruses. However, the compared methods differed in sensitivity to detect CSFV. The Real-Time PCR method of Hoffmann et al (2) and conventional PCR of Stadejek and Pejsak (5) which employed primers described by Katz et al. (3) proved to be the most sensitive.

Research of Porcine Parvovirus (PPV) in organs and stomach fluid of stillbirth, mummified and aborted fetuses and phylogenetic analysis of PPV isolated from fetal tissue

Camila Sa Rocha² Neide L. Simon³ Giseli A. Ritterbusch³  Aline Viancelli³ Nelson Mores³ Armando L. Amaral³ Paulo A. Esteves³ Janice R. Ciacci-Zanella¹ ⁴

¹. Virus and Prion Diseases Research Unit, NADC, ARS, USDA, Ames, IA, USA; ². Agroveterinarian Science Center – CAV – University of Santa Catarina State – UDESC, Lages, SC, Brazil; ³. Embrapa Swine and Poultry Research Center, Animal Health Laboratory, Concordia, SC, Brazil; ⁴. Labex-USA, EMBRAPA, Brasilia, DF, Brazil

Introduction
Porcine Parvovirus (PPV) was described for the first time in the 60’s (1) and until today it is known as the main infectious agent associated with swine reproductive failures (2). In Brazil, the porcine parvovirus infection is diagnosed as the cause of reproductive problems for at least 20 years (3). The fetal infection can occur through the placenta or from fetuses to fetuses (4) thus, those tissues are very important source of contamination (4, 5). Because it is an endemic disease in several countries, including Brazil, and recently another viral agents have been implicated as the cause of reproductive problems the purpose of this study was to investigate the presence and distribution of PPV in tissues and in stomach liquid of stillbirth, mummified and aborted fetuses from 27 swine farms with reproductive losses. In addition to that, the phylogenetic analysis of PPV isolated from fetal tissues was also performed.

Material and Methods
A total of 230 stillbirths, mummified and aborted fetuses were collected and necropsied from 27 selected farms. The farms of this study were located in the Southern States of Brazil and were chosen based on overall reproductive failure rates (6). Organs (heart, lung, liver, spleen, thymus, kidney, brain, cerebellum, spinal cord, submandibular lymph nodes, inguinal lymph nodes and mesenteric lymph nodes) from all 230 fetuses and the stomach fluid of 109 of those fetuses were collected. DNA was extracted by proteinase K method (7) and further amplified by nested-PCR using specific primers from the PPV nonstructural protein gene, NS1 (8). The positive samples were sequenced by the Big dye terminator method and phylogenetically analyzed.

Results and Discussion
PPV DNA was found in organs of six (2.6%) out of 230 necropsied fetuses by nested-PCR. The positive organs were cerebellum (50%), spinal cord (50%), brain (33.3%), lungs (33.3%), spleen (33.3%), inguinal lymph nodes (33.3%), mesenteric lymph nodes (33.3%), heart (16.7%), liver (16.7%) and kidney (16.7%). Stomach fluid from the 109 fetuses were also analyzed by nested-PCR and the PPV DNA was detected in three (2.8%) of them. Those findings confirm the results obtained by other studies about the most frequently infected organ, as heart and lung (9) and, together with others factors can help the understanding of virus pathogenesis in fetuses. This study indicated a low frequency of the infection by PPV on the studied farms, although the disease is considered endemic in Brazilian swine herds. Thus, vaccination and management measures may be playing an important role controlling PPV infection in Brazil. Sequencing and phylogenetic analysis showed that PPV samples isolated from fetuses had 97 to 100% identity with classical PPV. These samples were grouped with isolates from China (ZJ-EU790642), South Korea (VR-1-AY390557), United Kingdom (CHALLENGE-AY684866) and Germany (IDT-AY684872) (Figure 1), indicating that similar isolates are present in the various countries.

Figure 1. Phylogenetic tree of samples sequenced in this study (24LM).

Introduction
The aim of this study was to confirm previous results (1), to include new vaccines in the comparison and to study the impact if any on feed intake.

Material and Methods
The trial was a multicentric, randomised and positive controlled GCP study in three farrow-to-finish Spanish farms. Following a simultaneous 4-weeks batch farrowing, each sow of one farrowing batch was randomly assigned to one of 3 treatment groups (PARVORUVAX®, and 2 other different Parvovirosis and Erysipelas (P/E) vaccines coded VA and VB) according to parity. In total, 196 sows were included in the general study, and 95 of them in the part of the trial involving feed intake. Sows received a booster vaccination 1 week before weaning, being checked for rectal temperature and for swelling at the injection site before and after injection (at Day 0, Day 0 + 6 hours, Day 1 and Day 2 after injection). Daily feed intake (from Day -2 to Day 2) was determined only in one of the farms using dried feeding. For this purpose the experiment in this farm was repeated in two subsequent batches. Site reactions were classified in 2 categories: absent or inflammation. The statistical procedures used for rectal temperature and feed intake was the variance analysis implemented by the MIXED procedure of SAS®. The statistical model included the sow, group, site, day and their interactions and local site reactions were analysed using a logistic regression implemented by the LOGISTIC procedure of SAS.

Results
At 6 h post-injection a significant lower temperature was observed in the PARVORUVAX group (P group) compared to vaccine VA, -0.33º C (P<0.0001), and a close to significant difference, -0.16º C (P=0.05) with vaccine VB. Significantly, less local site reactions at Day 0+6h were observed (p<0.01) in the P group (14.9%) compared to the VA (55.8%) and VB (51.0%) groups. This difference persisted till the end of the experiment, at D2 (table 1).

</tr>
</tbody>
</table>

a,b values in the same column with different superscripts were significantly different (p<0.05).
* Temperature on Day 0 was used to covariate the rest of temperature analysis

Feed intake was influenced by the type of vaccine used. As shown in Figure 1, sows vaccinated with vaccine VA and VB ate on the day of vaccination, 0.18 and 0.14 kg less than sows in P group (P<0.05 and P=0.05 respectively).

Discussion and Conclusion
These results confirm that the use of some Parvovirosis/Erysipelas vaccines may have a safety concern as it can have welfare and production negative consequences in practice. Our results not only confirm the safety of PARVORUVAX compared to the vaccine VB, included in a former study, but also to vaccine VA, not analyzed previously. With our experimental design we have been able not only to reproduce the effects on rectal temperature and site reactions but also to proof an impact of these products in feed intake witnessing a general reaction. While hyperthermia and local reactions have an obvious impact in the animal wellbeing, a transient reduction of feed intake during lactation could have further consequences such as reduction of milk production and consequently pre-weaning growth retardation in the litter.

A genome characterization of Korean porcine Parvovirus

Hye-Young Jeoung; Dong-Jun An; Wooseog Jeong; Byoung-Han Kim
National Veterinary Research & Quarantine Service, Korea, Korea

Introduction
Porcine parvovirus (PPV) is classified in the genus Parvovirus, in subfamily Parvovirinae and the family Paroviridae. The large ORF1 and the small ORF3 encode for the non-structural proteins NS1, NS2 and NS3. The ORF2 encodes the structural proteins VP1, VP2 and VP3. VP1 and VP2 are a result of alternative spliced RNAs, giving VP1 a specific N terminus of 150 aa. VP3 is generated by proteolytic cleavage of VP2. Recently, PPV has gained importance as an agent able to potentiate the effects of porcine circovirus type 2 (PCV2) infection in the clinical course of postweaning multisystemic wasting syndrome, a significant economical disease worldwide. We researched two strains in this study that PVK1 and SK2 strain isolated from abortion fetus of sows in 1980 and 2008, respectively. According to molecular analysis of the two Korean strains and previous studied VRI-1 strain, we were to compare a genome characterization and virulence among other countries strains.

Material and Methods
Two Korean PPV sequences and 20 sequences from PPVs from around the world obtained from GenBank were aligned using the Clustal X 1.83 sequence alignment program. Nucleotide and amino acid sequence identities among the PPV strains were calculated using BIOEDIT 7.053. The phylogenetic tree was created by neighbor-joining method using MEGA 4.0 software and bootstrap analyses were conducted using 1000 replicates. The recombination among PPV strains was analyzed by the recombination detection program (RDP).

Results
Of six amino acid position sites within VP1/VP2 proteins, Korean SK2 strain was different only one position (T365I) and VRI-1 strain was just two positions (G528D and Q533H) comparison with Kresse strain whereas PVK1 strain was only two positions (T195S and R715K) comparison with NADL-2 strain. The sequences of NADL-2, POVNADL-2, POVG, SR-1, China and POVCAP in this region were the longest among the strains, and contained two identical 127-bp repeat units whereas strains 15a, 21a, 27a, 106b, Kresse and Tornau contained only one complete 127-bp unit (Table 1). Strains SK2 and PVK1 lacked 75 bases from 74 to 148 bases but VRI-1 strain can't analyzed due to data none. Phylogenetic tree analysis of VP2 protein of 22 PPV strains using a Neighbor joining (NJ) method in MEGA 4.0 software didn't divide clearly as the attenuated and moderate and highly virulent groups, but three Korean strains showed grouping similarly on tree topology.

Discussion
The genotypic grouping in this study could also be associated with neither clinical presentation nor geographical origin of the samples, whereas three Korean strains showed grouping similarly on tree topology. In our judgment of three genome analysis (mutation amino acid of VP1/VP2 protein, a 127-bp repeat of ORF right and phyogenetic tree), three Korean strains are presumed to include a moderate virulence. On the other hand, The genomes among all strains by in GENECONV, SiSCAN, BootScan, MaxChi, and 3Seq methods in RDP program analysis weren't determined a possible breakpoints of the two recombinants which are the major and minor parent strains. On accession of no breakpoint may be a very high homology among worldwide PPV strains as well as Korean strains.

In conclusion, two Korean strains have one or two difference of six amino acid position sites within VP1/VP2 protein with Kresse strain and on a 127 nt repeat after the right ORF encoding the VP1/VP2, strains SK2 and PVK1 lacked 75 bases. Three Korean strains on the phylogenetic tree analysis for VP2 gene were grouped similarly lineage. Korean PPV strains are presumed to include a moderate virulence.

Comparison of two attenuated PRV vaccines in Aujeszky’s Disease control
Liande Zhu; Shumin Chen; Aiguo Wang
Boehringer Ingelheim International Trading (Shanghai) Co. Ltd, Beijing, China

Introduction
Aujeszky’s Disease (AD) or Porcine Pseudorabies (PR), which had been eradicated successfully in many countries of North-America and Europe (1), is still a widely spread viral disease in China (2). The use of a gene-altered vaccine makes it possible to identify infected pigs from vaccination population. Attenuated live marker vaccines are routinely used for a combined vaccination-eradication program for PR eradication. Several kinds of marker vaccines, home-made or imported, are approved for PR control in China (2). In this study, efficacy of 2 imported marker vaccines was compared by gE-antibody test.

Materials and Methods
A North Chinese pig company (3,500 sows) has 2 farms with 2,000 sows in Farm 1 and 1,500 sows in Farm 2. There is 2 km between the two farms. Both farms implement continuous pig flow, all-in-all-out management. All sows are from same genetic farm and kept in same housing, feed and health management systems.

Both farms used home-made attenuated PRV vaccine. After 2 years’ vaccination, more than 95% breeding animals were still gE positive, with poor reproductive and growth performance.

In early March 2008, both farms decided to replace the local vaccine with imported PRV vaccines. Farm 1 switched to vaccine B (Ingelvac® Aujeszky MLV, Bartha K-61 strain, with water adjuvant). Sows and boars were vaccinated 4 times per year. In piglets, an intranasal vaccination was given at 1 to 3 days of age, and a second was given intramuscularly at 8 weeks of age. Farm 2 changed to vaccine M (another imported attenuated PRV vaccine, Bartha strain, with oil-in-water adjuvant). Sows and boars were vaccinated 4 times per year. In piglets, a first intramuscular shot was given at 8 weeks of age, and a second at 12 weeks of age.

Blood samples from boars, sows, 40-55-day old piglets and 130-150-day old fatteners, were collected from both farms in July–Oct. 2008 and May 2009. gE antibody were detected with IDEXX PRV-gE ELISA kit.

Results
Fig. 1 showed that the seropositive rate of field strain decreased more by Vaccine B in farm1 than Vaccine M in farm2. In 5 months, fatteners in farm 1 became gE antibody negative and that in farm 2 were not.

Discussion
Piglets born to sows infected with wild type virus should acquire gE positive colostral antibody. We reckoned it was colostral antibody that caused piglet gE positive, and fatteners were negative while gE antibody disappeared and no wild virus infected the group pigs in farm 1. In farm 2, the fatteners were gE positive which indicated wild virus infected the pigs earlier.

Intranasal vaccination is more effective than intramuscular vaccination by local replication and development of mucosal immunity in the presence of passively acquired colostral immunity. During acute infection, intranasal virus colonizes the trigeminal ganglia, and prevents infection and reduces latent infection (3) Two applications of intranasal and intramuscular vaccinations of Vaccine B ensure much better protection than two intramuscular vaccinations of Vaccine M. Vaccine B was more effective than Vaccine M in preventing latent infection.

Figure 1. Seropositive rates of both farms in July, Oct. 2008 and May 2009

The eradication of PR can be most successfully achieved by the slaughter of all the seropositive animals, strict control of pig movement. However, this is not cost-effective. For most Chinese farmers, the optimal method of eradication is to implement combined vaccination-eradication program (1).

In this study, Vaccine B (Ingelvac® Aujeszky MLV) was proved a powerful tool for PR control and eradication.

**Introduction**

In Asia, nowadays, pig producers need to protect their pigs and sows against several pathogens. Vaccination programs to prevent Aujeszky disease virus and Glässer disease (*Haemophilus parasuis*) contemplate sow and gilt vaccination. The combination of both vaccines implemented simultaneously in the same inoculation point, saving two intramuscular injections, can potentially improve both the pig welfare status and the labour efficiency. Therefore, the objective of this trial is to find out if the attenuated gE deleted Aujeszky virus Bartha K61 (AUSKIPRA®-GN) can keep alive when it is reconstituted with an inactivated *Haemophilus parasuis* vaccine (HIPRASUIS®-GLÄSSER) as a previous step to try in vivo the actual effect of these combined vaccines.

**Material and Methods**

**Material**

50 dose freeze dried tablets of AUSKIPRA®-GN vaccine (attenuated gE deleted Aujeszky virus), 50 dose of inactivated *Haemophilus parasuis* vaccine HIPRASUIS®-GLÄSSER, 100 ml aqueous solvent vials and PK15 cell line.

**Methods**

Two tablets of AUSKIPRA®-GN were reconstituted with HIPRASUIS®-GLÄSSER and with aqueous solvent respectively. After 0, 2, 4 and 6 hours post reconstitution the virus was titred in PK15 cell line.

**Results**

**Table 1. Results of titres per dose of vaccine virus Bartha K61. Vaccine virus titres Bartha K61 per dose (2ml) (TCID50/dose). Reading by CPE (Cytopathic Effect).**

* BARTHA K61 vaccine virus Bartha K61 (AUSKIPRA®-GN) kept viable and with a dosage titre value equivalent or higher of $10^{5.5}$ TCID<sub>50</sub> (minimum necessary effective concentration as product manufacturer recommendation) at 6 hours after reconstitution with the inactivated *Haemophilus parasuis* vaccine HIPRASUIS®-GLÄSSER (100ml). The same results were obtained when mixed with the usual prescribed aqueous solvent (100ml).

**Conclusions**

HIPRASUIS®-GLÄSSER vaccine allows the viability of the gE deleted Bartha K61 vaccine virus (AUSKIPRA®-GN) even 6 hours after the reconstitution. Further studies in vivo are required to discard any vaccine incompatibility.
Pseudorabies virus partial gE protein production for immunochromatographic strip test

Suparlark Nuntawan Na Ayudhya1 Roongtham Kedkovid1 Kampon Kaeoket2 Roongroje Thanawongnuwech1
1. Chulalongkorn University, Bangkok, Thailand; 2. Mahidol University, Bangkok, Thailand

Introduction

Pseudorabies virus (PRV) is a cause of an important infectious disease in the pig industry known as Aujeszky’s disease. The disease is lethal in piglets; however, in older pigs, the disease is not lethal characterized by severe depression, anorexia, pyrexia, ataxia and pneumonia. In pregnant sows, the infection may result in abortion. PRV eradication program is usually based on the use of the marker vaccine deleted in the non-essential glycoprotein E (gE) gene. The vaccinated pigs can be differentiated from the natural infected pigs by detection of anti-gE antibody, commonly done by the competitive ELISA. However, current ELISA assays have some limitations such as multi-step and time-consuming procedures, requirement of an ELISA reader and other equipments and subsequent calculations to interpret the results. The immunochromatographic strip test is a new diagnostic technique which has several advantages over the commercial ELISA, including less time-consuming (immediate results) and no requirement for skilled technicians or expensive equipments. Thus, this assay has a potential to be used as a field test. The objective of this study was to produce the recombinant gE protein for the immunochromatographic strip test.

Materials and Methods

The pseudorabies virus DNA was extracted and used for PCR to produce a partial gE fragment (coded for the major epitope domain of PRV gE gene, nucleotide position 156-714). The purified PCR product was cloned into the pGEM®-T-easy vector (Promega, USA.) and then cut with EcoRI. The DNA fragment was inserted downstream to the TAC promoter of the expression vector pGEX 5x-3, resulted in gE pGEX 5x-3. The recombinant plasmid was transformed into the E. coli Rosetta (DE3) pLysS strain (Novagen, USA.). For expression, the E. coli carrying recombinant plasmid was 1:50 (v/v) diluted into 1 liter of LB medium (with 100 μg/ml ampicillin and 34 μg/ml chloramphenical) and incubated at 37 °C for 3 h. Then, the protein synthesis was induced by isopropy 1- β-D-thiogalactopyranoside (IPTG, 0.1 mM final conc.) and the bacteria were further incubated at 37 °C for 4 h. The bacteria were harvested and then disrupted by sonication. The size and the specificity of the recombinant protein were examined using SDS-PAGE and western immunoblotting, respectively.

Results

The expressed products were determined by SDS-PAGE revealing the extra protein band of approximately 38 kDa molecular weight (Figure 1). The ability of the expressed product to bind with anti-gE antibody was further confirmed by the western immunoblotting analysis Figure 1, lane 3) using the IDEXX ELISA gE positive pig serum as a primary antibody.

Figure 1. SDS-PAGE and western immunoblotting analysis of the recombinant protein.

Expression of gE pGEX 5x-3 in E. coli showed an extra band by the SDS-PAGE (lane 2, ~38 kDa, arrow) compared with non induced E. coli (lane 1). The ability to bind with anti-PRV antibody was showed by western immunoblotting analysis (lane 3). L = protein marker.

Discussion

The recombinant gE protein could be expressed in the E. coli system and this recombinant protein was able to stain with the IDEXX ELISA gE positive pig serum demonstrating its specificity. This recombinant protein will be used for further study such as the checker-board titration and testing for the sensitivity and specificity to ensure the efficacy of the developing immunochromatographic strip test.

Other viral diseases – Pseudorabies virus
Introduction

Aujeszky’s disease (AD or pseudo-rabies) is one of the most important swine diseases of the developing world. The disease has effects on both reproductive and fattening performance of the herds. Live, gene-deleter vaccine strains formulated with oil adjuvants, are considered the most efficient tools (by DIVA) for AD eradication programs in the European Union. AD eradication still remains a heavy task in Eastern-Europe and in Asia. Virus strain of Auphyl® Plus vaccine is a gE (gI) deletant, UL21 mutant and gC positive AD virus (ADV), which is a recombinant derivate of the Bartha’s strain (K/61).

Material and Methods: Minimum Protective Dose (MPD) trial was dedicated to confirm the choice of vaccine dose of Auphyl® Plus in ADV sero-negative 8 week (w) old pigs.

Study design: Four vaccine dose-groups and a control group were formed using 5 piglets in each. Pigs in Group 1 (G1) received one shot commercial dose (6.1log10 TCID50). Animals of G2, G3 and G4 received 1/10-1/1000 (5.1-3.1 log10 TCID50) doses. The challenge (ch) was performed 1 month after the intramuscular vaccination. The ch-virus, strain AyV-NIA-3 was applied intra nasally in 2 ml/nostril. The re-titrated ch-dose was 6.7log10/ml TCID50.

Clinical parameters: 1) symptoms of AD, 2) rectal temperature, 3) body weight, 4) ch-virus re-isolation. Post-challenge (pch) observations were conducted till the 7th day (1) {European Pharmacopoea}.

Results

1. Two control pigs died on the 5th or 7th pch days (pchD). Central neural symptoms were shown in all controls and none in vaccinates. Total cumulative respiratory symptom scores were between 8 and 10 in G1-G4 and 29 in G5.

2. Rectal temperature increase of the controls was higher than in any of the vaccinates, but the difference was not significant. See figure 1.

3. Daily body weight gain was almost equal (0.4-0.3 kg) between pchD0 and pchD7 in G1, G2 and G3. In G4 it was 0.1 kg. Controls showed -0.4 kg daily body weight loss. See table 1.

Among the vaccinates, the less protected pigs were those animals which received 1/1000 dose of the vaccine.

4. Ch-virus re-isolation results (log10TCID50/ml) on pchD4 showed significant differences between the treatment groups: average geometrical mean in G1= 1.9log10, G2=2.6log10, G3=3.2log10, G4= 4.0log10.

Discussion

Auphyl® Plus vaccine was protective against death and central neural symptoms even in 1/1000 dose (3.1 log10TCID50/ml). 1/100 is the lowest dose which is protective against the significant daily body weight loss in 8 w old pigs.

Apply DIVA system. Due to these features the vaccine is recommended to perform AD eradication programs.

Eradication of PRV in Chinese farm with Ingelvac® Aujeszky MLV

David Xu; Liande Zhu
Boehringer Ingelheim International Trading (Shanghai) Co. Ltd, Beijing, China

The objective of this project was to eradicate PRV (Pseudorabies Virus) from a 1500 sows farm by combining vaccination with Ingelvac® Aujeszky MLV and positive animals elimination according to serology diagnosis. It is a one-site production system farm located in Jiangshu province China, suffered a severe loss due to PRV outbreak in 2003. Production performance after the outbreak could not reach back to normal level.

Materials and Methods
Pre eradication: Before eradication, 100 samples were randomly collected in each section for serology (HerdChek® PRV gB and HerdChek™ Anti-PRV g(gE) from IDEXX) to analyze the wild PRV infection in the farm. The results showed an over 50% positive rate in all herd (Table1).

Vaccinated program: Breeders: After first massive vaccination, a booster vaccination was implemented in a month, then with regular vaccination every 4 months. Piglets: intranasal vaccination at 1 day old, with another intramuscular booster vaccination on 65 days old. Gilts: vaccinated twice before mating.

Management: Strict management according to Madec’s 20 was implemented in this farm at the mean time.

Measurement: New herds were isolated for 30 days before introducing to farm with a serology and PCR test against PRV (positive results would be tested twice for confirmation). In the first 3 years blood samples were randomly collected from all herds of the farm to monitor the eradication effect (N=1,282 samples). In the 2nd year after the eradication implementation, all PRV-gE serological positive boars were eliminated; in the 4th year all PRV positive breeding swine (PRV-gE antibody and PCR tested) were eliminated; in the 5th year, randomly sampling from the whole herd for serology test to evaluate the eradication efficacy.

Results
Before eradication, the average abortion rate of the sows was above 30%. Intractable diarrhea and severe respiratory problems were prevalent in the nursery and fattening herds. The clinical signs were reduced gradually since the eradication and after 1 year, the whole herds were stabilized.

Serology surveillance was strictly implemented at the same time as vaccination began. During this period, seropositive animals were eliminated. Positive rate of the serology test decreased consistently and steadily every year. In the 2nd year and 4th year after eradication, 5 boars and 13 pigs were eliminated. Serology results showed the success since the 5th year (Table1). The all negative results indicated the success of the eradication. Since then, the farm stopped PRV vaccination in sows and piglets.

Discussion
This farm is now considered to be PRV negative. Vaccination with proved to be effective for the eradication of PRV in the field in this case.

References
Introduction

Aujeszky’s disease (AD or pseudo-rabies, PRV) is one of the most important swine diseases of the developing world. The disease has effects on both reproductive and fattening performance of the herds. Several inactivated or attenuated live, oil adjuvanted vaccines were developed against AD. Effect of oil adjuvant raises questions of general and local safety of the vaccine. Following topics are presented: i) safety of overdose of a gE (gI) deletant, UL21 mutant and gC positive virus strain MNC+ of Auphyl-plus vaccine strain and its solvent after the reconstitution, ii) safety of the vaccine on pregnancy and progeny.

i) Overdose safety test was conducted on two batches of the vaccine to prove its general and local safety.

Material and Methods

Three groups of 8 week old pigs were formed with 7 animals in each. Parameters of general and local tolerance: 1) rectal temperature, 2) body weight gain, 3) appetite, 4) colour of reactive zone at the vaccination site, 5) diameter of the reactive zone.

Results

1) Febrile effect of the vaccine batches was moderate (2.1°C and 2.4°C) in two pigs for 1 day, only. Temperature decreased by 0.7-1.0°C for the next day. The individual temperature increase values in each treatment group were calculated in comparison with the individual base line values. This parameter ranged between 0.6°C and 2.4°C. For another parameter, the group-mean increase values, non-significant difference (p=0.1462) was found for the next day. The individual temperature increase values in each treatment group were calculated in comparison with the individual base line values. This parameter ranged between 0.6°C and 2.4°C. For another parameter, the group-mean increase values, non-significant difference (p=0.1462) was found by ANOVA between of the treatment groups as the treatment stress has also caused temperature increase in the control group ranging between 0.5-1.3°C. 2) No remarkable feed refusal was recoded. 4-5) None of pigs showed remarkable feed refusal during the observation period. 3) No remarkable feed refusal was recoded. 4-5) One gilt showed red spot 1 hour after the first vaccination. This local reaction disappeared by the next day. No other local reaction was recorded. 6) Same litter size was delivered by both treatment groups of the sows (43-43 piglets). 95.3% and 97.7% life born, 7%-7% weak, 4.7%-2.3% still-born progenies were recorded, born from vaccinated and control sows, respectively. 7) Vitality of piglets was assessed by scoring of any clinical signs. Piglets of the vaccinated sows performed score value 21 while controls 18 within the 1 week observation period. 8) Body weight of piglets at birth and on PpD21: this parameter didn’t show a significant difference between the groups (P=0.13 and P=0.46). Mothers were also included in the calculation as they can affect the body weight of the new born piglets.

Conclusion

No immediate post vaccination reactions and no adverse effect on the feeding behaviour were recorded. Very mild and temporary local post-vaccination reaction, rarely appeared, mild and transient fever, normal body weight gain tendency, and good reproductive performance of vaccinated gilt were seen. Assessment of the litters of both groups showed good tolerance of vaccination from the progenies of vaccinated sows was proven. No adverse effect on vitality, normal body weight performance results of piglets originating from the vaccinates were recorded.

Safety of overdose, safety on pregnancy and progeny of Auphyl® Plus (deleted mutant live pseudorabies vaccine) vaccine on swine

Other viral diseases – Pseudorabies virus
Study on seropositivity for Pseudorabies virus in swine farms in Pinerolo District: correlation with management and geographic factors

Giuseppe Martano; Giorgio Burzio

ASI TO3, Vigone, Italy

Introduction

The aim of this study is to evaluate PRV seropositivity in Pinerolo district and to underline the most probable risk factors about the seropositivity for Aujeszky’s disease.

We collected data on potential risk factors for infectious disease in 41 pig farms in Asl To3, Pinerolo district, Northwestern Italy. UTM geographic coordinates were recorded for each farm and entered in a geographic information system (GIS). Herds size ranged from 15 to 11.050 animal. Results of 6564 tests effected in the course of 613 herd’s visit have been compared in geographic areas of Asl To3, from 1997 to 2009. The number of PRV+ herds has clearly decreased from 1997, even though areas with higher risk exist.

Material and Methods

Aujeszky’s disease is a viral disease due to porcine herpesvirus-1 which belongs to the Alphaherpesvirinae subfamily, herpesviridae family.

In April 1997, a programme to eliminate Aujeszky’s disease virus infection from the swine herds in Italy was initiated. The programme was based on intensive compulsory vaccination, with gE-deleted vaccines of all pigs. From May 1997 to December 2009 we collected 6564 serum samples from pigs and they were tested for antibodies to pseudorabies virus (PRV) by the enzyme-linked immunosorobent assay (ELISA test). Every farms was tested at least one time for year. Also we collected data about management and bioscurety level in 41 farms. The data were developed by Epi-info 6. UTM geographic coordinates were recorded for each farm and entered in a geographic information system (GIS).

Results

Analysis of spatial arrangement shows that the farms PRV+ are closer together compared to all the farms. Proper application of the vaccination plan and observance of basic principles of biosecurity to ward off the risk of infection.

Movement of infected pigs is considered the most likely route of Aujeszky’s disease route in PRV-free herds.

Farrow to growing farms were the first to become PRV free. A high pig density in the area and presence of finishing pigs in farm was associated with a increase in odds of a herd being seropositive.

Discussion

The results show that if a correct vaccination and satisfactory biosecurity level applied, the risk of viral circulation decreased rapidly in few years.

Evaluation on seropositivity and antibody titre for Aujeszky’s Disease in fattening and farrow to feeder pig herds

Giuseppe Martano; Igor Ferenz

ASI TO3, Vigone, Italy

Introduction
In North-West Italy control and eradication for Aujeszky’s disease represents a target still to be reached. The aim of this work is to obtain an evaluation for seropositivity prevalence Aujeszky’s disease in farrow to feeder and fattening herds. The antibodies titres has been evaluated on pigs in fattening herds. The examination has been carried on 64 herds in the period 2007-2008.

Materials and Methods
In Italy, Aujeszky’s disease has been a subject of a mandatory eradication program since 1997. The vaccination program prescribes three inoculation/year for the sow and three inoculation for the fattening pigs (the first at 60-90 days, the second 30 days later and the third at 180 days). We used a gE- delete dead vaccine in the farrow to feeder herds and a gE- delete live vaccine in fattening herds. In our district, the pigs were slaughtered at 270 days old. From January 2007 to December 2008 a survey was conducted in Pinerolo District, North-west Italy. Sixty four randomly selected farms was tested to evaluate the provincial pseudorabies virus (PRV) herd seroprevalence. The sample included 34 farrow to feeder herds and 30 fattening herds. The farms were randomly selected. Blood sample collection for each farm was calculated so as to detect disease with an estimated prevalence of 20 % and at a confidence limit of 95 %. 2117 pigs were tested during 152 inspections and they were tested for antibodies to pseudorabies virus (PRV) by the Enzyme-Linked Immunosorbent Assay (ELISA test). Antibodies against PRV (glycoprotein gB and glycoprotein gI) were examined.

Results
Seropositivity prevalence in farrow to feeder herds was 6,1% and in fattening herds was 13,5%.

The seropositive pigs prevalence was 1,21 % in farrow to feeder herds and 5,34 % in fattening herds.

In seronegative fattening herds a significant percentage of pigs with low antibodies titres (glycoprotein gB ) has been observed.

Discussion
The target is to reduce seroprevalence in swine herds stopping the entry of the virus through latently infected pigs.

The current report shows that in seronegative fattening herds a significant percentage of pigs with low antibodies titres has been observed. This indicates that the herd immune status of the farms was insufficient to prevent a field virus infection. Probably the vaccination in some fattening herds is carried out not correctly. Fattening herds could became an important reservoir for pseudorabies virus.

It is necessary to use a correct vaccination program with management improvements and rigorous biosecurity measures.

Introduction
Aujeszky’s disease (AD or pseudo-rabies) is one of the most important swine diseases of the developing world. The disease has effects on both reproductive and fattening performance of the herds. Live, gene-deleted vaccine strains formulated with oil adjuvants, are considered the most efficient tools (by DIVA) for AD eradication programs in the European Union. AD eradication still remains a heavy task in Eastern-Europe and in Asia. Virus strain of Auphyl® Plus vaccine is a gE-deleted, UL21 mutant and gC positive AD virus (ADV), which is a molecularly modified derivate of the Bartha’s strain (K/61).

Materials and Methods
Duration of Immunity in Progeny: DOI by maternally derived antibodies (MDA) in the progenies of vaccinated sows was tested by challenging 4- and 6-w-old piglets.

Study design: 4 sows were vaccinated 3 times at 2, 3 months of age and 3 ws before farrowing. Their progenies (16 piglets) had no vaccination but were sero-positive due to the MAD transfer. Each of 8 piglets were challenged at 4 (G2) or 6 (G1) ws of age. 8 piglets from the progenies (G3) of non-vaccinated sows were involved as ch-controls at 6 ws of age.

Challenge circumstances and clinical parameters were the same as detailed in the MPD trial.

Results
1. All control piglets (G3) died within 7 pchDs. All piglets of G2 (4-ws-old) were protected but 2 out of 8 piglets from the G1 (6-ws-old) died.
2. The ANOVA didn’t show any significant difference between rectal temperatures of the groups (p>0.05). Note: the rectal temperature decrease in Group 2 is a virtual one as pre-moribund or moribund animals showed lower rectal temperature a day or two days after their fever peak. All pigs from this group died one or two days after that their rectal temperatures declined.

Discussion
Auphyl® Plus vaccine was efficient to protect swine against death, nervous symptoms and body weight loss caused by Aujeszky’s disease. The vaccine used by the prescribed application regime, significantly decreased the virus shedding.

Virus strain of Auphyl® Plus vaccine is a gE-deleted, UL21 mutant and gC positive AD virus (ADV), which is a molecularly modified derived of the Bartha's strain (K/61). Duration of Immunity (DOI) in Fatteners test was conducted to show the level of protection in 6 month old pigs.

Material and Methods: Study design: 8 pigs received primo-vaccination (G1) at 2 month-of-age and it was boosted one month later. 4 sero-negative, non- vaccinated controls were involved (G2) in the study, with same age. Challenge was performed at 6 months-of-age, 3 months after the last vaccination.

Challenge circumstances and clinical parameters were the same as detailed in the MPD trial.

Results
1. No death occurred in control group within 7-day observation period. Central nervous symptoms were observed in each of the controls but not in any of the vaccines. Total cumulative respiratory symptom score was 15± in G1, 26± in G2.
2. Rectal temperatures of controls (G2) were significantly higher than in the vaccinates from pchD3 till pchD7 (p-value = 0.01).

3. Post-ch DBWG in vaccinated group was +0.34 kg versus -1.14 kg in controls: Difference 1.48 Kg fulfilling the requirement of the (1) European Pharmacopoeia.

Discussion
The 4 month duration of immunity of vaccine Auphyl® Plus was proven. It was protective against death and central nervous symptoms of AD. The vaccine diminished the fever response in challenged animals. The vaccine was highly protective against the body weight loss and significantly decreased the ch-virus shedding.

Pathogenesis and transmission of feral swine pseudorabies virus isolates

Eraldo L. Zanella1,2 Kelly M. Lager1 Laura C. Miller1 Sabrina L. Swenson1 Troy T. Bigelow4 Marcus E. Kehrli, Jr1

1. National Animal Disease Center-USDA-ARS, Ames, IA, USA; 2. College of Agronomy and Veterinary Medicine – University of Passo Fundo, Passo Fundo, RS, Brazil; 3. National Veterinary Services Laboratories, USDA, Veterinary Services, Ames, IA, USA; 4. National Center for Animal Health Programs, USDA, Veterinary Services, Des Moines, IA, USA

Introduction

Aujesky’s Disease or pseudorabies, is one of the oldest recognized swine diseases. It is caused by pseudorabies virus (PRV), an alpha-herpesvirus that can induce respiratory disease, reproductive failure, and affect the central nervous system. PRV vaccines, in conjunction with serologic tests, have been used to eradicate the virus from swine herds and even from entire countries. One weakness in PRV control and eradication programs is the indigenous PRV infection of feral swine. This wild-life reservoir is responsible for frequent infection of domestic swine.1 A better understanding of this source of infection may lead to improved PRV control programs. This report summarizes studies investigating the pathogenicity and transmissibility of feral swine PRV isolates from the USA.

Materials and Methods

Seventy-three four-week-old pigs were randomly allocated to one of nine treatment groups, each housed in a separate isolation room. Pigs in each group received either a low dose (LD - about 10^3CCID50) or high dose (HD - about 10^6CCID50) intranasal challenge of virus: Group 1 (n=7) LD feral swine isolate FS268; Group 2 (n=7) HD FS268; Group 3 (n=7) LD feral swine isolate C3R Ossabaw Is; Group 4 (n=7) HD C3R Ossabaw Is; Group 5 (n=7) LD domestic swine isolate ISUVDL4892; Group 6 (n=7) HD ISUVDL4892; Group 7 (n=10) LD panther isolate of a feral swine virus FP117-05; Group 8 (n=10) HD FP117-05; Group 9 (n=11) controls that received three ml of cell culture media. Nasal swabs (NS) were collected on days 0, 2, 4, 7, 9, 11, 14, 21, and at necropsy 28 days-post-inoculation (dpi) at which time blood, lung lavage and tissues were collected for virus isolation and detection of viral DNA by real-time PCR.2

On 2 dpi, ten direct contact pigs (DC) were comingled with the pigs inoculated with HD C3R Ossabaw Is isolate, and five DC pigs were comingled with the pigs inoculated with HD FP117-05. After five days of contact the inoculated pigs were moved to different rooms and each group of DC pigs was maintained for about 16 weeks.

Results

Clinical signs: Mean body temperature spiked 2 dpi in all PRV inoculated groups and returned to normal by 5-7 dpi. For each virus pair the HD pigs were more affected than LD pigs. By 1 dpi some pigs were lethargic and at 2 dpi respiratory distress (sneezing, dyspnea, dysphonia (altered squeal (laryngeal edema)), congested nasal passages, and dog sitting) was observed. Transient anorexia was detected in most pigs. Central nervous system disease was observed in some pigs (ataxia, opisthotonos, paddling, and seizure). Most pigs from the feral swine isolate groups recovered; however, six out of seven group 6 pigs were euthanized or died in the first 7 dpi. In group 4, two pigs and in group 1, one pig were euthanized in the first 8 dpi. Clinical signs in DC pigs exposed to C3R Ossabaw Is isolate were mild. In contrast, all DC FP117-05 exposed pigs had moderate to severe respiratory disease, but each pig did recover.

Virology: Virus was isolated from NS from 2-14 dpi with most positives between 2-9 dpi, and more frequently from the HD than LD challenge groups. Virus was isolated infrequently from 28 dpi tissues.

Serology: Based on a commercially available ELISA, all PRV inoculated pigs seroconverted by 14 dpi. Likewise, all DC pigs seroconverted by 14 days post contact and were seropositive throughout the duration of the study, about four months.

Discussion

Collectively, results from these studies indicate natural infection of domestic swine with feral swine PRV isolates should be detected either through detection of virus during the acute phase of the infection, or through detection of antibody in the convalescent phase of the infection. This conclusion supports many current control programs that screen sera for PRV-specific antibody, and may test tissues for virus by real-time PCR.

Isolation and in vivo and in vitro characterization of the first Chinese porcine teschovirus strain (PTV-8)

Shangjin Cui
Harbin Veterinary Research Institute of CAAS, Harbin, China

Investigations were made to identify the causal agent of a case of acute diarrhea, respiratory distress and death in a swine farm in the Jilin Province, northern China. Only porcine teschovirus (PTV) was isolated from samples of organs and identified as PTV-8. Presence of virus which was designated Jilin/2003, was confirmed by the production of a specific cytopathic effect on susceptible cells and by the results from IPMA assay, polymerase chain reaction, and electron microscopy. Other main pathogenic agents causing diarrhea, respiratory distress and death (e.g., porcine rotavirus, transmissible gastroenteritis virus of swine, Porcine epidemic diarrhea virus, classical swine fever virus, pseudorabies virus, porcine circovirus, porcine reproductive and respiratory syndrome virus, Japanese encephalitis virus, mycoplasma, leptospira, Streptococcus, Listeria, and Brucella species) were eliminated as possible causal agents because they were not consistently associated with the disease of the pigs. The PTV-8 strain was adapted to growth in swine primary kidney (PK-15) cells and in a swine testicular cell line (ST cells). When inoculated into healthy pigs, PTV-8 Jilin/2003 caused the same symptoms as observed in the affected herd. We conclude that PTV-8 Jilin/2003 was the causal agent of this disease. To the best of our knowledge, few reports so far indicate that PTV strains infect swine in China.
Teschen Talfan Disease - contagious swine paralysis - a case report

Katja Brase1 Eva Ursula Peitzmeier2
1. Landwirtschaftskammer Niedersachsen, Oldenburg, Germany; 2. Praxis, Meente 24, Hille, Germany

Introduction
The enterovirus encephalomyelitis of pigs (porcine enteroviral Polioencephalomyelitis) rarely occurs in German pig population. The Tescher Disease, caused by porcine Teschovirus (PTV) Type 1 has not been reported in Germany for over 20 years. It is a human analogue of the spinal polio disease, which mainly is caused by Porcine Teschovirus (PTV) strains. Porcine Teschovirus enters the body by oral route, reproduces in the gastro-intestinal organs and will be excreted by feces for up to 8 weeks. The majority of infected animals will not show any symptoms but will excrete the virus with the feces for weeks. If neurovirulent strains of the virus reproduce and spread in the brain, general illness with paralysis of different degree can be the result. The animal’s awareness of the environment will not be influenced, sensitivity of the skin stays intact. An improvement of symptoms after a few days can be considered the rule. Usually an immunity to the virus within the contained group of animals will be established within 6 weeks. If tonic-clonic muscle spasms, nystagmus and other paralytic symptoms appear during the course of the disease, morbidity and mortality will be high due to dyspnoea and cardial insufficiency. Hardly any information about therapy of this disease can be found in literature. Diagnosis via PCR and serological determination of the type of virus will decide about the obligation to report, as is the case with PTV type 1. Only the virus extraction from the CNS can be considered proof, the antigen itself has to be traced. The large number of different Teschovirus makes determination of types difficult. For clinical considerations, proof of the species Teschovirus can be considered sufficient. In differential diagnosis, ESP and AD will have to be considered.

Material and Methods
The described farm has 160 sows in a closed system. Jung sows come from different farms in Denmark with a yearly replacement of 35%. Piglets are weaned after 28 days of nursing. First clinical signs can be observed 7 to 10 days later in flatdeck. About 10% of a group show high degree paralysis of the limbs. Animals are aware of their environment, food and water intake appear to be normal. They show a swaying gait with dropping down in front while the hind quarters remain upright. Sensitivity of body surface stays intact. In almost all affected animals edema of the eye lids is prominent. In some bad cases, animals are lying on the side with walking motion off he legs, show opisthotonus, nystagmus and tonic-clonic spasms. About 4% of affected animals die within 12 hours after onset of symptoms. The others recover within a few days. None of these animals show long term signs of paralysis. Treatment with cortisone und vitamins B did not change any of the clinical symptoms. In this farm is, however, no reliable inventory of immunity. There remain clinical symptoms in the piglets in flatdecks.

Results
By autopsy and following microbiological examination, porcine Enterovirus type 8, 9 and 10 could be proven in organs and large intestine as well as PTV virus in the large intestine. Infection by ESP and AD could be excluded in blood samples. Cerebrum, cerebellum and brain stem showed low grade edema. The Bioscreen Laboratory in Münster examined organ matter for PTV virus (before: porcine enterovirus type 1 to 7 and 11) and porcine enterovirus type 8, 9 and 10. The examination was performed via multiplex PCR. A type determination of the different PTV virus types is not possible in German laboratories. Thus it could not be proven if the isolated virus is PTV type 1.

Discussion
By definition of the government from 12.08.2005 the Tescher disease has to be proven by virus breeding and Type 1-identification. Additionally, histological proof of non-purulent polioencephalomyelitis is needed. A durable immunity against the virus probably could not be established because too many strains were present in the contained group. A possible reason might be the acquisition of young sows from different sources. There are no cross-immunities, so there will always be susceptible animals supporting virus reproduction. As enterovirus is spread by the feces of sick animals, controlled access to the feces of older sows would be desirable to reach quick contamination of every animal. By this measure, maternal protection of piglets should be optimized, so a durable immunity can be established. It is important to keep access to the feces on a moderate level, since enterovirus may not only cause neurological symptoms but also abortions.

Group-specific vaccines cannot be produced at this point of time.

Introduction
Porcine teschovirus (PTV), previously named porcine enterovirus 1, causes disease in pigs (1). Based on serology more than 70% of the swine population in Taiwan were positive. The percentage of detected lesion samples in Taiwan from which PTV was isolated was higher than that of other swine viral pathogens (PRRSV etc). The aim of this study was to assess the number of PTV serotypes, and their distribution, in Taiwan.

Material and Methods
A total of 525 swine fecal samples were collected from 5 pig farms of each county and city in Taiwan. Each fecal sample was mixed in MEM solution and a 10% mixture filtered through a filter membrane with a pore size of 0.22um. The filtrate was mixed with growth media (MEM) and incubated with PK 15 cells at 37oC in 3.5% CO2, for 3 days. Culture fluid was analysed for the presence of PTV by RT-PCR.

The VP1 gene fragment of PTV was amplified in a reverse transcription-polymerase chain reaction (RT-PCR) using extracted PTV viral RNA and PTV-specific primers. The PTV VP1 amplimers were then purified by gel filtration and sequenced. Using DNAstar software, phylogenetic analysis was carried out using the PTV VP1 sequences and sequence data obtained from web sources (4).

Results
A total of 58 samples positive for PTV, out of a total of 525, from 21 counties and cities in Taiwan, were obtained by virus isolation and RT-PCR. The phylogenetic analysis of the sequences of 58 PTV isolates in Taiwan and 20 reference PTV strains covering 11 serotypes of PTV showed that all the isolated PTV strains had sequence homologies similar to 10 different serotypes of PTV (the exception of serotype 5). The 10 serotypes were distributed randomly around Taiwan (figure 1).

Discussion
In this study, 58 fecal samples out of 525 were positive for PTV. Infected pigs did not show any clinical symptoms, consistant with the findings that PTVs specifically infect pigs and are shed in pig feces (5), and that PTV infections are most frequently asymptomatic (3,6). Previous workers have shown that specific PTV sequences equate to the serotypes 1-11 (2). The results of the phylogenetic tree analysis indicated that the 58 isolated PTVs, were aligned among 10 different serotypes (PTV1-PTV4 and PTV6-PTV11) and these serotypes were distributed randomly around Taiwan. Many of the larger pig farms located in the prefectures within middle and southern Taiwan (TCP, NTP etc) had animals shedding more than 1 isolate serotype. However, there was only one serotype in some counties. We concluded that at least 10 different serotypes of PTV existed in Taiwan now. The distribution of these serotypes was not restricted geographically.

Impact of Torque teno virus (TTV) on porcine dendritic cell function and activity
Laura Martinez-Guinó1 Kenneth C. McCullough2 Artur Summerfield2 Joaquim Segales1 Tuija Kekarainen1

Introduction
Torque teno virus (TTV) is a small, non-enveloped single stranded circular DNA virus classified in the floating genus Anellovirus, which infects several vertebrates including human and swine. Two genetically distinct genogroups have been described in swine, genogroup 1 (TTV1) and genogroup 2 (TTV2). TTV is ubiquitous and considered non-pathogenic but it has been linked to several diseases or pathological conditions in humans and, lately, in swine (1). To date, information related with the immunological events behind TTV infection is not available. Several viruses are known to modulate dendritic cell (DC) function. One example is porcine circovirus type 2 (PCV2), related genetically and structurally to TTV. It has been reported that PCV2 DNA is a potent modulator of DC and mediated inhibition of IFN-α production by plasmacytoid DC (pDC) (2). In the present work, the role of viral DNA from two genetically distinct swine TTV genogroups was analyzed for its potential interaction and modulation of DCs activity.

Material and Methods
PCV2 and TTV genomes were isolated by digestion from plasmids containing double-stranded DNA forms of the complete viral genomes. Peripheral blood mononuclear cells (PBMCs) were isolated by Ficoll-Paque differential centrifugation. pDCs were then enriched by magnetic antibody cell sorting (MACS). Enriched pDCs were incubated with decreasing amounts of PCV2, TTV1 or TTV2 DNA prior to stimulation with CpG-ODN. Supernatants from activated cultures were tested for IFN-α production by ELISA.

Results
Preliminary results showed that TTV1 and TTV2 viral DNA mediated inhibition of IFN-α production by CpG-ODN induced pDCs. The effect was dose dependent (Figure 1). TTV DNA was compared with DNA from PCV2, and it was observed that the inhibitory capacity of TTV1 was similar than the one observed for PCV2 and different from that of TTV2 (Figure 2).

Discussion
TTV viral DNA was found to interfere in the ability of swine pDC to produce IFN-α in response to known CpG-ODN stimuli (2). This study also reconfirms the effect or PCV2 DNA (2). The immunomodulatory effect observed for these viruses could potentially interfere in the development of efficient host innate and adaptative immune responses.

Introduction

Torque teno virus (TTV) is a non-enveloped, circular, single stranded DNA virus that may infect human, non-primate and domestic species including swine. Two specific TTV genogroups (TTV1 and TTV2) have been described in pigs. Even though the infection in pigs is considered non-pathogenic, TTVs have been somewhat linked with porcine circovirus diseases like postweaning multisystemic wasting syndrome (PMWS) and a porcine dermatitis and nephropathy syndrome (PDNS)-like syndrome (1,2,3).

Two years ago, at the IPVS 2008 in Durban (South Africa), an in situ hybridization (ISH) method was described for the detection of TTV2 in formalin-fixed, paraffin embedded tissues (4). The study was performed on tissues of healthy, PMWS, and PDNS affected animals. Major conclusion of such study was: “TTV2 amount, location and cell type labelled resembled substantially those of PCV2 in PMWS affected animals. These findings raise the question on the potential role of TTV2, in co-infection with PCV2, in the pathogenesis of PMWS”. During the development of the technique, a number of positive and negative controls were used to validate the technique. Once presented as an oral communication in the IPVS 2008, further validation studies were carried out. However, by the authors’ surprise, different validation results were obtained from the initial ones and investigating in depth it was concluded that the oligonucleotide probe to detect TTV2 was also detecting PCV2. The parallelism between TTV2 and PCV2 amount was explained by the probe cross-reactivity, and presented results were discarded. Therefore, in view of these previous regrettable results, the authors further insight in the development of a new, specific ISH and fluorescent ISH (FISH) method to detect TTV DNA in TTV-DNA transfected cells and formalin-fixed, paraffin embedded pig tissues.

Materials and Methods

Cells and tissues. PK-15 cells were transfected with 0.5 μg/well (six-well plate) of cloned TTV2 genome and fixed on coverslips. Formalin-fixed, paraffin-embedded tissues (lymph node, lung, kidney and liver) from healthy and PMWS pigs were tested with a TTV semi-quantitative PCR (data not shown) and tissues with the highest amounts of virus were selected for ISH and FISH.

ISH and FISH. To prepare TTV2 specific probe for hybridization, total TTV2 viral DNA was labelled with digoxigenin (DIG), previous digestion with XhoII and SmaI. Negative controls and specificity test of the TTV probe were: non transfected, pGFP (plasmid-green fluorescent protein) transfected, and PCV2 transfected PK-15 cells. The detection was made by an anti-DIG antibody and developed with NBT/BCIP as chromogen. The FISH method was performed using Cy3 labelled anti-DIG-antibody. In tissues, to enhance the signal, TSA (tyramine signal amplification) system was used. ISH and FISH methods were based on previously described protocols (5,6) respectively.

Results

Both techniques, ISH and FISH, displayed positive cytoplasmic cell labelling using TTV2 probe on TTV2 transfected cells, while no labelling was observed in any of the negative controls including PCV2 transfected cells. Once a specific positive signal was obtained in the transfected cells, ISH and FISH methodologies were applied on formalin-fixed, paraffin-embedded tissues carrying TTV2 (detected by PCR). No specific labelling was found in any of the tested tissues.

Discussion

ISH and FISH were successfully developed to detect TTV2 nucleic acid in PK-15 transfected cells. In contrast, no specific ISH and FISH positive signal was found in formalin-fixed, paraffin embedded tissues from TTV2 infected pigs. These tissues were positive by PCR; considering the lower sensitivity of ISH techniques versus PCR, it is likely that the TTV2 DNA amounts in the tissues were below detection limit of ISH. However, we can still not rule out if formalin fixation and paraffin embedding alters the detection by ISH or FISH. Nowadays, experiments are being done to determine the detection limits of the technique.

Genetic variability and phylogeny of swine Torque teno virus 1 (TTV1) and 2 (TTV2) based on complete genomes

Martí Cortey1 Lisa Macera1,2 Joaquim Segales1 Tuija Kekarainen1
1. Centre de Recerca en Sanitat Animal (CreSA), Bellaterra, Spain; 2. Retrovirus Centre and Virology Section, Department of Experimental Pathology, University of Pisa, Pisa, Italy

Introduction
Torque teno viruses (TTVs) are circular, single-stranded DNA viruses classified in the floating genus Anellovirus. They are currently considered non-pathogenic although they have been lately linked to several diseases in human and swine (1-3). The aim of this study was to determine the level of genetic variability in full-length genomes of swine TTVs, study the types and effects of mutations and to determine phylogenetic relationships with all known swine TTV genomes. For these reason 13 novel full-length genomes of swine TTVs were obtained from Europe and analysed together with 10 published genomes.

Material and Methods
Sera samples used in the study were collected during 2005-2007 and stored in the CreSA sera collection. Full-length genomes of TTV1 and TTV2 were amplified with a proofreading DNA polymerase and sequenced by DNA walking.

Results and Discussion
TTV genomes presented an untranslated region and three potential ORFs. Conserved regions like Arginin rich N-terminus and rolling-circle replication domains were found in all swine TTV genomes. TTV1 genomes showed a high amount of variable positions compared with TTV2 (46.3% vs 23.9%), that were differently distributed along the genome: lower in the UTR (13.2% for TTV1 and 11.4% for TTV2), and higher in the translated region (59.8% for TTV1 and 29.7% for TTV2). Low variability in the UTR region is most likely due to its importance in replication and transcription (4). The pattern of substitutions among ORFs was also different, more skewed for ORF1 and more evenly distributed for ORF2 and ORF3. TTV ORF1 seems to be affected by stronger levels of purifying selection compared with ORF2 and ORF3, most likely caused by the function of the protein products encoded by every ORF (5). TTV1 and TTV2 should be considered as species confirming the classification proposed (6). The phylogenetic reconstructions indicate that TTV1 is divided into three types. One of them (1c) is being reported here for the first time (Fig.1). Also, a certain kind of geographic structure among phylogenetic types may exist. Quite the opposite, the proposed subtypes for TTV2 clustered mixed and its definition was unclear.

Figure 1. Neighbor-Joining tree based on the percentage identity among 23 swine TTV genomes.

Rolling circle amplification to detect anelloviruses in pig serum samples
Lisa Macera1 Martí Cortey1 Fabrizio Maggi2 Joaquim Segales1 Tuija Kekarainen1
1. Centre de Recerca en Sanitat Anima (CReSA), Bellaterra, Spain; 2. Retrovirus Centre and Virology Section, Department of Experimental Pathology, University of Pisa, I-56127, Pisa, Italy

Introduction
Anelloviruses are vertebrate infecting single-stranded circular DNA viruses which have been recently linked to swine diseases (1). In swine two genetically distinct Anellovirus genogroups are described, namely Torque teno virus 1 (TTV1) and 2 (TTV2) (2). It is probable that novel swine genogroups exist as shown in the human TTV counterpart. Rolling-circle amplification (RCA) is a novel technique used to amplify circular DNA templates using random hexamers, yielding 109 or more copies of a circular sequence in about an hour (3). The potential of this technique has been shown to be increased when combining it with Sequence-Independent Single Primer Amplification (SISPA) (4). The aim of the present study was to apply the combined RCA-SISPA approach and optimize a novel RCA method using Anellovirus-specific primers (Anello-RCA) to discover new members of the genus Anellovirus in pigs. Also, efficiencies of the two techniques were compared.

Materials and Methods
A TTV2 positive swine serum sample (assayed by nested PCR) was selected to test the RCA-SISPA technique. Standard RCA involves the prolonged elongation of random primers bound to a circular DNA template by Phi29 DNA polymerase. The RCA products, that are tandem repeat copies of the viral complete genome, were used for the SISPA method, based on the use of endonuclease restriction of target sequences. These products were separated on agarose gel and different length products were ligated to specific linkers followed by PCR amplification and sequencing.

Short Anellovirus-specific primers were designed corresponding to a highly conserved region among all full-length Anellovirus genomes from several species available in the GenBank. Anello-RCA was optimized using short Anello-specific primers (6 nt) using swine sera known to contain TTVs. Furthermore, Anello-RCA was applied using swine sera and plasma samples negative for TTVs. The resulting products from Anello-RCA were used as template in inverse-PCR with Anello-specific PCR primers (12 and 15 nt in length). PCR products purified from agarose gel were sequenced.

Results
Typically, the combined RCA-SISPA method resulted in several fragments of various lengths (Figure 1A). After sequencing 66 fragments, 3 of them were positive for TTV2 demonstrating that the RCA-SISPA is applicable to detect TTV in swine sera. Anello-RCA approach resulted in fragments between 2 and 3 kb of length (Figure 1B); sequencing of 12 fragments yielded 5 as positive for TTV1 and 1 for TTV2.

Discussion
Both described methods are applicable for Anellovirus detection in pig samples. The RCA-SISPA is more tedious than Anello-RCA due to the high number of different size fragments to be analysed. Anello-RCA technique resulted in larger and fewer fragments for analysis and is, therefore, more straightforward and less laborious. However, Anello-RCA detects only Anelloviruses while RCA-SISPA could detect any circular DNA virus present in a sample. Since primers used in Anello-RCA are located in the highly conserved region, this technique could be applicable for Anellovirus detection in other species as well.

Torque teno virus tissue distribution by a semi-quantitative PCR method

Mario Aramouni; Joaquim Segalés; Martí Cortey; Tuija Kekarainen
CReSA/UAB, Bellaterra (Barcelona), Spain

Introduction

Torque teno viruses (TTVs) are small, non-enveloped viruses with a circular single-stranded DNA genome, belonging to the family Anelloviridae, genus lotatorquevirus. TTVs are widely distributed and may infect human, non-primate and domestic species including pigs. In swine, two genetically distinct genogroups have been identified so far, TTV1 and TTV2 (1). The aim of the present study was to study the distribution and age-relation of swine TTV1 and TTV2 in tissues. Viral DNA obtained from tissue extractions were tested by a semi-quantitative PCR for the presence of both TTVs.

Materials and Methods

Thirty healthy animals corresponding to six different age-groups (second and last third of gestation, 5 days and 5, 15 and 24 weeks of age), 5 pigs per group, were sampled for 9 different tissues: brain, lung, mediastinal lymph nodes, heart, liver, spleen, kidney and bone marrow. Presence of TTV1 and TTV2 was tested with a semi-quantitative PCR, amplifying the virus in three different dilutions of extracted DNA (90 ng, 9 ng and 0.9 ng) at 43 cycles (optimal cycling for detecting the lowest standard concentration of 101 molecules). Negative samples at 43 cycles were tested at 50 cycles to enhance the detection sensitivity and ensure the negativity of the sample. The degree of TTV1 or TTV2 positivity was graded into highly positive (4), medium (3), low (2), very low (1), and negative (0). Contingency tables (Chi-square) were used to compare prevalence and grades of TTV1 and TTV2 in different samples at the different studied ages and in the different tissues. Statistical significance level was set at p<0.05.

Results

No significant differences were found between genogroup prevalence in the same tissue at any age, while the prevalence increased with the age reaching 100% in all the organs by 5 weeks of age onwards. The first three age groups had negative to low levels of virus, and the last three groups, medium to high levels. Negative tissues were only found in foetuses and 5 day-old pigs. The only TTV1 PCR negative organs in some pigs were kidney, mediastinal lymph node, brain and heart. For TTV2, those negative tissues were brain and heart, mediastinal lymph node in some pigs.

Discussion

Both TTV genogroups followed similar infection dynamics in all the tested tissues, increasing progressively in prevalence and virus load over the time. The highest prevalence (100%) was reached at 5 weeks of age, and the highest loads of virus in the different tissues were seen in the oldest animals (15 to 24 weeks of age). Those results are in agreement with an earlier study reporting increasing prevalence in sera in a longitudinal analysis (4). No animals were found to be negative to TTV, even foetuses, supporting the role of vertical transmission of TTV (2,3). In conclusion, the present study indicates that swine TTV1 and TTV2 can be found in tissues like brain, lung, mediastinal lymph nodes, heart, liver, spleen, kidney, mesenteric lymph nodes and bone marrow. Both swine TTV genogroups were present in high levels in most if not all adult animals while viral negative tissues were only found in 5 week-old pigs or foetuses.

Figure 1. Mean grade of TTV1 (black bars) and TTV2 (grey bars) in different age groups for some tissues. (IIg: 2nd third of gestation, IIIg: last third of gestation, 5D: 5 days, 5W: 5 weeks, 15W: 15 weeks, 24W: 24 weeks). See definition of grading in Materials and Methods.

References
**Introduction**

Torque Teno virus (TTV) is a non-enveloped, circular, single-stranded virus that has been detected in humans and animals, including pigs (1). Two swine TTV genogroups (TTV1 and TTV2) have been described (2) and the ubiquitous nature of this infection suggest that TTV have been infecting pigs for a long period of time. Moreover, recent studies suggest that swTTV could play an aetiological role in pig diseases, in particular PMWS (3). The main objective of this retrospective study is to assess whether there was a statistically significant association between swTTV and PCV2 infection.

**Materials and Methods**

Ninety five pig sera sampled between 1990 and 2009 were used in this study (no more information about these sera was available). A maximum of 10 pig sera per year were analysed. As much as possible, were analysed two year periods at the time (Table 1). Samples were stored at -80°C until analysed. Sera were tested to detect swTTV1 and swTTV2 using specific PCR methods. Moreover, some PCR products from both swTTV genogroups were sequenced and phylogenetically analysed.

**Results**

Both swTTV genogroups were found in pig sera from the very first year examined (Table 1).

Taking into account the whole period under study, 73 out of 95 animals (76,84%) were infected with one or the other genogroup of swTTV, while 27 out of 95 pigs (28,42%) were co-infected with both genogroups. swTTV genogroup 1 (54 out of 95, 56,84%) was more prevalent than genogroup 2 (46 out of 95, 48,42%). Moreover, 41 out of 95 animals (43,16%) were also infected with PCV2 (Table 1). Moreover, 20 out of 95 animals (21,05%) were co-infected with swTTV1 and PCV2, while 27 out of 95 animals (28,42%) were co-infected with swTTV2 and PCV2 (Table 2).

Phylogenetic analyses indicated no relationship between the date of virus detection and the cluster in the distance trees.

**Discussion**

This study indicates that TTV genogroups have been circulating at least since 1990 in the Italian pig population. Moreover, these results indicate a statistically significant association between swTTV2 and PCV2 infection, but not between swTTV1 and PCV2 (Fisher’s exact test with p<0.05).

Phylogenetic analyses show no significant changes in the proportion of viral genogroups over time.

Detection of TTV-2 by PCR in feces samples from different pig herds in São Paulo State, Brazil

Cíntia M. Favero1, Alessandra M. M. G. de Castro1, Cíntia M. Baldin2, Tais Nishikata1, Simone Miyashiro1, Paulo E. Brandão1, Leonardo J. Richtzenhain1

1. Faculdade de Medicina Veterinária e zootecnia-Universidades de São Paulo, São Paulo, Brazil; 2. Faculdade de Jaguariúna, Jaguariúna, SP, Brazil

Introduction

Torque teno virus is a small non-enveloped virus with circular single strand DNA genome classified within the Anellovirus. Two distinct TTV genogroup were identified circulating among domestic pig population, TTV-1 and TTV21. TTV have been detected by PCR in lungs, lymph nodes, tonsil, ileum, serum, marrow bone, liver and kidney2,3,4. Swine TTV has been detected in serum, plasma, nasal swab, rectal swab and feces, indicating fecal-oral transmission as the most significant way of spreading5,6. The aim of this work was to detect TTV-2 DNA in fecal samples from pig herds in São Paulo state, Brazil.

Materials and Methods

Ninety seven fecal samples were collected from two different phases (nursery and growing) between 2009 and 2010 in three different swine herds from São Paulo state, Brazil. The samples were frozen, thawed three times and DNA extraction was carried out by phenol:chloroform:proteinase K protocol. TTV2 amplification was performed according to previous procedure described 7.

Results

Twenty six from a total of 97 fecal samples from three different pig herds were positive for TTV-2 (27 %). The number of positive samples within each pig herd (1, 2 and 3) was 11/42 (26 %), 13/40 (33 %) and 2/13 (13 %), respectively (Fig. 1). Considering breeding phase (nursery and growing) we found an interesting data, since the number of positive animals were 10/68 (15 %) and 16/29 (55 %) for nursery and growing, respectively (Fig. 2).

Discussion

The presence of TTV-2 in three commercial pig herds from São Paulo state, Brazil was investigated and the proportions of infected animals shedding virus were 27 %. A study carried out on Canada with commercial swine herd showed a higher proportion of infected animals (60.3 %). According to the results obtained in recent researches, the proportion may vary due the phase of breeding. A higher percentage of positive animals for TTV-2 was seen in growing (55 %) than in nursery (15 %). This finding are agreement with the results published6 where <20 % of the rectal swabs were positive for TTV in pigs ranging from 1 to 15 weeks. In conclusion our results contribute for the understanding of the dynamic excretion of the TTV. This is the first description of excretion of TTV2 on feces in different commercial swine herds from São Paulo state, Brazil.

Prevalence and age distribution of porcine TT viruses

Vladimir Celer; Veronika Jarosova
University of Veterinary and Pharmaceutical Sciences, Brno, Czech Republic

Introduction
Torque teno sus virus 1 (TTSV1) and Torque teno virus sus 2 (TTSV2) belong to the genus Iotatorquevirus within the family Anelloviridae (Carstens, 2010).
The role of swine TT viruses in the pathogenesis of swine diseases is currently being investigated. Although it seems that TTSV infection is not directly responsible for any disease, the possibility that they play a role in different co-infections still remains. In a recently published study a significantly higher prevalence of swine TT viruses was found in sera from PMWS affected animals compared to non-affected animals. The main goal of this work was to estimate the prevalence of porcine TT viruses in the Czech Republic in different age categories of pigs.

Materials and Methods
Samples
Two hundred twelve pig blood samples from pigs from 27 swine herds were tested to obtain an overview of the presence of TTSV in the Czech swine population. Samples originated from animals of different ages (newborn piglets n = 66, weaned pigs (4-12 weeks) n = 127, gilts n = 11, sows n = 8) and with different health status with regard to PMWS infections. All specimens used were fresh or stored frozen before DNA extraction.

PCR
The sequence of primers for two rounds of amplification was based on primers already published by Martinez et al. 2006.

Results
The results of snPCR testing performed on the panel of 212 samples are shown in Table 1. TTSV1 was detected in 91 samples. TTSV2 was found in 99 samples. In 66 samples both TTS viruses were detected together. The prevalence of individual TT viruses in the Czech Republic could be estimated at 42.9% (TTSV1) and 46.7% (TTSV2). The average prevalence of TTS viruses is thus 44.8%.

The age distribution of both genogroups is shown in Table 1. TT viruses were not distributed equally in all age categories. Although the prevalence of TTSV1 and TTSV2 was determined to be 52.7% and 60.6% respectively in piglets at weaning, the percentage increased to 90.9% (TTSV1) and 63.6% (TTSV2) in gilts and 75% (TTSV1) and 87.5% (TTSV2) in sows.

Both viruses were detected in newborn piglets (1-2 days post parturition). In 59 samples from a group of newborn piglets TTSV was detected in 16 cases, which suggest possible transplacental transmission.

Detection of Torque teno virus (TTV-2) by PCR in tissue samples from Brazilian swine population

Cintia M. Favero1, Alessandra M. M. G. de Castro1, Cintia M. Baldin2, Tais Nishikata1, Sueli Taniwaki1, Paulo E. Brandão1, Leonardo J. Richtzenhain1

1. Faculdade de Medicina Veterinária e zootecnia-Universidades de São Paulo, São Paulo, Brazil; 2. Faculdade de Jaguariúna, Jaguariúna, SP, Brazil

Introduction
Torque teno virus is circularized single stranded DNA viruses, classified belonging to genus Anellovirus. Cattle, sheep, pigs, cats, dogs and chickens are described be infected with species-specific TTV2,3. Two distinct TTV genogroup were identified circulating among domestic pig population, TTV-13 and TTV24. TTV have been detected by PCR in lungs, lymph nodes, tonsil, ileum, serum, marrow bone, liver and kidney.1-7,8 Prevalence varying between 24 % and 100 % in different parts of the world are related1,5,6. The aims of this study were to standardizing a PCR and detect TTV-2 in samples from swine collected between 2002 and 2003 in five Brazilians states.

Materials and Methods
The partial sequence of 250 bases of the non-coding region of swine TTV was amplified8 and inserted into pTZ57R/T (InStAclone - Fermentas4), according to the manufacturer’s instructions. Cloned DNA was selected and plasmid DNA quantified with a NanoDrop 1000 (Thermo Scientific). Sensitivity of the PCR technique was performed with ten-fold dilutions of recombinant plasmid (10-1- 10-10). Threshold detection was 25 copies of virus DNA. Eighteen samples of tissue from five different Brazilian states (SP, GO, SC, MS and PR) collected between 2002 and 2003 were homogenized by Stomacher 80 (Seward=Lab System) in 20% (v/w) TE buffer. DNA extraction was carried out by phenol: chloroform: proteinase K protocol and the TTV2 amplification was performed according to previous procedure described 8.

Results
TTV-2 was detected in 12 (67 %) out 18 tissue samples (67 %). Among the 12 TTV-2 positive samples, seven (7/7) belong to the fattening, three (3/6) to the growing and four (4/7) to the nursery pigs (Fig. 1). According to Brazilian states, the following distribution were observed: four belong to SP (4/4), one to MS (1/1), three to GO (3/4) and four to SC (4/8). The unique sample from PR was negative for TTV-2 (Fig. 2).

Discussion
This study represents the first report of TTV-2 in swine tissues from different Brazilian states. The results found in this work, that is, 67 % of positivity for TTV-2, are in agreement with the high percentage of this genogroup observed in pigs herd from Spain (over 70%)5. However, the high percentage of positive animals in the fattening pigs was not observed in Italy, which related a higher percentage on TTV-2 positive animals in weaners (57.4%) than fatteners (22.9%).

Thus we conclude the TTV-2 is spread at least in four Brazilian states since 2002 and here to for there is no association with clinical disease. Future prospects about sites of viral replication, viral pathogenesis and TTV-2 relation to co-infection with TTV-1 and PCV are necessary.

First report of TTV-2 DNA detection in samples from sows with reproductive failure in Brazil

Cíntia M. Favero1, Alessandra M. M. G. de Castro1 Cíntia M. Baldin2 Tais Nishikata1 Tânia A. Coutinho1 Andrea M. Moreno1 Paulo E. Brandão1 Leonardo J. Richtzenhain1

1. Faculdade de Medicina Veterinária e zootecnia-Universidades de São Paulo, São Paulo, Brazil; 2. Faculdade de Jaguariúna, Jaguariúna, SP, Brazil

Introduction
Torque teno viruses (TTVs) are small, non-enveloped, single-stranded, negative sense, circular DNA viruses, belonging to the genus Anellovirus. Swine are infected with the two identified genotypes TTV-1 and TTV-21. Transmission route of TTV in pig population are mainly fecal-oral2 but there is evidence of vertical transmission. Recently, it has been verified that colostrum is an important source of TTV infection on piglets3. Also, a high prevalence of TTV genogroups has been detected in boar semen4 and in utero infection was repoted as a commum event on multiparous sows5. The aim of this study was the detection TTV-2 DNA in abortion, stillborn and mummified fetuses.

Materials and Methods
Pool of tissues (heart, lungs, liver, kidney, and spleen) from forty two fetuses were collected in different pig farms located in São Paulo and Paraná state in Brazil. Samples were segregated in three fetal stages: abortion, stillborn and mummified. The samples were homogenized by Stomacher 80 (Seward=Lab System) in 20% (v/w) TE buffer. DNA extraction was carried out by phenol: chloroform proteinase K protocol and the TTV2 amplification were carried out according to previous procedure described6.

Results
Fourteen of 42 tissue samples from different animals were positive for TTV-2. Within the fetal stages, 6/8 (75 %) abortion, 8/25 (32 %) stillborn and none mummified fetuses were PCR TTV-2 positive (Figure 1 and 2). From all six abortion positive fetuses for TTV-2, a high detection was obtained in fetuses samples from sows in the last third of the gestational 4/6 (67 %) than on first third of gestational 2/6 (33 %) period

Discussion
This is the first report of TTV-2 infection in fetal stages in Brazil. PCR positive for TTV-1, 15 out of the 30 (50%) and for TTV-2, 2 out of the 30 (7%) in serum from stillborn fetuses have already described3. However, our results showed a higher number of positive samples in stillborn tissues (30 %) probably due to the kind of the sample. Serum had higher virus quantities than tissues, on other hand TTV-2 is easily found in tissues7. The lack of positive samples for mummified fetus must be due the difficulty to separate suitable tissue. An interesting result was the higher prevalence of TTV-2 in aborted fetuses (75 %) occurring in the last third of the gestational period than in the first. Further studies are necessary to confirm this hypothesis, but it is possible that TTV infection affects the development of fetuses and it can be responsible for mummified, stillborn and weak piglets5.

Inclusion Body Rhinitis and Porcine Cytomegalovirus in pigs in Denmark

Peter Astrup¹ Uffe Nielsen²

¹ Intervet/Schering-Plough Animal Health, Skovlunde, Denmark; ² LVK, Hobro, Denmark

Introduction

Porcine cytomegalovirus (PCMV) was discovered in 1955 as the causative agent of inclusion body rhinitis (IBR) of pigs, and is closely related to human herpesviruses. Cytomegalovirus is associated with cytomegalic cells and large intranuclear inclusion bodies. In pigs, the turbinates and the respiratory tract are major sites of infection, and clinical signs may be fetal death, and rhinitis, pneumonia, reduced weight gain and death in piglets (1).

It is stated that the herd prevalence in Europe is greater than 90%, and that within herds, as many as 98% of pigs may be seropositive. PCMV can be transmitted horizontally or vertically, and in commercial farms the infection is believed to take place perinatally or early postnatally (2).

There has been only one Danish study in fattening pigs to investigate the prevalence of PCMV. The result was 43% PCR positive and 24% PCR positive in control and case groups, respectively (3). This paper describes the first case of IBR diagnosed in suckling pigs in Denmark.

Materials and Methods

The herd studied is a high health herd, which had been declared infected with APP type 6 and 12, M hyopneumoniae and PRRS genotype US. The 440 sows and pregnant gilts are fed and reared conventionally. Piglets are weaned at 7 kg and sold, after the nursery period, at 30 kg. Replacement gilts are selected from the nursery and reared on farm. The sows are routinely vaccinated against Glässers disease, type C enteritis, E coli, PPV and erysipelas.

The herd was investigated according to usual consultative clinical procedures and submissions to The Pig Disease Laboratory, Danish Pig Producers, Kjellerup, Denmark.

Results

In the farrowing unit, widespread sneezing and coughing was heard amongst the piglets. Pigs from 2 weeks old to weaning age showed nasal discharge, ill-thrift and dyspnea. Stenosis of the turbinates was audible on expiration. The litters were relatively small with fewer than 13 live born pigs per litter, but the mortality rate was as low as 10%.

The symptoms remained prominent for 2 weeks after weaning, but the pigs recovered clinically thereafter. The estimated mortality rate in the nursery period was only 1%.

Five pigs of 18 days of age were submitted for post mortem examination. They were in normal body condition, and most pigs exhibited macroscopically catarrhal bronchopneumonia, peritoneal edema, hepatic congestion and petechial bleeding in the kidneys. Bacteriological examination of the liver, kidney and lungs revealed no specific pathogens, and nose swabs were negative for B bronchiseptica and P multocida toxin. Lungs tested negative for Mycoplasma spp by cultivation, and negative for SIV, M hyopneumoniae, PCV2 and PRRSV by PCR. Nasal swabs tested negative for PRRS, but positive for PCMV by PCR. Finally, histological examination of nasal epithelium revealed mononuclear infiltration in the lamina pro-pria and enlargement of the mucus gland epithelium cells with basophilic inclusion bodies.

Discussion

The histological findings are considered pathognomonic, and the symptoms in general are in accordance with previous descriptions of infection with PCMV in pigs (1). Thus the proper diagnosis of the herd’s respiratory disease problems is IBR caused by infection with PCMV. Based on the clinical description, a number of Danish herds must be suspected of suffering from IBR.

No specific treatment or vaccination against PCMV is available. In order to control the infection, batch farrowing, all in/all out management and McRebel procedures are all recommended. Replacement gilts should be naturally immunized before mating, and secondary infections in general should be controlled by appropriate vaccination.

Congenital tremors of suckling pigs in Jeju, Korea
Hyoung-Seok Yang1 Seong-Hwan Moon1 Chan-Woo Jung1 Byeong-Hak Kim1 Kyung-Ok Song1 Jae-Hoon Kim2
1. Jeju Veterinary Research Institute, Jeju, Korea; 2. College of Veterinary Medicine, Jeju National University, Jeju-si, Korea

Introduction
Congenital tremor (CT) is a congenital abnormality caused by hypomyelination or demyelination of the brain and spinal cord. Unlike in splaylegged pigs where the deficit in myelin formation specifically affects the motor system, with CT there is an overall reduction of myelin in the spinal cord (Lamar et al., 1975). CT in pigs is associated with myelin deficiency and may be caused by genetic abnormalities (Harding et al., 1975), or in utero infection with classical swine fever virus (CSFV, Harding et al., 1966) or Aujeszky's disease virus (ADV, Maré et al., 1974). In the recent investigations, porcine circovirus infection has been detected in tissues of CT pigs (Stevenson et al., 2001).

Materials and Methods
January 2010 in Jeju, Korea, 1 day-old suckling pigs showed acute nervous signs including paddling, tremors, and clonic muscular contraction. Two suckling pigs were necropsied in the diagnostic lab of Jeju Veterinary Research Institute. After gross examination, brain, spinal cord, and internal organs were fixed in 10% neutral buffered formalin, processed routinely and embedded in paraffin wax. Sections (4μm) were cut and stained with Hematoxylin and Eosin (H&E) and Luxol Fast Blue (LFB) method for histological examination. For bacterial culture, the swabs from the cerebrums were inoculated on sheep blood and MacConkey agar and aerobically incubated for 48hr at 37°C. Polymerase chain reaction (PCR) for porcine circovirus type II (PCV-2), CSFV, ADV, Japanese encephalitis virus (JEV), and porcine reproductive and respiratory syndrome virus (PRRSV) were carried out on brains and spinal cords.

Results
Grossly, there were no lesions in cerebrums, cerebellums and spinal cords of suckling pigs. Histo-pathologically, there were no significant lesions in brains. However marked hypomyelination was observed in the spinal cord of pigs. Hypomyelination is most evident and reduction in cross-sectional area is greatest in the white matter of spinal cord. In bacterial examination, pathogenic bacterial colonies were not observed on blood and MacConkey agars. PCR analysis of brain and spinal cord resulted in amplification of PRRSV-specific nucleotide sequence, but not in PCV-2, CSFV, ADV and JEV.

Discussion
Based on the clinical and histo-pathological finding and LFB staining, this case was diagnosed as CT. Hypomyelination was predominant lesion in the white matter of spinal cords of two suckling pigs. PRRSV nucleic acid was detected in the brain and spinal cord. Therefore PRRSV should be considered as a possible cause of CT in suckling pigs.

Detection and Phylogenetic analysis of Porcine encephalomyelitis virus in South Korea

Introduction

Porcine encephalomyelitis virus (PHEV), which belongs to the order Nidovirales, family Coronaviridae, genus Coronavirus, was first isolated in Canada in 1962. PHEV infection is known to be widespread in worldwide and usually remains subclinical, because pigs are protected by colostral antibodies and subsequently they develop age-related resistance against PHEV. However when PHEV-seronegative piglets (less than 3 weeks old) are introduced to this virus, the mortality reaches almost 100%. This is significant for gnotobiotic pig farms or SPF pig farms [1] where the pigs do not receive colostral antibodies. Also, even in not one of those specialized farms, nonimmune subpopulation might be existed in a large gilt pool and they might act as potential sources of PHEV to induce clinical syndromes [2]. There are two types of clinical syndrome, the vomiting and wasting disease (VWD), and the encephalomyelitis form. There are not many isolates of PHEV which are registered in GenBank so our final goal is to isolate new Korean strain of PHEV. To achieve this final goal, we preferentially performed PHEV screening test from pig tissue samples and sequencing of specific gene, N gene, to compare with each other and existing strains.

Materials and Methods

From 2009 Nov. to 2010 Jan., a total of 90 swine tissue samples including solid organs and brains were tested for PHEV. The age range of these pigs was from suckling to finisher. They had respiratory, enteric or neurologic sings but some were unknown. Viral RNA of each samples were extracted from 10% homogenates and their cDNA were synthesized using specific external reverse primer of N (nucleocapsid protein) gene. The primers for RT-PCR and nested PCR of PHEV were based on the nucleotide sequences of nucleocapsid gene of the HEV-JT06 strain and designed as follows: NF (external forward primer) CAGGGAGGCTGGTTGTACCC, NR (external reverse primer) CCCAACAAATGCA CTTG, N2F (internal forward primer) TGCAAC GGAGTCCC AT CTA, N2R (internal reverse primer) GCCAAGTT TGC CAGAACAA. The size of amplified product was 472bp. The final PCR products were sequenced and aligned to evaluate the relationship with others using the Clustal X (1.83) multiple sequence alignment program and the phylogenetic tree was constructed by MEGA (4.1).

Results

Among 90 samples, 9 showed positive results for PHEV after performing nested PCR. The sequence results of these PCR products were confirmed PHEV by BLAST, showing 97-98% nucleotide identity. These sequences of the 9 samples were aligned with three reference strains, JT06, VW572 and IAF-404, and the sequence identities of the samples were the highest with IAF-404. The 9 samples had their unique nucleotides compared to the reference JT06 strain in the region between 586 and 622. The phylogenetic tree was drawn below.

Discussion

This study showed that PHEV is actually present in some of the farms in South Korea. Even though the positive samples established a new group, there were not so much variations compared to existing PHEV strains. Since the use of gnotobiotic and SPF pigs for xenotransplantation and transformation is common these days, this virus is not negligible when handling PHEV-seronegative pigs.

Seroprevalence of Bovine Viral Diarrhea virus in finisher hogs on Ontario swine herds

Terri L. O’Sullivan1 Robert Friendship1 David Pearl1 Bev McEwen2 Susy Carmen3 Cate Dewey1
1. University of Guelph, Guelph, ON, Canada; 2. University of Guelph Animal Health Laboratory, Guelph, ON, Canada; 3. University of Guelph Diagnostic Virology Laboratory, Guelph, ON, Canada

Introduction
The genus pestivirus contains four species currently recognised by the International Committee on Taxonomy of Viruses namely, Classical Swine Fever virus (CSFV or hog cholera virus), Bovine Viral Diarrhea virus Type 1 (BVDV-1) and Type 2 (BVDV-2), and Border Disease virus (BDV) of sheep. BVDV under natural conditions mainly infects cattle and sheep; however, the virus has been associated with disease in goats and swine as well (1). Herd level prevalence of BVDV (in CSFV-free countries) has been reported anywhere from 2-43% with cattle implicated as the most common source of infection of BVDV in pigs (1). Pestivirus infections in animals can lead to fertility problems, diarrhea, immuno-suppression, thrombocytopenia, and central nervous system disease. In pregnant animals, transplacental infection can lead to abortion, stillbirth, foetal malformation, and persistent infection of offspring (1).

Interest in the prevalence and clinical significance of pestivirus’ in swine herds has recently been highlighted with the documentation of a neurologic and reproductive disease outbreak associated with a novel pestivirus in the USA (2) and a disease outbreak in Australia (3). Such novel strains of pestivirus have yet to be identified in Ontario swine herds and the current prevalence of BVDV in Ontario swine herds is unknown. The objectives of this study were to determine the prevalence of neutralizing antibodies to BVDV type-1 and type-2 in Ontario swine herds and to determine if the presence of cattle on the same premise was a risk factor for seropositivity.

Methods
Five hundred samples of stored finisher pig sera (10 samples per herd) were tested. The stored samples were from 50 swine herds that participated in a swine sentinel herd program at the University of Guelph in 2005 (4). The Ontario sentinel herds were distributed across the province and the program collected herd level information and blood samples from each herd. The samples were tested by virus neutralization (VN) for BVDV-type 1 and BVDV-type 2 by the Animal Health Laboratory at the University of Guelph. The degree of contact with cattle for each herd was compiled from the sentinel project herd records.

Results
All 500 samples from, the 50 herds, tested negative (titres < 1:2) for antibody to BVDV-type 1 and BVDV-type 2. Of the 47 herds with information available on the presence of cattle, cattle were present on 27.6% of the farms. On the remaining 72.3% of the farms, only pigs were present.

Discussion
The results indicate that BVDV did not appear to be present in Ontario swine herds in 2005 regardless of the presence of cattle on the same premise. These findings correspond to other findings where the seroprevalence of ruminant pestiviruses in swine was found to be low (1, 5). The Ontario swine industry is experiencing a rapid decline in the presence of mixed farming practices and has moved almost exclusively to species specialization of farms, a phenomenon witnessed in many parts of the world today. It has been speculated that this trend in farming practices has resulted in the decline of BVDV in swine worldwide as supported by this study (1).

Introduction
Poxvirus infections of pigs are either caused by Vaccinia virus and Cowpox virus (Orthopox) or by Swinepox virus (Suipox, SwP). SwP is a severe disease in young pigs [1]. Adult pigs generally develop a mild, self-limiting form of the disease. Morbidity can be up to 100% in pigs up to 4 months of age. Transmission by insects is less common; horizontal transmission between pigs may occur. Small skin injuries may facilitate the entry for Swinepox virus (SwPV). Macroscopic examination of skin lesions often leads to an insecure diagnosis. However, other methods that allow for a rapid and accurate diagnostic are appreciated. This paper describes the diagnostic procedure including electron microscopic analysis and a novel SwPV-specific PCR.

Materials and Methods
Between Nov. 2008 and March 2009 piglets in a German two side production unit showed clinical signs of red skin lesions first at maculae stages, following by papula-, pustule and finally crust stages. The lesions were equally distributed over the entire body surface of the nursery piglets. Nearly 50% of the piglets were affected. First symptoms were seen 1–2 weeks after relocation into the nursery. First macroscopical diagnosis was SwPV-infection. For PCR, scraped skin tissues from crusts as well as epidermal biopsies were collected. SwPV specific PCR primers (for: 5’-CC-GAGGAGTATAGACGTGTTATCG-3’, rev: 5’-AGGAATCCGTAGATA-CAGCCGA-3’) were designed (PrimerQuestSM, Integrated DNA-Technologies) based on published DNA-sequences of the thymidinkinase-gene (TK-gene) of the SwPV (GenBank: Acc. Nr. AF410153, M64000 and M59931). Orthopoxvirus-DNA was included to exclude orthopox infections. PCR products were sequenced and aligned to confirm identity of SwPV.

Electron microscopy (TEM) was performed by negative staining of sample suspensions including enrichment with ultracentrifugation. Moreover, epidermal biopsies embedded in Epon were prepared for tissue sectioning. Ultrathin sections stained with UA were analysed in a TEM (Zeiss 906,80kv).

Results
SwPV was confirmed by PCR and sequencing of the TK-gene; PCR for Orthopox was negative. All amplified products of the TK-gene were 473bp long and did show 100% homology to published sequences (Acc. Nr. AF410153, M64000 and M59931). Histology revealed marked ballooning cytoplasmatic degeneration and central nuclear clearing of epidermal cells of the stratum spinosum. As revealed by TEM, infected epithelial cells were greatly distended by huge cytoplasmic lipid A-type inclusion bodies, filled with mature virions and uniformly granular, electron dense material. Intracellular mature virions within inclusions had gained additional outer coats formed by this granular material. Intracellular virus particles found in A-type inclusions have the typical structure of poxviruses; extracellular virus particles often exhibited a second outer virus membrane. Immature virions in B-type inclusions (= virus factories) developed by formation of dense foci of viroplasm were surrounded by crescent shaped, phospholipid membranes later closing to circular membranes. Like in other poxviruses [2,3], virus crescents reveal no continuity between cellular intermediate compartment (IC), though proteins from IC are of the same origin. Like in other poxviruses, the transport of immature virions and crescents within the cell seem to be in accordance with filaments seen in contact with virus stages. Early A-type inclusion formation involves the attachment of intracellular mature virions to small lipid globules.

Discussion
PCR, sequence analysis and electron microscopic analysis helped to confirm an infection with SwPV in the above mentioned herd. Electron microscopy confirms the practitioner’s first diagnosis. The described PCR-assay enables a rapid and an accurate diagnosis of SwPV, that my help to review management practices and the implementent of control measures and treatments.

Detection of porcine endogenous retrovirus (PERV) A/C recombinants in U.S. pigs by quantitative real-time RT-PCR

Shayleen Harrison¹ Rodney Baker¹ Narinder Pal¹ Linda Scobie² A Tucker³ Tanja Opriessnig¹
1. Iowa State University, Ames, IA, USA; 2. Glasgow Caledonian University, Glasgow, UK; 3. University of Cambridge, Cambridge, UK

Introduction

Retroviruses are RNA viruses that exist in two main groups: endogenous or exogenous retroviruses. Pigs carry porcine endogenous retroviruses (PERV) in their genome (1) and three PERV subtypes have been identified to date, PERV-A, B, and C. PERV-A and PERV-B are present in genomes of all pigs. In contrast, PERV-C is absent from many pigs and this virus with its host range mostly restricted to porcine cells is not infectious to human cells (2). More recently, the possible existence of exogenous retrovirus; a recombinant between PERV A and PERV C (PERV A/C), as opposed to endogenous retroviruses in pigs was proposed (3,4). The objective of this study was to determine if there is a relationship between retroviremia and clinical disease in pigs by using real-time PCR methods to detect the different PERV types on serum samples obtained from clinically healthy and clinically affected 3 to 25 week old pigs.

Material and Methods

A total of 369 serum samples were collected from 204 pigs from three commercial swine operations in the U.S. during 2006 and 2007. Farm 1 consisted of a total of 84 pigs with subclinical porcine circovirus associated disease (PCVAD). Farm 2 samples were obtained from 60 three-week-old pigs. Thirty of the 60 pigs were clinically healthy and the remaining 30 pigs suffered from weight loss and diarrhea associated with Salmonella typhimurium and E. coli. Samples collected on Farm 3 were obtained from 60 25-week-old pigs with a recent PCVAD outbreak resulting in 30% mortality. As with Farm 2, at the time of blood collection, 30 pigs were clinically healthy and 30 showed clinical signs consistent with lethargy, decreased weight gain or weight loss and respiratory disease. The presence of PRRSV, PCV2, and respiratory disease was confirmed by routine diagnostics. The RNA of all samples was extracted and all samples were tested by three different real-time PCR assays: A general PERV-ABC real-time RT-PCR, a real-time RT-PCR specific for PERV-C, and a quantitative real-time RT-PCR specific for PERV-A/C recombinants. Pairwise t-tests were used for data analysis with a level of significance of <0.05.

Results

While all 369 samples were found to be positive for PERV-ABC RNA, PERV-C RNA and PERV-A/C RNA were detected in 24.1% (89/369) and 18.7% (69/369) of the serum samples respectively. Twenty percent (43/215) of the samples collected during the nursery stages (3-9 weeks of age) were found to be positive for PERV-A/C RNA versus 16.9% (26/154) of the samples collected during the grow-finish stages of production (12-25 weeks of age). When clinically affected pigs were compared to unaffected pigs, 25.0% (15/60) of the samples from affected pigs were found to be positive for PERV-A/C RNA, whereas in clinically healthy pigs 8.3% (5/60) of the samples were found to be PERV-A/C positive. Interestingly, PERV A/C was also identified in the same pigs on more than one consecutive bleeding time.

Discussion

In this study, it was determined that 100% of the investigated pigs were positive for PERV-ABC as expected. PERV-C and PERV-A/C were found in varying percentages (24.1% versus 18.7%) on all farms and production stages. Finally, when we compared clinically healthy and diseased pigs, in one of the two investigated farms, evidence was found that clinically affected pigs had a higher incidence of PERV A/C. Since the current study was limited to selected farms further studies using sample sets from pigs with different clinical expressions are warranted.

Development of a real-time PCR assay for the detection of novel swine boca-like virus DNA (SwBoV)

Catherine Duffy1 Julie McClintock2 Michael McMenamy1 Irene McNair2 John McKillen2 Michael Welsh2 Gordon M. Allan1
1. Queen’s University Belfast, Belfast, UK; 2. AFBI, Belfast, UK

Introduction
Two antigenically distinct swine boca-like viruses (SwBoV) have been isolated from pigs in Northern Ireland. The viruses were recovered from a small intestinal tissue and faecal specimen from two pigs on different PMWS-affected farms by virus isolation in primary cell cultures. Although both samples exhibited a CPE, PCR testing for a range of known porcine viruses failed to identify either agent. DNA sequencing and molecular characterization subsequently established that both isolates share genetic homology and possible genomic arrangement with parvoviruses BPV-1, CMV and HBV. The isolates were designated as SwBoV1 and SwBoV2. The discovery of a novel porcine boca-like virus (PBo-likeV) in PMWS-affected pigs in Sweden has also recently been reported1. Here we describe the development of a real-time PCR assay for the detection of SwBoV DNA.

Materials and Methods
Primers were designed against conserved nucleotide sequences of SwBoV1 and SwBoV2. Real-time PCR was carried out on a MJ Research Opticon 2 instrument using SybrGreen PCR master mix (Qiagen, West Sussex, UK) in 25 μl reaction volumes containing 2 μl of template. Assay optimisation involved determination of optimal Ta, Mg2+ and primer concentrations. To determine assay sensitivity, serial dilutions of quantified amplicons were prepared for each isolate. Assay specificity was assessed against a number of cell lines, porcine and non-porcine DNA viruses. A 2.8Kb representative amplicon, derived from a UK sample, served as PBo-likeV positive control DNA. All nucleic acid extractions were performed using the MagNA Pure LC Total nucleic acid extraction kit (Roche, Burgess Hill, UK).

Results
PCR optimisation resulted in an assay designed to work at a Ta of 52°C and 0.5 μM primer concentration. Amplification was achieved using 40 cycles of 95°C for 30sec, 52°C for 30sec, 72°C for 30sec followed by a melt-curve between 60-95°C. Amplicons of 313-316bp, Tm of approximately 79°C and 78°C and detection limits of 2x101 and 2x102 copies/μl of PCR product were determined for SwBoV1 and SwBoV2, respectively. The specificity of the assay was also confirmed against a range of cell lines and DNA viruses.

Discussion
New and re-emerging pathogens continue to pose a risk to both human and animal health. Bocavirus infection is already associated with a number of disorders in other species2. The discovery of a SwBoV therefore warrants further investigation. The results suggest that this PCR assay may offer a sensitive method for the detection of SwBoV DNA. The development of a SwBoV-specific PCR assay provides a means to investigate the prevalence, clinico-pathological significance, epidemiology and genetic diversity of SwBoV within swine populations.

Distal ulna osteochondrosis in fattening pigs

Friederike Zeeh1 A. Gutzwiller2 W. Zimmermann1 P. Kircher3 H. Stich4 P. Schawalder5

Vetsuisse Faculty Bern, Division of Surgery, Orthopedics and Stomatology, Bern, Switzerland

Introduction

Osteochondrosis (OC) is a major predisposing factor to lameness, impairing growth performance and animal welfare. It is defined as generalized disturbance of the enchondral ossification at predilection sites such as the articular cartilage and metaphyseal growth plates. Little is known about the pathogenesis, and diverging views regarding the causes of the disease exist. Most reports focus on the articular lesions. In a feeding trial the hypothesis was tested that ad libitum feeding of a diet containing excessive amounts of calcium (Ca) and protein combined with a high physical activity, i.e. risk factors for the development of canine panostitis, cause osteochondrosis in growing pigs.

Materials and Methods

From 25 to 105 kg body weight (BW), four groups of five Large White pigs received either restricted amounts of feed containing the recommended nutrient level (“R”) or an enriched diet (“E”: Ca +30%, crude protein +20%, 2000 IU/kg vitamin D) ad libitum and were either individually housed in small (S) pens or group housed in large (L) pens (Table 1).

Every week, each pig was weighted and clinically monitored, in particular for lameness, leg deformities and accessory bursae. After slaughtering, one forelimb per pig was radiographed in lateral and antero-posterior position. Findings at the distal ulna growth plate (DUGP) were recorded.

Two radiologically normal and four altered legs were histologically evaluated using light microscopy. For this, bones were sawed in 5mm slices in the area of the DUGP and fixed in 70% alcohol. Bone sections were embedded in acryl and stained with Fuchsin/Acetic-Light Green.

Results

The ad libitum intake of feed E as well as housing in small pens significantly increased the daily weight gain (ES 841g, EL 757g, RS 716g, RL 693 g).

Limping or stiff walking were observed in 7 pigs from 16 weeks of age onwards but were always slight or moderate and disappeared within one or two weeks without therapy. Bowed legs (17 pigs) and accessory bursae or callosities (20 pigs) were frequent and occurred in all 4 groups.

Radiographs showed OC lesions as radiolucent, widened and irregular growth plates and/or subchondral sclerosis in the distal ulna of 14 pigs. Four of the 14 pigs with radiologic changes had a history of lameness.

Histological findings ranged from normal growth plates to severe lesions in the distal ulna. Irregular width, abnormal ossification or mineralization, and separation in the area of the cartilage breakdown zone were observed. In one case, separation extended to the metaphyseal bone (Fig. 1). On the rims of the clefts, reparation processes occurred.

Discussion

Severe lameness could not be provoked by the study design. Nevertheless, radiological and histological investigation revealed OC lesions in all 4 study groups. The separation in the distal ulna epiphysis (fissure) has been described in literature, but recent reports are lacking. Thus, we want to draw attention to this histological finding as part of the OC features.

Microbial etiology of infectious arthritis in nursing piglets

Marie Sjölund1,3 Maria Lindberg2 Ulrika Grönlund-Andersson1
1. SVA Statens Veterinärmedicinska Anstalt, Uppsala, Sweden; 2. Swedish Animal Health Services, Uppsala, Sweden; 3. SLU Swedish University of Agricultural Sciences, Uppsala, Sweden

Introduction
Infectious arthritis is one of the most common causes of antimicrobial treatment of nursing piglets with approximately 10% of the piglets receiving antimicrobial treatment because of lameness (1, 2). Affected piglets mostly receive treatment during the first three weeks of life. At present, there are few studies on the prevalence of pathogens isolated from affected joints of piglets with clinical signs of arthritis.

As infectious arthritis causes both suffering of the individual animal and economic losses due to reduced growth rate, increased mortality, costs for treatments and increased labor, it is most important to initiate treatments as soon as possible with the most appropriate antimicrobial to minimize both losses and other negative effects. Therefore, the aim of this study was to, on a national level, obtain a basis for an optimal treatment regime.

Materials and Methods
From each herd with ≥100 sows (n = 400), one nursing piglet (0 to 35 days of age) with clinical signs of infectious arthritis such as lameness, fever and swollen joints were identified by the regional Animal Health Service veterinarian on a regular visit. The piglets were euthanized with an intra peritoneal injection of barbiturates (≥ 1 ml/kg body weight) and then frozen at -20°C before being sent to SVA for necropsy.

At necropsy, two affected joints per piglet were sampled for bacterial cultivation including Mycoplasma sp., and Haemophilus sp. Antimicrobial susceptibility was determined by broth microdilution using VetMIC™ (SVA, Uppsala). Epidemiological cut-off values according to EUCAST were used to determine if the isolates were resistant or not (www.eucast.org). Isolates of Staphylococcus (S.) hyicus were in addition examined for penicillinase production by the “clover-leaf” method.

Results
The preliminary results from 36 herds, represented by 36 piglets and 72 joints, demonstrated bacterial isolation from 39 of 72 sampled joints. The dominant finding was Streptococcus dysgalactiae subsp. (S.) equisimilis isolated from 23 joints, followed by Escherichia (E.) coli isolated from 5 joints and then S. hyicus isolated from 4 joints. Mycoplasma sp. and Haemophilus sp. could not be isolated from any of the 72 sampled joints. From seven joints, the bacterial species have not yet been identified.

In 10 piglets, the same bacterial species could be isolated from both joints sampled. S. equisimilis was isolated from both joints in eight piglets and E. coli in two piglets. In nine of 36 piglets, bacterial cultivation was negative from both joints.

All streptococci were susceptible to penicillin. Three of four S. hyicus isolates were penicillinase producers. However, all S. hyicus and E. coli isolates were susceptible to trimethoprim.

Discussion
The isolation of the same bacterial species from both of the sampled joints in 10 piglets indicates a hematogenic spread of the infection which is in accordance with previous findings (3). In four of the nine piglets where no bacteria could be isolated, lameness was most probably caused by trauma. The other five piglets had gross pathological lesions indicative of arthritis.

This study shows that treatments with penicillin would be successful in 22 of 25 piglets, provided that treatments were initiated early on during the course of infection. However, as three S. hyicus were penicillinase producers, and three E. coli isolates were resistant to ampicillin, some cases of treatment failure using penicillin could be expected. Thus, given the results, trimethoprim-sulphonamides should be considered as the second hand choice after penicillin.

Hind limbs paralysis outbreak in a pig herd. A case report

Eduardo J. Kwiecien1 Carolina Gutierrez2 Evelyn Cadenas2

Introduction
Locomotory disturbances in swine are a significant and common problem in pig herds 1,2,3. Nutritional, bacterial and viruses infection are the main factors related to paralysis of hind legs in young pigs4,5. Even though the incidence of pathology is low6, no field reports have been done so far. The aim of this study is to describe an outbreak of hind limbs paralysis in an pig farm in Venezuela.

Materials and Methods
The study was carry on in a 600 sows farrow to finish herd in the Cojedes State of Venezuela. A historical morbility records showed and incidence in 5 to 10 pigs with hind legs recumbence or paralysis in the last three months before to this study. An interview with the owner and stockmanship in the farrowing and weaner areas was scheduled to assess the key factors intervening in the cases. Data of numbers of pigs suffering this condition, mortality attributed to hind quarters paralysis was taken to determine the prevalence and incidences. Necropsy was performed in pigs and samples of limb nodes and spinal cord were taken for bacteriological and histopathological study.

Results
Interview results and management procedures in the farrowing area showed failures during piglets processing after farrow. Findings necropsy showed an intervertebral abscess at L4-L5. Nodular proliferative abscess were presented in the spinal cord canal (Fig. 1, ). Degenerative changes were manifest grossly as narrowing of the intervertebral space and conversion of the nucleus pulposus to a red dark, granular mass (Fig. 2). A mix of mononuclear and neutrophils infiltration in spinal cord on microscopic view was observed.

Changes in processing piglets and an antimicrobial medication injectable and in the weaner feed reduced the incidence of this pathology.
**Etiology of the ear necrosis syndrome – investigation of bacteria, fungi and mycotoxins in feeding stuff**

Tierärztliche Klinik Düemmerland, Steinfeld, Germany

**Introduction**

During the summer months lesions of the so-called ear necrosis syndrome can be observed frequently in weaners during the raising period. The stages range from mild epidermal changes to severe ulcers and necrosis (1). In the past, contaminants of feeding stuff have been discussed to be responsible for the development of ear necrosis, but the exact etiology of this disease could not be determined. Aim of this study was the evaluation of bacteria, fungi and different mycotoxins in feeding stuff of pigs with ear necrosis syndrome.

**Materials and Methods**

A total of 15 farms were included in the study. Feeding stuff of piglets with clinical signs of the ear necrosis syndrome in an initial stage was collected 3 times, once during summer time, when the symptoms occurred for the 1st time, once in winter after storage and once again in summer. The investigated parameters are summarized in table 1.

### Table 1: Contaminants in feeding stuff

<table>

</tr>
</tbody>
</table>

**Results**

Aerobe mesophile bacteria could be detected in a concentration between $1.0 \times 10^4$ to $3.0 \times 10^7$. Concentrations up to $10^6$ are of no clinical relevance. 34.4% of the samples had results higher than $10^6$. *Aspergillus* spp., *Fusarium* spp. and *Penicillium* spp. were determined in a concentration of $10^3$, which is not harmful to pigs. Only 1 sample exceeded a *Penicillium* and 2 samples a *Fusarium* amount of $10^4$. Concerning the mycotoxin concentrations, T2 toxin, HT2 toxin, Diacetoxyscirpenol, Acetyldeoxynivalenol and Nivalenol could not be detected. Table 2 shows the results of the other toxins.

Max = maximum, MV = mean value, SD = standard deviation

**Discussion**

Especially mycotoxins can cause ear necrosis. A good quality of feeding stuff can be an essential prophylactic tool. The general hygienic status of the feeds tested in the present study was moderate, which could be an initiating factor for the development of several diseases. Increased mycotoxin concentrations could also be detected. Whereas DON and ZON amounts were mostly tolerable, the detected alkaloid concentrations were unexpectedly high. If those concentrations are sufficient for the development of ear necrosis still needs to be investigated.

Etiology of the ear necrosis syndrome – data collection through questionnaires

Christiane Lang1 Rosmarie Pyrek1 Thomas Voglmayr2 Franz Waxenecker3 Ursula Hofstetter1 Georg Bruns4 Mathias Ritzmann1
1. Clinic for Swine, Vienna, Austria; 2. Traunkreis VetClinic, Ried im Traunkreis, Austria; 3. Biomin GmbH, Herzogenburg, Austria; 4. Tierärztliche Klinik Düenmerland, Steinfeld, Germany

Introduction
During the summer months lesions of the so-called ear necrosis syndrome can be observed frequently in weaners during the raising period. The stages range from mild epidermal changes to severe ulcers and necrosis (1). In the past, various pathogens have been discussed to be responsible for the development of ear necrosis, but the exact etiology of this disease could not be determined. Aim of this study was the data collection through questionnaires in farms with pigs with ear necrosis syndrome.

Materials and Methods
Questionnaires were sent to Austrian and German veterinarians. The parameters of interest were kind of necrosis (tip of the ear (T), margin of the ear (M) or flank (F) necrosis) stadium of disease, severity, percentage of affected pigs, age and weight of pigs, additional symptoms, feeding, husbandry, positive experience with any treatment or prophylaxis, previous illness as well as occurrence of cannibalism.

Results
In total, 54 questionnaires were returned to the clinic for swine. 88.7 % of them declared to see the ear necrosis syndrome often and 94 % estimated ear necrosis to be a considerable problem in swine production. 90.7 % reported to have problems with necrosis at the tip of the ear, 57.4 % with necrosis at the margin of the ear, and only 14.8 % with flank necrosis. Percentage of affected pigs, as well as age and weight of pigs are presented in table 1. Most of the animals, independent of the kind of necrosis, were in a chronic stadium of disease, there were only a few acute cases. The severity of disease was estimated as follows: flank necrosis: mild symptoms, both kinds of ear necrosis: moderate symptoms. In about half of the farms the pigs showed wasting, 32.1 % had diarrhea. Concerning feeding, only one veterinarian reported a low quality of feeding stuff. 22.6 % associated the occurrence of ear necrosis with a change in the feeding strategy. Only 5.6 % observed a reduced feed intake. Related to husbandry the main problem was the pig density. All other parameters as temperature, cleaning, disinfection were not considered to be problematic. 72.2 % reported positive experiences with different treatment or prophylactic measures (68.4 %: antibiotics, 2.6 %: vaccination, 2.6 %: management improvement, 28.2 %: combination of different measures). 22.2 % of the farms reported any illness previous to the occurrence of ear or flank necrosis (41.7 %: bacterial infection (gram negative), 25.0 %: bacterial infection (gram positive), 8.3 %: viral infection, 25.0 %: multifactorial infection). Cannibalism was considered to be the reason for the occurrence of ear necrosis in 51.0 % of the cases.

Discussion
The present study showed that ear and flank necrosis is of concern to swine practitioners. If ear necrosis appears, about one third of the pigs are affected. The economic losses increase because of concomitant symptoms as diarrhea and wasting. Not only infectious diseases seem to be relevant; management, feeding and husbandry are also significant factors. The results of this evaluation pointed out clearly that ear and flank necrosis are mainly caused multifactorial as shown in other studies (2, 3).

**Introduction**

Fusarium spp. are recognized as a source of common mycotoxins, and storage fungi include the genera Aspergillus and Penicillium, which account for several mycotoxins important in swine production. A few of significant mycotoxins include aflatoxin and Ochratoxin A belonged to Aspergillus spp, ochratoxin, deoxynivalenol, zearalenone, fumonisin and T-2 toxin belonged to Fusarium spp. Aflatoxin and ochratoxin mycotoxins, as well as Fusarium, have been shown to be the destruction of the immune system and immunosuppressive. This study was to survey about fungi and mycotoxins occurrence in Swine Feed of different regions in Korea [1].

**Materials and Method**

A total of 202 feed samples were evaluated for survey of Fungi and Mycotoxins. Also all samples were classified by growth period, regions. Culture processes of samples were performed by potato dextrose agar. Then microscopic examination was performed after staining process. The photomicrographs captured by OPTIMAS 6.1 were referred to mycology online and CAB International by E-mail. Simultaneity, the samples collected were examined by ELISA technique after processing. AgraQuant® Mycotoxin Test Kit was used to estimate mycotoxin ELISA titre.

**Results**

In morphologic diagnosis process, 3 types of fungi, Aspergillus spp., Fusarium spp. and Rhizopus spp. were identified by microscopic examination. Aspergillus spp., Fusarium spp. and Rhizopus spp. were observed in 97, 25 and 19 samples, respectively. The rests of 61 samples were unidentified. By analyzed samples from various growth period, belonged to Aspergillus spp., in growing, fattening, pregnant, and farrowing were 17, 32, 27 and 21, respectively. In Fusarium spp., were 2, 12, 9 and 2 samples, in Rhizopus spp., were 1, 11, 4 and 3 samples, respectively. By regions, belonged to Aspergillus spp., in Gangwon-do, Gyeongsang-do, Chungcheong-do, Gyeonggi-do and Jeolla-do were 37, 21, 19, 11 and 9 samples, respectively. In Fusarium spp., were 4, 5, 3, 7 and 6 samples, in Rhizopus spp., were 3, 5, 2, 3 and 6 samples, respectively. By feeder type, 30 samples were dry and humid-typed feeder and 41 samples were dry-typed feeder. In dry and humid-typed feeder, Aspergillus spp., Fusarium spp. and Rhizopus spp. were observed in 12, 5 and 6 samples. Whereas, in dry-typed feeder, those were observed in 9, 4 and 4 samples, respectively. By ELISA analyze of mycotoxins, incidences of contaminated samples were 75.24% for aflatoxin, 5.94% for ochratoxin A, 47.02% for zearalenone, 68.31% for fumonisins, not detected for T-2 and 78.91% for deoxynivalenol, respectively. The mean value of contaminated samples were 7.67±1.86 μg/kg for aflatoxin, 5.10±2.87 μg/kg for ochratoxin A, 128.32±99.04 μg/kg for zearalenone, 880.00±800.00 μg/kg for fumonisins, not detected for T-2 and 510.00±210.00 μg/kg for deoxynivalenol. Eleven samples were against MEL regulation with those contaminated at a concentration of over 10ppb of aflatoxin. Among them, 6 samples had mixed contamination with zearalenone, fumonisin and deoxynivalenol.

**Conclusions**

The most of the fungi identified from swine feed were Aspergillus spp. By growth period, any fungi were not observed in feed of weaned pig. In rest period, 3 types of fungi were similarly observed. But generally, a number of fungi were observed in feed of fattening pig. By province, the most of fungi were observed in Gangwon-do, Gyeongsang-do and Chungcheong-do. Eleven samples exceed maximum exposure limits regulation on aflatoxin, although T-2 has not been detected in our samples. Detection rates of humid-typed feeder were shown higher than those of dry-typed feeder. Based on the results, the development of mycotoxins might be associated with environment. Therefore, the management of feed would consider important to provide against the damage by mycotoxins, as environment and climate are responsible for the development of it.

Biochemical parameters in blood from pigs experimentally intoxicated with aflatoxin B1 and Fumonisina B1

Susana E. Mendoza, Elvira Abel Ciprian-Carrasco, Carolina Moreno-Ramos, Eliseo Hernández-Baumgarten, Ernesto Moreno-Martínez, Francisco Quezada, Jorge Tortora-Perez, Rosalia Meléndez-Pérez, Horacio Lara-Puente, Isabelle P. Oswald, Patricia Pérez, Sara Valdes-Martinez

1. FESC-UNAM, Cuautitlán, MEX, Mexico; 2. Laboratorios Avi-Mex, S.A de C.V., Iztapalapa, Mexico; 3. Pharmacology and Toxicology Laboratory, UR 66, National Institute of Agronomic Research INRA, Toulouse, France

Introducción
The mycotoxins are secondary metabolites produced by fungi, of which the aflatoxin B1 (AFB1) and Fumonisina B1 (FB1) are important due to their toxicity and carcinogenicity. Aflatoxin affects negatively growth, feed conversion and consumption in pigs. The most affected organs are: the liver, and kidney. Fumonisins on the other hand causes pulmonary edema (1,2,3).

Material y Methods
The FB1 used was a standard (SIGMA), in 5 mg and 10 mg vials with 98 % purity. A stock solution was prepared at a concentration of 87ppm in distilled water. The FB1 was administered to weaned pigs in 12ppm (mg/kg live-weight) by the oral route by means of a probe. For AFB1 we used a Sigma standard in presentation 5 mg per vial with a 98 % purity. A stock solution was prepared in benzene-acetonitrile. The administration of the AFB1 to weaned pigs was at a dose of 8 ppb (μg/kg live-weight) by mouth using a probe. The experimental animals were 16 pigs 21 to 36 days of age of either sex, with an average weight of 7 kg. The animals were distributed randomly into 4 groups, each group was composed of 4 pigs, with the following distribution: negative Group A: Control.; Group B: intoxicated with FB1. Group C intoxicated with 8ppb of AFB1. Group D: intoxicated with 12ppm FB1 and 8ppb with AFB1.

The studied variables were body weight, the serum concentration of total proteins, albumin, the enzyme concentration of AST, (γ-glutamic tranferase) GGT, direct, indirect and total Bilirubins. The data were evaluated by ANOVA with a 95 % significance level, using the statistical programme Statgraphics Plus version 5.0.

Resultados
The results of the measurement of daily weight gain were: 0.22 kg for Group A, 0.043 kg for Group B, 0.074 kg for Group C and finally 0.002 kg for Group D. Evaluation of AST and GGT serum, results showed an increased activity in groups B, C and D. Protein levels showed no significant changes. Levels of albumin showed a slight decrease in the group B. The bilirubulins were increased in groups B, C and D, and the effect was more marked in Group B.

Discusión
The daily weight gain showed significant differences between group A and D, with values of 0.22 kg and 0.002 kg respectively. These results differ from those reported by Zomborszky et al 4., where they cite that the differences in body weight gain was not statistically significant at the end of the experiment. AST levels in groups, B, C and D showed increased values that is consistent with Dilkin, P. et al, 5 . The GGT levels reported in literature are very diverse, but all showed an increase in intoxication by mycotoxins. The decrease in protein levels was notorious in group B compared with the other groups. The variability of values is due to the concentration of mycotoxins, time of exposure and age of the animals (6). The decrease in levels of serum albumin was more pronounced than total proteins. Albumin has a plasma half-life of 21 days, so that as a measurement of liver function is not very pronounced until three weeks of intoxication (6) that the liver failure is triggered. The decline of bilirubin was most significant in Group B, this show that the FB1 affects the liver.

Conclusions.
The assessment of biochemical parameters shows sensitivity and effectiveness to detect liver damage using small doses of mycotoxins.

Salinomycin and tiamulin toxicosis in Finish pigs
Kialane C. de Almeida¹ Michelle d. Gabardo¹ José Cristani¹ Joselito Daniluz² Sandra D. Traverso¹
1. UDESC, Lages, SC, Brazil; 2. COOPERCAMPOS, Campos Novos, SC, Brazil

Introduction
The Salinomycin ionophore is an antibiotic used as anticoccidial in poultry and as growth promoters in cattle, sheep and pigs (1). The tiamulin is used in treatments for respiratory and enteric complications (2). These, when used alone in appropriate doses, do not cause damage to animals, but ionophores are myotoxic in excessive doses (3). Poisonings occur because of mixing error of the drug with the feed (4), dosage error (5), use on non-target species (6), or normal doses associated with drugs that maximizing its effects, such as chloramphenicol and tiamulin (7). The tiamulin acts by reducing the elimination of the ionophore, leading to intoxication (8). Clinical signs are characterized by vomiting, inapetency and locomotor disorders (9). The work aims at reporting an outbreak of natural poisoning by salinomycin associated tiamulin in pigs in Brazil.

Materials and Methods
Epidemiological data were obtained with the vet about the animals. Two pigs were euthanized for necropsy. Samples of viscera, brain, heart and skeletal muscles were collected, fixed in 10% formalin, processed routinely for histological examination (10).

Results
A batch of 940 finishing pigs were fed with diets containing 30 ppm of salinomycin. The pigs received tiamulin at a dose of 110 ppm in-feed for eight days, for control of respiratory diseases. In the first day after the end of treatment, one animal was found slumped. On the next day two animals showed coordination disorders, stiff gait, reluctance to move, muscular trembling, depression, emaciation and recumbence. These animals were euthanized for necropsy, which presented slight pallor of the muscles of the leg. Histological examination showed, marked extensive hyaline necrosis of skeletal myofibers with mild to moderate infiltration of macrophages. The lesions were more intense in longissima, diaphragm and masseter muscles. The heart had mild multifocal infiltration of macrophages, loss of myofibers and areas with regeneration. The feed of the entire batch was replaced. On the following days, several animals showed locomotor disturbances and after the grace period of medicines, all animals were sent for emergency slaughter.

Discussion
Epidemiological data, clinical and lesion sign observed and reported are consistent with toxic myositis and are similar to those described in ionophore poisoning in pigs (9). In this outbreak the doses of salinomycin and tiamulin were in accordance with the therapeutical dosage for age and species when used alone, indicating that tiamulin probably interfered in the excretion of salinomycin. Concerning pigs in Brazil, the poisoning ionophore should be distinguished from Vit.E – Se deficiency, where the muscle injuries are usually accompanied by cardiac and hepatic lesions similar to those observed in mulberry heart disease and hepatitis dietetica (11); Aescinomene indica poisoning (12), where locomotor difficulties are secondary to specific neurological lesions and Cassia occidentalis (13) poisoning which can be distinguished through the epidemiological data of the supply of ionophore to animals or through the evidence of the plant mixed in the diet.

1. University of Veterinary Medicine Vienna, Vienna, Austria; 2. Medical University of Vienna, Vienna, Austria

Introduction
Outcome after prolonged normovolemic cardiac arrest is poor. The technique of evaluating the neurologic state and the overall performance category in pigs resuscitated after cardiac arrest has already been optimized (1). Emergency preservation and resuscitation (EPR), which is the induction of hypothermia during the arrest, followed by hypothermic stasis during transport to resuscitation with cardiopulmonary bypass (CPB), might be a new concept for patients with prolonged cardiac arrest. We have shown previously that induction of deep cerebral hypothermia via ice cold saline aortic flush during cardiac arrest just before resuscitation improved neurologic outcome in pigs (2). To avoid fluid overload, we further developed a cardiopulmonary bypass cooling system (CPBCS) for rapid induction of hypothermia (3). We hypothesized that changes in cytokine expression during EPR could be predictive of resuscitability and 9-day survival.

Materials and Methods
21 Large White sows (31-38 kg BM) were subjected to 15 min of untreated ventricular fibrillation, followed by cooling with a CPBCS for 1, 3, or 5 min achieving brain temperatures (Tbr) of 30.4 ± 1.6°C, 24.2 ± 4.6°C, and 18.8 ± 4.0°C, respectively. After 40 min of rewarming with CPB, pigs were defibrillated and kept at Tbr of 34.5°C for 20 hrs, survival was for 9 days. Plasma samples were analysed for interleukin (IL)-6, tumor necrosis factor-a (TNF-a), and IL-10 levels by ELISA. Total RNA out of PBMCs was analyzed by real-time PCR for IL-1, IL-2, IL-4, IL-10, TNF-a, interferon-γ, iNOS, and heme oxygenase-1 (HO-1) gene expressions.

Results
11 out of 21 pigs survived to day 9. In the plasma of all animals, a remarkable increase in proinflammatory cytokine levels could be observed following cardiac arrest and resuscitation. However, no significant differences in cytokine expressions could be found as a consequence of different intra-arrest hypothermia levels. On the other hand, IL-10 was identified as prognostic marker with decreasing mRNA levels during cardiac arrest in 9-day surviving animals but increasing ones in the non-survivors.

Discussion
The systemic changes in the postresuscitation syndrome are mainly characterized by a proinflammatory state similar to the systemic inflammatory response syndrome (SIRS) and thus termed a sepsis-like syndrome (4). Interestingly, SIRS is not only characterized by elevated inflammatory cytokine levels including IL-1, IL-6, and TNF-a, but also may be the consequence of a more profound dysregulation of the immune system, which is inferred from elevated IL-10 titers (5). Our study confirmed that pigs upregulate markers of systemic inflammation following cardiac arrest, intra-arrest hypothermia, and resuscitation, thus resembling the postresuscitation syndrome. The slight increase of IL-10 mRNA in non-survivors may account for a change in the functional properties of white blood cells. These findings hopefully will lead to improved intervention methods for the benefit of survival rate after restoration of spontaneous circulation following cardiac arrest.

Chemotherapy induces partial remission of mast cell leukemia in a minipig

Wolfgang Sipos1 Johannes Hirschberger2 Wolfram Breuer2 Isabella Zenker2 Sabine Elicker3

1. University of Veterinary Medicine Vienna, Vienna, Austria; 2. Ludwig-Maximilians University Munich, Munich, Germany; 3. Veterinary Practice Entenfellner, Stössing, Austria

Introduction
Mast cell tumors are classified as cutaneous or systemic. Cutaneous mast cell tumors represent a comparably frequent malignancy in dogs and cats, but only single reports about cutaneous mast cell tumors in pigs and only one referring to a case of porcine mast cell leukemia (1) can be found in the literature. In the following, a chemotherapy in a porcine leukemia patient is presented for the first time.

Case Report
This report describes a chemotherapeutic approach of treating mast cell leukemia in a three-year old, male-castrated Göttingen miniature pig weighing 27 kg. The animal had been submitted to the clinic due to a mildly depressed behaviour lasting for a month and a mild anemia. Hematologic analysis (Cell-Dyn 3500®; Abbott) including a modified Wright stain led to the diagnosis of a mast cell leukemia. Three days after the diagnosis of mast cell leukemia, chemotherapy was started based on a protocol applied in dogs suffering from cutaneous mast cell tumors (2). Induction therapy comprised weekly IV infusions of 2 mg/m2 vinblastine sulfate for four weeks. Concomitantly, 2 mg/kg prednisolone were given daily per os. IV infusions were performed under general anaesthesia achieved with IM application of 20 mg/kg ketamine and 2 mg/kg azaperone. Combined chemotherapy led to a reduction of total leukocyte count from 30.6 G/l to 25.3 G/l and a reduction of mast cell count from 18.05 G/l to 10.57 G/l. Animal’s behaviour became undisturbed again and no adverse side effects could be observed. For the next two weeks, no vinblastine was given. During this time, mast cell number increased to 35.34 G/l. As a consequence, weekly vinblastine applications were restarted and prednisolone was replaced by oral 50 mg cyclophosphamide boli supplemented by oral 20 mg furosemide boli, both given every second day. Furosemide administration aimed at achieving an accelerated clearance of cyclophosphamide metabolites and at abrogating the establishment of a hemorrhagic cystitis. Again, no adverse side effects could be recorded, but mast cell number continued to increase and peaked at 55.59 G/l one month thereafter. The multiagent protocol was applied for 6 weeks. Then vinblastine was given in a two-week interval. After 17 treatment rounds corresponding to an overall treatment period of half a year, overall behaviour became depressed again and feed consumption was decreased. At that point, total white blood cell number had increased to 83.7 G/l with a mast cell count of 33.48 G/l. At the same time, red blood cell count had dropped markedly. Therefore, the owner decided to stop treatment and to euthanize the animal. At necropsy a reduced body condition, an anemic state, a splenomegaly, and gastric ulcers were evident. Histologically, an infiltration of inner organs as well as bone marrow by neoplastic cells, which stained multifocally positive for CD117 and more diffusely positive for chloroacetate esterase, could be found.

Discussion
Minipigs, which are kept as pets, are increasingly cared for at a higher medical standard as conventional pigs (3). Unfortunately, there is a lack of suitable treatment regimens of systemic mast cell tumors. Therefore, humans suffering from mast cell leukemia are treated mainly by corticosteroids and antihistamines. Prognosis for human mast cell leukemia is poor. Also in dogs systemic mast cell tumors are bad responders to chemotherapeutic interventions (4). In the presented case, the initial response to a vinblastine-prednisolone combination protocol was quite satisfying with mast cell number decreasing during the first four weeks of chemotherapy. Due to the following relapse another cytotoxic agent, cyclophosphamide, was included, but was unsuccessful in averting tumor progression.

Improved neurologic deficit score for pigs in a cardiac arrest model

Katharina Haas¹ Michael Holzer² Alexandra Graf² Fritz Sterz² Wolfgang Weihs² Andreas Janata² Wilhelm Behringer² Wolfgang Sipos¹

¹ University of Veterinary Medicine Vienna, Vienna, Austria; ² Medical University of Vienna, Vienna, Austria

Introduction

Cardiac arrest is unique in that when the heart stops, many otherwise healthy organs suffer injury, particularly the brain, the myocardium, and the endothelium. Therefore the goal of resuscitation is to restore victims to full health, including good neurological outcome. Resuscitation research studies the pathophysiology of acute terminal states and clinical death. Acute and short-term experiments in animals help to better understand mechanisms of dying and to evaluate the short-time effect of new resuscitation protocols. To evaluate long-term benefit of potential new treatments on neurologic recovery in resuscitation research, clinically realistic long-term outcome studies including evaluation of neurologic and histologic brain damage in animals high on the phylogenetic scale are necessary.

Recently, our group published a novel and reliable score for evaluation of neurologic outcome in pigs after cardiac arrest.1 The neurologic deficit score (NDS) consists of four equally weighted sections: mental status, breathing pattern, cranial nerve reflexes, and motor and peripheral sensory functions. Aim of this study was to re-evaluate and optimize the neurologic examination procedure in order to make it even more observer-independent by elucidating and then topping off the critical points of the NDS.

Materials and Methods

16 female Large White pigs (32 kg in the mean) were put into ventricular fibrillation cardiac arrest of 15 min duration followed by cooling to achieve different degrees of preservative hypothermia for 40 min. After resuscitation (ROSC: restoration of spontaneous circulation), controlled ventilation was for 24 h, and intensive care for 3 days. Neurologic evaluation was done independently by two observers, blinded to the experiments, at 72 h and 9 days post ROSC. The critical points of the NDS as published by Sipos et al. (2008), namely the evaluation of the mental state and, interestingly, the breathing pattern, were optimized.

Results

A significant difference in the NDS score between hypothermia groups was found (f-test p=0.0127). No significant difference in the NDS score was found between the two observers. The ICC (intra-class correlation coefficient) determined using analysis of variance components for the NDS score was 20.7 % indicating that 20.7 % of the total variability can be explained by the variability between the pigs. The largest contribution to the total variability came from the variability between time points (intervisit SD=68.22). Furthermore, a large contribution came from the variability between hypothermia groups (inter-treatment SD=47.15). The large variation over days and treatments also explained the small ICC. Practically no contribution to the total variability came from the variability between the observers (interrater SD <0.001), which indicates a good repeatability of the score between observers.

Discussion

The evaluation of a pig’s mental state is very tricky under special situations, as for sure is the immediate post-no-flow time, as pigs are, by their nature, psychically very autonomous animals. However, the optimized NDS showed to be even more examiner-independent than the already published one, as also the mental state as well as the breathing pattern were now judged the same by both investigators in the majority of cases. At the same time, also the published overall performance category (OPC) score (1) was optimized (data not shown). The OPC score gave nearly 100 % identical results by both investigators and may be even more appropriate than the NDS in specific clinical settings.

Ovariectomy and calcium shortage have no obvious effect on bone metabolism in adult sows

Wolfgang Sipos\textsuperscript{1} Martina Rauner\textsuperscript{2} Peter Pietschmann\textsuperscript{3}

\textsuperscript{1} University of Veterinary Medicine Vienna, Vienna, Austria; \textsuperscript{2} Carl Gustav Carus Universitätsklinikum Dresden, Dresden, Germany; \textsuperscript{3} Medical University of Vienna, Vienna, Austria

\section*{Introduction}

For a long time, osteoporosis was ascribed nearly exclusively to an increased activity of osteoclasts, but now it has been recognized, that also depressed osteoblastogenesis contributes to osteoporosis. Recently, osteoimmunology has emerged as a central area of interest as peripheral blood cells, cytokines, and other soluble immunomodulators exert their impact on a series of osteopathologies including osteoporosis (1). Thus, osteoporosis has been recognized to involve more than simply a skeletal system with decreased bone mineral density. Consequently, new therapeutic strategies need to be developed. To date, the majority of basic osteologic experiments has been performed using rodents, which have a lot of advantages in terms of laboratory management, but also large animal models might be beneficial for osteoporosis research due to biomechanical issues.

Multiparous sows – in contrast to nulliparous sows – being fed a standard diet containing 1.5 % calcium exhibited significantly increased plasma PTH and calcitriol levels at 8 months post ovariectomy and alkaline phosphatase levels at 12 months post ovariectomy. No significant changes concerning bone chemistry and histomorphometry could be observed (2). On the other hand, there have already been successful efforts to establish an osteoporosis minipig model (3). Ovariectomy in 4 months old minipigs resulted in a 6 % decrease in bone mineral density (BMD), 15 % in bone volume, and 13 % in trabecular number, and an increase of 15 % in trabecular separation, whereas ovariectomy in combination with a mild nutritive calcium shortage (0.75 % Ca\textsuperscript{2+}) led to a 10 % reduction in vertebral BMD and significant increases in final erosion depth and vertebral marrow star volume. These data implicate, that an ovariectomy alone is sufficient to induce an osteoporotic phenotype in (mini)pigs, which can be even more pronounced by restricting calcium supply.

\section*{Materials and Methods}

32 Large White sows aged 33.5 months in the mean were included and distributed equally to four groups:

1. sham-ovariectomy, 0.75 % Ca\textsuperscript{2+}
2. sham-ovariectomy, 0.3 % Ca\textsuperscript{2+}
3. ovariectomy, 0.75 % Ca\textsuperscript{2+}
4. ovariectomy, 0.3 % Ca\textsuperscript{2+}

Blood samples were collected by venipuncture every 2 months. The experiment was terminated after 10 months. Serum levels of following bone metabolism markers were determined by commercially available ELISA kits: receptor activator of nuclear factor-kB ligand, osteoprotegerin, calcitriol, PTH, bone specific alkaline phosphatase, osteocalcin, CICP, pyridinoline, and crosslaps.

\section*{Results}

Analyses of indicated marker kinetics revealed no meaningful trends in general or differences between the four groups and thus gave no evidence of any ovariectomy- or calcium shortage-induced change in bone metabolism.

\section*{Discussion}

Interestingly, ovariectomy and calcium shortage alone as well as a combination of these two did not lead to any effect on bone metabolism as delineated from the analysed marker kinetics. This is quite surprising, as other authors (2) found increasing PTH, calcitriol, and BAP plasma levels in sows of the same age group as the ones we investigated, although those were only ovariectomized but fed a standard diet. On the other hand, most investigators analysing the effects of ovariectomy and/or calcium shortage used minipigs or growing pigs, thus making a comparison with the data obtained from our study difficult.

Cytokine modulation of yeast derivatives investigated on a lipopolysaccharid-activated monocyte-macrophage cell line

Anja Ganner; Christian Stoiber; Manuela Pelz-Studlar; Simone Schaumberger; Gerd Schatzmayr

Biomin Research Center, Tulln, Austria

Introduction

Cytokines are signaling molecules which play an important role in cellular communication. Modulation of cytokine secretion may offer novel approaches in the prevention and treatment of a variety of diseases in human and veterinary medicine. TNF-alpha, IL-1, IL-6 are important cytokines which are secreted by immune cells such as macrophages after endotoxin (LPS) exposure and are involved in endotoxic shock which can cause severe economic losses in swine production. Therapeutical approaches in veterinary field aim to minimize or to prevent inflammatory parameters triggered by endotoxins. Counteraction of pro-inflammatory cytokines with feed additives such as yeast derivatives might be an interesting approach.

Yeast derived beta-glucan fractions are described in the literature to interact with cytokines. Aim of the present study was to investigate the effect of different yeast derivatives such as beta-glucans, whole yeast, yeast extract and yeast nucleotides on nitric oxygen (NO) production, pro-and anti-inflammatory cytokine levels after LPS stimulation of the murine monocyte-macrophage cell line J774A.1.

Materials and Methods

Monocyte-macrophage cell line:

J774A.1 is a BALB/c mouse derived monocyte-macrophage cell line isolated from a tumour. Cells were cultured in tissue culture flasks at 37°C in DMEM complete growth medium supplemented with 10% fetal bovine serum. Subcultures were prepared by scraping adherent cells 1 to 2 times per week and re-seeded 1:4 into fresh media.

Cell culture assay:

J774A.1 cell number and viability were assessed by trypan blue dye exclusion on a Neubauer hematocytometer. For the experiment, cells were seeded at a concentration of 106 cells/well in a 24-well tissue culture plate. Cells were incubated for 48 hours with LPS of E. coli 0127:B8 and the yeast derivative, which was either yeast derived beta-glucan, yeast nucleotide, yeast extract or whole yeast (0.1%, 0.02%, 0.01% solutions in phosphate buffered saline). Produced nitric oxygen was determined after 48 hours of incubation in the supernatant of the cultures using a Griess reagent which provides a colorimetric reaction. Pro-inflammatory cytokines IL-1, IL-6, TNF-alpha and the anti-inflammatory cytokine IL-10 were detected with ELISA assay (R&D Systems).

Results

Yeast extract and yeast nucleotides inhibited LPS induced NO-production between 20 and 50%; beta-glucan fraction up to 80% depending on the used concentration. Whole yeast did not affect LPS induced NO-production. IL-6 was inhibited between 20 and 40% by beta-glucan, by yeast nucleotide around 20%. Whole yeast did not inhibit IL-6 on a notable level. IL-1 was inhibited to 70% by a yeast nucleotide product, between 40 and 100% by beta-glucan and to 50% by whole yeast. TNF-alpha was inhibited around 40% by nucleotides, beta-glucans and also by whole yeast. All yeast derivatives tested induced IL-10 production.

Discussion

The present results revalue that yeast derivatives inhibited LPS induced pro-inflammatory cytokines and elevate anti-inflammatory IL-10 levels. However, the mechanism behind, the mode of action is not yet understood. A fully chemical characterization concerning mannan-and glucan content and nucleotide profile might be illuminating.

In conclusion, yeast derivatives which interfered in this in vitro study with IL-1, IL-6, TNF-alpha and IL-10 might be an interesting approach in the control and prevention of endotoxic shock in swine production and this might impact positively on animal health. However, it is too early to estimate to what extent these expectations are going to be fulfilled in vivo. In any case they justify further multidisciplinary research in this field.

**Isoimmune thrombocytopenic purpura in newborn piglets: a case report**

Elena Galletti1 Giuseppe Merialdi1 Andrea Antonelli2 Elisa Brini3 Laura Fusaro3 Giuseppe Sarli3 Maria C. Fontana1 Brunella Spaggiari1 Paolo Martelli4

1. Istituto Zooprofilattico Sperimentale della Lombardia e dell’Emilia Romagna, Bologna, Italy; 2. Veterinary Practitioner, Ravenna, Italy; 3. Veterinary Clinic Department, University of Bologna, Bologna, Italy; 4. Department of Animal Health, University of Parma, Parma, Italy

**Introduction**

Isoimmune thrombocytopenic purpura (ITP), firstly described by Stomorken et al. in 1963, is a sporadic disease affecting newborn piglets, mainly from secondiparous or multiparous sows. Large White and Landrace are the most affected breeds. ITP is an immune-mediated disease subsequent to colostral transfer anti-platelet (PLTs) antibodies produced by sow against the antigens originating from the boar semen (Saunders and Kinch, 1968). Multiple haemorrhages develop in piglets when platelets are lower than 30,000-50,000/μl, leading to death the whole litter or a part of it. The Authors describe a case of ITP occurred in a farrow to finish pig herd.

**Materials and Methods**

An hemorrhagic syndrome occurred in 28 litters of a farrow to finish pig herd between May 2008 and Jan 2009. Only one of the sows was primiparous. Sows had been inseminated during 3 days using mixed semen from different boars. During the first week of age seventeen percent of the piglets showed haemorrhagic diathesis, characterised by multiple haemorrhages, spontaneous petechiae and diffuse ecchymoses. The death rate ranged from 0% to 50%. Six piglets were submitted to necropsy, histological bacteriological, virological and toxicological examinations. Furthermore, 6 piglets with haemorrhagic syndrome and 3 coetaneous healthy piglets from the same farrowing batch were submitted to complete blood cell count (CBC).

**Results**

Hemorrhagic lesions characterised by multiple haemorrhages, spontaneous petechiae and ecchymoses were detected in piglet skin, subcutaneous tissue, inner organs and mucous/serous membranes. The most affected sites were head, abdomen, groin and soles. Kidneys and lymph nodes presented disseminated haemorrhages and hemorrhagic suffusions were evident in mesocolon and epicardium. Histology confirmed the presence of multivisceral interstitial hemorrhages, extramedullary hema topoiesis and interstitial pneumonia. Bacteriological, virological and toxicological examinations provided negative outcomes. CBC results are presented in the following table.

**Discussion**

On the basis of laboratory results ITP was diagnosed. BCC showed a marked decrease in PLTs (absence of PLT aggregation), Hb, HCT and RBCs in affected animals. Moreover, a pattern of regenerative anemia and reticulocytosis was detected. For differential diagnosis, infectious and toxic diseases were ruled out. Combining all data a diagnosis of an immuno-mediated disease was suggested. The marked thrombocytopenia and the absence of direct or indirect signs of erythrocytolysis allowed to rule out the haemolytic disease of newborn pigs (Taylor 2008). From Jan 2009 the insemination practice was modified using the semen from one boar only for each sow. Consequently, one boar was associated with the occurrence of the diseases in offspring and it was culled.

**Agents isolated in pericarditis cases from pigs in the nursery, growing and finishing in Brazil**

Jose L. Santos; Lucas F. Santos; Daniel L. Santos; Hellen P. Pasqualon; Walter V. Guimaraes

Microvet, Vicosa, MG, Brazil

**Introduction**

Pericarditis in pigs can be caused by various pathogens, such as Haemophilus parasuis, Pasteurella multocida, A. pleuropneumoniae, A. suis, Streptococcus suis and Mycoplasma sp (Mores, 2007). Pericarditis is the inflammation of the parietal and visceral surfaces of the pericardial cavity. May occur independent of other lesions, but is often observed in association with a pleurisy. Among the various forms of pericarditis, fibrinous pericarditis is more commonly found. It’s characterized by the presence of a serous fluid and marked fibrin deposition on the surfaces of the pericardium and epicardium, leading to heart failure (Jones et al., 2000). This study aims to identify the mainly agents involved in fibrinous pericarditis in pigs in the nursery, growing and finishing.

**Materials and Methods**

We evaluated 129 cases of fibrinous pericarditis in animals with ages ranging from 20 to 106 days. Swabs were collected from pericarditis, then added 3 ml PBS and plated on blood sheep agar and blood sheep agar with staff nurse. The plates were incubated at 37° C for 24 to 48 hours. And were performed the morphology identification of the colonies and biochemical tests for confirmation of the agent. And serology for H. parasuis and S. suis were performed in Microvet laboratory.

**Results**

We obtained a result quite varied among the several agents. The mainly agent observed was the H. parasuis (Hps) 38/129, distributed as: non serotypable (14/129), serotype 5 (10/129), serotype 4 (4/129), serotype 1 (3/129), serotype 2 (3/129), serotype 12 (2/129) and serotype 14 (2/129). Other agents were observed such as: P. multocida type A (Past A) 20/129 and P. multocida type D (Past D) 12/129. S. suis 8/129, distributed as: serotype 2 (4/129), serotype 3 (2/129), serotype 7 (1/129) and serotype 8 (1/129). A. pleuropneumoniae (APP) 4/129, A. suis (3/129). Some co-infection were observed between APP and the Past A (1/129), Hps serotype 12 and the Past D (1/129), Hps non serotype and Past D (1/129) and S. suis serotype 2 and Past D (1/129). And 40 animals had were negative for bacterial isolation (Graphic 1).

**Discussion**

This study allows us to conclude that the onset of pericarditis is actually connected to various agents as described by Mores, in 2007. However, it is noteworthy that the H. parasuis has a great contribution to pericarditis. The serotype 5 is closely associated to conditions of Glasser’s disease in Brazil (Santos et al. 1998), and was found in most reported cases of pericarditis caused by this agent, like H. parasuis non serotypable. Other agents such P. multocida A and D, can also has great importance in the development of fibrinous pericarditis.

Positional and functional genomics to resolve genetic disease resistance in swine

Gerald Reiner
Department of Veterinary Clinical Sciences, Justus-Liebig-University, Giessen, Germany

Introduction
This review deals with genetic disease resistance in pigs as a prospective opportunity to improve swine production. Even under favourable terms of housing and management, infectious diseases are widespread, and have to be ranked among the major sources for production losses, decreased production efficiency and suffering in international pig production. Thus, breeding for disease resistance might be the prophylactic measure of first choice. Increased resistance to a certain pathogen or even a group of pathogens would reduce infectious pressure, followed by a decreased incidence of disease. Using disease resistant breeds is already of considerable importance in some livestock species. Examples with highest significance are the resistance to coccidiosis and Mareks disease in fowl, to trypanosomiasis and ticks in cattle, to mastitis in dairy cattle, and to gastro-intestinal nematodes in sheep. In pigs, however, examples of disease resistance in commercial breeding programs are sparse. The prime example is resistance to fimbriated F18 Escherichia coli, the cause of postweaning diarrhoea and edema disease. It is an exceptional case of single-gene control of disease resistance. Other examples include the breeding for improved immune responsiveness, and resistance to fimbriated F4 Escherichia coli (neonatal diarrhoea). Today worldwide efforts are concentrating on marker development and genomic selection strategies to improve genetic disease resistance. In spite of the currently limited commercial application in swine, a wide range of genetic variation in disease resistance has been observed regarding different bacterial, viral and parasitic diseases. The problem is to recognize breeding animals with favourable or unfavourable gene variants. Their identification is impeded by highly variable and influential farm-specific environmental effects (e.g. load of pathogens, immunity, housing, feeding and management conditions), the polygenic mode of inheritance in most of the resistance traits, the limited availability of animal models, and the limited knowledge on pathogenicity of several porcine diseases. Improved knowledge of the porcine genome combined with the tools and technologies developed in the context of the genome projects are creating new opportunities to dissect the genetic control of complex traits, including host responses to infection. Thus, one alternative might be to identify the gene variants responsible based on informative families tested under defined environmental conditions. Upon the development of a genetic marker for disease resistance, breeding stock could then be chosen by marker-assisted selection independently from environmental factors. The aim of our studies is to develop such animal models and to describe disease resistance on a molecular basis. Our models deal with the Pseudorabies virus (PrV; Reiner et al., 2002), Sarcocystis miescheriana (S.m.; Reiner et al., 2007), Salmonella typhimurium, PRRSV (Reiner et al., 2010), and A. pleuropneumoniae (APP).

Materials and Methods
Potential host-pathogen models are studied based on accurate infection models with purebred breeds or lines. Functional genome analysis with DNA microarray techniques gives first hints on candidate genes. They are combined with positional genome analysis (QTL (quantitative trait loci) analysis) to define candidate genes worth looking for single nucleotide polymorphisms (SNPs) that might be useful as markers in future selection.

Results and Discussion
Our results show marked differences in resistance to PrV, S.m., PRRSV and APP. Moderate to high heritabilities point towards favorable and unfavorable gene variants. QTL analysis has identified the chromosomal regions involved, and some candidate genes have been suggested for further research. In spite of the polygenic character of disease resistance, our results verify that also single outstanding loci, suitable for selection are involved. We have further provided evidence for common mechanisms of resistance in different disease models. This is of high significance for future breeding programs, because it implies that selection towards the resistance to a specific pathogen might also increase resistance against other pathogens. Although there is still a long way from the model to the marker, our results and those of others give hope for applicable functional markers in the near future.

Unfolding the genetic architecture of clinical-chemical and haematological traits in swine

Gerald Reiner; Hermann Willems

Department of Veterinary Clinical Sciences, Justus-Liebig-University, Giessen, Germany

Introduction
Clinical-chemical and haematological traits are essential parameters for veterinary practice to evaluate the health status of individuals and herds. A major concern with the interpretation of haematological values is their pronounced variability caused to a great extent by non-systematic factors. Differences in clinical-chemical and haematological traits within breeds and populations provide evidence for genetic factors as primary cause, but little is known about the genetic architecture underlying these traits, especially in swine. Involvement of additive genetic variance of some of these traits argue for the existence of favourable and unfavourable gene variants that are responsible for phenotypic variation. Identification of these variants might improve the diagnostic use of such traits in the future. It might also provide a measure to advance general health of pig populations by selection. Linkage mapping using dense genetic maps is a straightforward approach to locate genes that control inherited diseases. The effects of gene loci contributing to this phenotypic variation were considered undetectable until the introduction of quantitative trait loci (QTL). QTL mapping may be a valuable first step towards the identification of genes and causal polymorphisms responsible for variability of clinical-chemical and haematological traits. The aim of the present study was to detect and evaluate QTL for such traits in swine, and to define potential candidate genes.

Materials and Methods
The experiments were based on a Pietrain/Meishan F2 family. 139 F2 pigs were consecutively included into the study. All pigs were clinically healthy at the start of the experiment and free of internal and external parasites. In the course of eleven study periods, groups of five to eleven pigs were housed in tiled boxes of 16 m2 on straw beddings and fed ad libitum with a customary cereal diet (energy content: 11.5 MJ/kg) without food additives throughout the whole period of observation. Blood samples were taken at four time points, representing baseline values (day 0, directly before challenge with Sarcocystis miescheriana), acute (day 14 post infection [p.i.]), subclinical (day 28 p.i.) and chronic (day 42 p.i.) stage of Sarcocystosis. Further details on clinical and clinical-chemical patterns of Sarcocystosis have been described elsewhere (Reiner et al., 2006). A broad aspect of clinical-chemical and haematological traits was analysed by standard procedures. QTL analysis was based on 101 informative microsatellite markers using the web-based application “QTL express”. For more details see Reiner et al. (2007).

Results
54, 38, 27, and 38 QTL for clinical-chemical, erythroid, blood gas, and leukocyte traits have been mapped, respectively. 15, 9, 5, and 9 QTL, respectively were genome-wide significant, the remaining showed chromosome-wide significance. 30, 40, 42, and 45 QTL were associated with different traits during basal stage, acute, subclinical and chronic disease, respectively. Many of the QTL involved were only detected under the burden of the model disease on the metabolism. A variety of candidate genes for different traits has been defined based on their physiology and chromosomal location (e.g. erythropoietin and erythropoietin-receptor: red blood cells; GOT1: aspartate-aminotransferase; and many others). SNPs identified within such candidate genes significantly improved the effects of the QTL and allowed to retrospectively detect QTL effects even on basal traits that had not been visible before. Also the confidence intervals for the QTL were significantly reduced.

Discussion
Our study confirms that clinical-chemical and haematological traits in swine are influenced by multiple genes, partly representing reasonable effects on their traits. The data represent a significant first step to define candidate genes and to identify the associated polymorphisms. Identification of the molecular basis of this variation has the potential to improve future diagnostics. As individuals with sound values of crucial clinical-chemical and haematological traits should need a higher burden to reach pathological thresholds, breeding animals with favourable gene variants might be selected for higher robustness of individuals and herds in the future.

Development of genetic markers for the resistance against infections of the respiratory tract of swine (RePoRI)

Gerald Reiner; Natalie Bertsch; Hermann Willems; The RePoRI Consortium
Department of Veterinary Clinical Sciences, Justus-Liebig-University, Giessen, Germany

Introduction
Animal health is one of the major concerns in production economics, animal welfare, and food safety. Genetic predispositions of different breeds to infection is well documented for all major domestic species and for many diseases. RePoRI, which is processed in a network of six co-operating research facilities, is a follow-up project of IRAS (Infection and resistance in the respiratory tract of swine) which is granted by the Federal Ministry of Education and Research of Germany. In the scope of the RePoRI project following major tasks are to be conducted: 1) breeding of a segregating F2 family from two pig breeds differing in susceptibility to \textit{Actinobacillus (A.) pleuropneumoniae}, 2) aero-gen exposure to the pathogen with clinical, phenotypical, and pathological-anatomical characterization of animals, 3) genotyping of the F0, F1, and F2 population, 4) expression analysis of the lymph nodes and/or lungs in the most extreme quartils, 5) QTL analysis and identification of putative positional candidate genes, 6) eQTL analysis, 7) identification and characterization of functional and pseudo-functional SNPs, and 8) modelling of host-pathogen interactions and developing of hypotheses accounting for host resistance.

The task of the present study is to provide information about positional candidate genes derived from QTL and eQTL analysis. To achieve this, the following objectives had to be established: i) a panel of informative microsatellite markers with a distance no more than 15 cM, ii) multiplex PCR conditions for marker amplification, and iii) genotyping of the complete F2 pig families. Additionally, informative microsatellite markers should be positioned on the physical pig map.

Materials and Methods
The F0 family consisted of two (relative) resistant boars and 6 susceptible dams which were mated to generate a F1 family with a total of 21 animals. Rearing and infection of the segregating F2 population is in progress. Primers to amplify microsatellites were taken from the USDA list (www.marc.usda.gov/genome/swine/swine.html) and were synthesized (biomers, Germany) with forward primers labelled with DY-780 or DY-680. In a first PCR markers were tested for informativity with DNA extracted from blood of the 2 resistant boars and 6 susceptible dams. All PCR reactions were performed in a total volume of 10 μl, consisting of 5 μl of 2x Multiplex Mastermix (Qiagen, Germany), 2.5μl of primermix (final concentration [f.c.] 0.4 μM) and 2.5μl of template DNA (50 ng). PCR products were run on 6% polyacrylamide gels and analyzed with 1DScanEX (Scanalytics). Only PCR conditions from markers with 100% informativity were optimized. Finally, multiplex PCRs were established combining primers with identical or nearly identical annealing temperatures using the same PCR setup as described above. Only primer concentrations had to be optimized so as to generate bands with equal or nearly equal intensity.

Multiplex PCR reactions were run with three different touch-down protocols each consisting of 23 cycles. Denaturation (95°C, 30 sec) and extension (72°C, 30 sec) steps were identical for all three protocols, only annealing temperatures varied. The first 8 cycles had annealing temperatures of 70, 65, and 63°C, the following 8 cycles 68, 60, and 59°C and the last 7 cycles 66, 55, and 55°C, respectively with annealing times of 90 sec.

Results and Discussion
A total number of 434 microsatellites were tested for informativity, of which unexpectedly only 188 (43.3%) proved to be informative. The average distance of the microsatellite markers was 14.5 cM. Nevertheless, a few gaps with distances greater than 15 cM could not be closed because either the microsatellite markers were not informative or there were no further microsatellites available in the corresponding maps for the respective chromosomal region. 174 microsatellite markers were combined in 50 multiplex reactions with 3 to 4 markers per reaction and were tested with animals from the F0 and F1 generation. In conclusion, a panel of informative microsatellite markers has been established for the genotyping of F2 pigs from the ongoing challenge with \textit{A. pleuropneumoniae}, in order to find markers for the resistance to this important respiratory disease in swine.

Mapping QTL for innate immune response in a Duroc x Pietrain resource population
Muhammad J. Uddin; Mehmet U. Cinar; Dawit Tesfaye; Ernst Tholen; Chirawath Phatsara; Christian Looft; Karl Schellander
Institute of Animal Science, Bonn, Germany

Introduction
Cytokines and Toll-like receptors are basic components of the innate immune system. Immune responses are reported to be under the genetic control. QTL mapping and candidate gene studies have been widely used to investigate genetic variation, to identify genes and chromosomal regions contributing to immune response. Therefore, this research was conducted to identify chromosomal regions controlling the variability in cytokines (IL-2, IL-10 and IFN-γ) and Toll-like receptors (TLR-2 and TLR-9) production by QTL analysis.

Materials and Methods
A total of 334 Duroc x Pietrain F2 animals used for QTL analysis was genotyped by 82 genetic markers. Blood was collected from pigs at 52, 83 and 115 days of age and serum was separated for phenotyping. IL-2, IL-10 and IFN-γ were measured by sandwich-ELISA (Invitrogen). TLR-2 and TLR-9 were measured by in-house developed indirect-ELISA (CosmoBio). Descriptive statistics were performed by using SAS (vs. 9.2) whereas QTL Express (Seaton et al., 2002) was used for both single and two-QTL analysis.

Results
The level of IL-10 and IFN-γ were increased over the time from 52 to 115 days of age. The variations of production were found significant between 52 and 83 days for IFN-γ (P ≤ 0.05) and IL-2 (P ≤ 0.001). In case of IL-2, the differences between 83 and 115 days, and between 52 and 115 days were also significant (P ≤ 0.001). In all time points, TLR-9 responses were higher than that of TLR-2. Th1 type cytokines (IL-2 and IFN-γ) were 5 - 6 times lower than that of Th2 type cytokine (IL-10). Date of sampling, month of birth and year of birth were found to have significant effect on immune traits. Parity, litter and sex had also effect on these innate immune parameters at some age points. A total of 67 single QTL were detected by QTL Express on almost all porcine autosomes, of which 38 for cytokines (IFN-γ, IL-2 and IL-10) and 29 for TLRs (TLR-2 and TLR-9). All the QTL were significant at 5% chromosome-wide level, of which 12 and 52 QTL were significant at 1% and 5% genome-wide level, respectively. A total of 38 QTL were detected for cytokines, of which 12, 9 and 17 QTL influenced IFN-γ, IL-2 and IL-10, respectively. A total of 29 QTL regions influencing Toll-like receptors were identified, of which six for TLR-2 and 23 for TLR-9. Besides single QTL, ten QTL were identified by two-QTL model of which three were in coupling phase and two were in repulsion phase. Most of the QTL were identified on SSC3, 5, 11, 12 and 17. IFN-γ, IL-10 and TLR-9 are found to be controlled by the chromosomal regions of their location but all innate immune traits are influenced by multiple chromosomal regions implying multiple gene action.

Discussion
Most of our QTL are supported by the presence of genes which play immunologically important roles. TOLLIP, TRAF6, IRAK4 and CASP8 are found to be influencing TLRs production whereas IL3, IL5, IL13, IL10, IFN-γ and BPI are influencing cytokines in this study. The QTL knowledge of cytokines and TLRs may contribute towards a more complete understanding of the innate immune system in terms of whole animal physiology. Furthermore, these findings will be helpful to research in these QTL regions to identify new cytokines and their utilization in marker-assisted selection to improve the innate immune response and disease resistance in pigs.

The comparison of the base alignments of D-loop region in the mitochondrial DNA of Ryukyu wild boars with those of the others

Yoshikazu Adachi; Chihiro Nagahama
School of Agriculture, Ibaraki University, Ami-machi, Japan

Objective
Small type wild boars and large types live in Japan and Ryukyu wild boars are small type. The range of Ryukyu wild boars is not in Taiwan, China, and the other east Asia. They were in Vietnam and were different from those in Taiwan, China, and other east Asia. Our aim is to analysis the genetic diversity of Ryukyu wild boars.

Materials and Methods
Samples of Ryukyu wild boars have been collected in Ishigaki Island, Nago City and Kadena Cho in Okinawa Island while 9 samples of wild boars in Honshu island e.g. Large type, were collected in Yamaguchi, Ibaraki and Miyagi Prefectures.

DNA extract, PCR and sequencing: Template DNA extracted from the root of the hair was used for PCR and the primers consisting of; Forward 5'-GGAGACTAACTCCGCCATCA-3' and Reverse 5'-TGTCGCCGTAAACCATTGACTG-3' were used. Sequencing has been performed using BigDye Terminator V3.1 Cycle Sequence kit by ABI PRISM 3100 sequencer. PCR-RFLP has been studying on analysis of Hinf I digested PCR product.

Results and Discussion
The base alignments of D-loop region in the mitochondrial DNA of Ryukyu wild boars and others have been analyzed. Especially, the base alignment of Ryukyu wild boar was consistent among the Ryukyu wild boar, and the homology between the Ryukyu wild boar and Japanese wild boar was 98 % while a cluster unlike a Japanese wild boar on the phylogenetic tree based on D-loop was drawn. Ryukyu is a province name of Okinawa Prefecture in Japan and located on southern islands. On the other hand, the presence of a cross breed pig called Inobuta in the wild boar which was captured in Okinawa Prefecture was confirmed and we perform attempted to perform PCR-RFLP using PCR products by Hinf I digestion of a D-loop part fragment with Hinf I site. The results, demonstrated the distinguishment of Ryukyu wild boar from other wild boars, Inobuta and a pig completely (Fig.1).
Introduction
Pigs vary widely in their susceptibility to many common viral and bacterial pathogens, both between breeds and between different litters on the same farm, suggesting there may be a genetic basis for the variation. If so, genetic selection for higher innate disease resistance should be possible. We have been identifying genetic defects in innate immune genes involved in innate resistance to infectious disease. Previously we identified porcine mannan-binding lectins (MBLs) and ficolins, two collagenous lectins, as bacteria-binding proteins in porcine plasma [1,2]. Within the genes encoding the two porcine MBLs we identified single-nucleotide poly-morphisms (SNPs) similar to those found in the human MBL gene that predispose humans to infections [3,4,5]. Some SNPs alter the structure and function of the protein while others decrease the amount of the protein produced. Earlier studies suggest these SNPs are more frequent in pigs having common infectious diseases [6,7]. This study looked for associations between these SNPs and SNPs found in other collagenous lectin genes with animals having common diseases and pathogens, as well as the effects of these SNPs on production. For comparison, we included known or newly identified SNPs in other porcine innate immune genes.

Materials and Methods
DNA was collected from 1324 healthy Duroc, Landrace or Yorkshire/Large White pigs from production facilities in Canada and the United States and 461 diseased pigs submitted to the Animal Health Laboratory (Guelph, ON). Pigs were genotyped for a panel of 27 innate immune SNPs by Sequenom MassARRAY (Analytical Genetics Technology Centre, Toronto, ON). Gross necropsy and histological evaluation were used to classify the pigs into disease groups, with pathogen grouping based on bacteriology and virology tests as requested by the case pathologist. Genotype frequencies (% of animals possessing the mutant allele) were compared between healthy pigs and pigs in disease and pathogen groups. In the disease and pathogen groups (pathogens: 54.2-66.7%), in all disease groups except serositis (healthy: 31.4%, diseased: 45.8-75.4%) as well as 4 of 6 bacterial groups and in pigs with PRRSV identified (pathogens: 72.0-83.0%). The third collagenous lectin SNP was in the MBL1 gene, encoding MBL-A. The T allele at position 273 was more frequent in pigs having common infectious diseases (healthy: 45.8%, diseased: 66.0-75.4%) as well as 4 of 6 bacterial groups and the PRRSV group (pathogens: 72.0-83.0%). The same allele was more frequent in all disease groups except septic (healthy: 31.4%, diseased: 50.5-54.7%), as well as in 4 of 6 bacterial groups and the PRRSV group (pathogens: 54.2-66.7%). In the other innate immune genes, the C(96)T SNP in galectin-4 (8 of 14 disease and pathogen groups) and the C(1919)T SNP in Toll-like Receptor 5 (7 of 14 disease and pathogen groups) were significantly more frequent most often. Significant associations between SNP frequency and production parameters were rare.

Discussion
Out of 27 SNPs, five were significantly associated with most of the common diseases and pathogens of swine examined. The identification of several mutations consistently more frequent in pigs with infectious diseases, but without significant negative effects on production, suggests that genetic selection for disease resistance based on some innate immune genotypes might be possible. Further work to examine genetic defects in the entire set of genes involved in innate disease resistance is required. Innate immune genotypes that reduce the severity of infectious diseases might facilitate marker-based selection, decrease production costs, improve animal welfare, and reduce antimicrobial use in pork production.

Traceability and genetic evaluation in order to improve the swine products quality

Sam Balasch1, Joan Tibau2, Joaquim Soler2, Marina Gispert2, Maria Angels Oliver2, Agnès Juvanteny1, Glòria Cucurull1, Paula Grassi1
1. Alea! Technological Centre of the Animal Life, Masies de Roda, Spain;
2. Institute for Food and Agricultural Research and Technology - IRTA, Monells (Girona), Spain

Introduction
The purpose of the Project is the development and implementation of a traceability system along the production process, starting in the focus of reproductive sows and finishing when the product arrives at the slaughterhouse as loin and ham. This traceability will allow us to evaluate the genetics provided by Gepork in a productive and a meat quality scale.

Total traceability will allow us to monitor the treatments that animals would have received along their productive lives and will allow us to obtain meat products free of antibiotic.

Finally, a customers' survey will be done in order to discover the customers' priorities referring to the gene of porcine stress.

Material and Methods
**Selection of 150 hybrid sows LDxLW and 45 boars, assigned for coverage.

**Specific software and devices (electronic ear tags and reading terminals for the farms).

• Identification by electronic ear tags of all the animals taking part in the Project.
• Coverages in batches of 25 sows; with an interval of 6 weeks.
• Monitoring of many processes: gestation, birth, breastfeeding and weaning (feeding, weight, treatments, etc.).
• Extraction of a biological sample of each animal.
• Monitoring of different indicators: daily growth, feeding daily consumption, corporal composition, etc. in 3 genders: male, female and immunocastrated male pigs.
• Evaluation of the productive results of the descendants of the boars used in each one of the coverages of the 6 batches.
• Monitoring of some indicators in the slaughterhouse (individual weight before the slaughtering, carcass pork flesh weight, fat thickness, etc.) and monitoring of the traceability in the slaughterhouse referring to loin and ham.
• Slaughtering in controlled conditions at 110 Kgs., including:
  1. Analysis before slaughtering (alive animal weight, interpretation of back fat and loin).
  2. Analysis in the slaughterhouse (carcass pork flesh weight, back fat thickness -G34FOM- and muscle MFOM-, pH, etc.).
  3. Analysis of carcass pork flesh quality in the butchering room (pH and CE in loin and ham -pHuLT, pHuSM, CEuLT and CEuSM-, color, veined, muscle area in loin, etc.).
• Evaluation of the incidence of the porcine stress gene by means of the crossbreed of boars of the three genetics (NN, Nn and nn) with sows negative to the stress gene.
• Elaboration of a consumers' survey about ham and fresh loin, addressed to 200 consumers.

Results
We got 100% of traceability in controlled conditions in the slaughterhouse and 97.01% of traceability in the commercial slaughterhouse.

We discovered that genetics and gender affect the carcass pork flesh (% loin and fat), as the descendants of NN animals have more fat thickness and less % loin that the descendants of nn genetics.

Referring to gender, female pigs have better values than entire male pigs (best carcass performance, % loin, fat thickness and muscle thickness -MFOM-). The immunocastrated male pigs have a bigger alive weight, but carcass performance is worse than females' carcass performance, they are less conformed and MFOM values are just sufficient.

Conclusions and Discussion
First of all, we verified that it is possible to ensure the traceability of the evaluated animals from the farm until the slaughterhouse.

Referring to carcass quality, the descendants of Nn boars can be placed between the descendants of NN and nn, but referring to meat quality values, the results obtained are better, overall in the NN boars that are descendants of the crossbreed of NNxNP, thanks to the analysis of Microsatellite Moleculars Markers (MMM).

Referring to conformation, the descendants of nn boars are more conformed than the descendants of NN boars.
Poster Presentations

Introduction

There are several methods of extracting DNA, some fast, efficient and useful in the isolation of high-quality DNA extraction kits such as commercial. However, most of them are expensive and serve a small number of samples, since they have to standardize, thus arises the need for DNA extraction methodologies fast, simple and low cost allowing genomic DNA obtained good quality, free of secondary compounds, proteins and polyphenols, which inhibit DNA. The Mexican regulations restrict the mobilization of semen and blood plasma within and between different regions of Mexico as a biosecurity measure, so the objective was to standardize a technique of extraction and purification of DNA from hair, non-invasive technique which allows evaluation of animals from different sources without being stressed at the time of sampling.

Materials and Methods

Different farms were sampled in the country, pig hair was collected from pulling back sharply with the thumb, index and middle, removing the hair bulb of about 50 hairs per animal. We obtained the DNA extraction and purification from pig hair for being a non-invasive sample. The methodology developed was based on a combination of various pre-established protocols and modified by reference to the proposal by Sambrook et al. (1994), which was to establish the extraction protocol in which they conducted a first lysis step through the detergent SDS and subsequently for total DNA purification method was applied to phenol-chloroform-isoamyl alcohol enabling removal products degradation, which preserves the DNA for longer periods, finally washed with alcohol to eliminate waste and verify the quality of DNA in agarose gel 1%.

Results

The extraction method was efficient resulting standardized DNA integrity of a good quantity and quality, a technique that allows for non-invasive samples such as hair, thus avoiding sampling techniques that involve the capture or stress on animals. In this research, the electrophoresis gels show the specificity of the DNA extraction technique hair of pigs used in this study (Fig. 1). The extraction of DNA from hair was standardized despite being listed as a protocol difficult from the standpoint of DNA extraction methods, results revealed that it is highly reproducible and reliable “almost perfect”, in the form PCR amplification, all samples were amplified, these tests were conducted with the objective of finding a methodology to obtain samples without any restrictions.

Discussion

This standardized extraction method, will allow for non-invasive samples such as hair and although they usually do not recommend this type of sample for extraction, were successful in securing a high quality genomic DNA, quantity and purity. Moller y Brinkmann (1994). Although it took a long period of incubation and careful series of steps to follow when handling, they showed a high specificity of the technique (100%) and that often gets lost during the processing of samples, attributed perhaps a shortage of nucleated cells containing the hairs, located in the bulge or the inhibitory effect of soluble melanins generated during the DNA extraction process. This option opened doors to sample farms which hardly can be entered for biosecurity.

Innate immunity and management in two different herds

Livia Moscati1 Marco Sensi1 Lorenzo Battistacci1 Massimo Amadori2
1. Istituto Zooprofiliattico Sperimentale Umbria e Marche, Perugia, Italy; 2. Istituto Zooprofiliattico Sperimentale Lombardia Emilia Romagna, Brescia, Italy

Introduction
Various environmental effects may adversely bear on welfare of farmed pigs under intensive farming conditions, which may cause chronic rather than acute stress as a long-term effect of modern husbandry techniques. These may in fact overtax the animals’ coping ability and force them to long-lasting homeostatic control actions.

Materials and Methods
This investigation was carried out in winter on pigs from Danish genealogy book in two fattening farms. Farm 1 consisted of two pens housing weaned and growing-finishing pigs. In this herd there were frequent arrivals of animals of various origins, so that no all-in-all-out housing scheme was applied during the trial. A chronic respiratory syndrome by Actinobacillus pleuropneumoniae had been present for a long time with high morbidity and mortality. Herd 1 was compared with herd 2, located in the same area and consisting of two fattening pens. In this latter farm pigs were born in the same breeding unit, moved to herd 2 at a weight of some 30 Kg and further reared up to a slaughter weight of 160-170 Kg. An all-in-all-out housing scheme was routinely applied. The overall clinical conditions of pigs were satisfactory. The time-course of clinical immunology and clinical chemistry parameters was evaluated in the two herds with such a different sanitary and management status. Blood samples from 15 randomly chosen animals of the same age were collected in herds 1 and 2 at monthly intervals in vacuum tubes without anti-coagulant. The following parameters were investigated: haemolytic complement activity (CH50/150μl) as previously described by Barta (1), serum lysozyme (SL) (3), serum bactericidal activity (SBA) (2), haptoglobin (Hp) by a commercial kit (Tridelta Development Ltd.), zinc (Zn) and iron (Fe) were assessed by a Konelab 2001 biochemical analyzer. Results were submitted to a statistical examination was performed by ANOVA.

Results
Results are shown in Tables 1 and 2. Animals of the herd 1 showed at time 0 a significantly higher serum haptoglobin concentration (P<0.01) about two weeks after a respiratory syndrome and a trend to high serum levels was evidenced at later samplings, too. Reduced plasma levels of iron and zinc were always evidenced in herd 1, as a possible indicator of a steady-state inflammatory condition, the greatest differences being revealed at time 3 (p<0.001). Interestingly, animals of both “problem” and healthy herd showed low SBA and high lysozyme concentrations in later samplings (Table 2) as a possible outcome of difficult adaptation during the growing phase.

Discussion
Our results indicate that animal health and welfare in pigs can be monitored by combining clinical, environmental and innate immunity investigations, as a multi-disciplinary approach to animals’ environmental adaptation. Most important, the important role of immunological parameters for evaluation of welfare conditions confirms that the effector mechanisms in the immune response are remarkably similar for both infectious and non–infectious stressors.

The interferon-alpha response in piglets at weaning

Elisabetta Razzuoli; Riccardo Villa; Enrico Sossi; Silvia Dotti; Massimo Amadori
Istituto Zootecnico Sperimentale Lombardia Emilia Romagna, Brescia, Italy

Introduction

Our interest into the functions of type I interferon (IFN) under health conditions was stimulated by established models of physiological IFN response (1) and constitutive expression in lymphoid and non-lymphoid tissues in the absence of any specific inducer (2), as well as from clinical studies documenting serious inflammatory disorders in humans with a defective type I IFN response. In the veterinary field, pigs under intensive farming conditions are an interesting model for such studies, since an IFN-α response following stressing events like weaning and truck transportation has been known for a long time (3). In the present study we investigated the IFN-α response in pigs weaned at different ages.

Materials and Methods

The study was carried out in May-June 2008 on 40 Landrace x Large White, randomly selected piglets of four litters. Group 1 (2 litters, 20 piglets) was weaned at 28 days of age, and group 2 (2 litters, 20 piglets) at 22 days of age. All piglets were given the same starter feed containing amoxicillin (400 ppm), colistin (120 ppm) and zinc oxide (2000 ppm) over the first 10 days after weaning. Pigs were clinically inspected and blood samples in vacuum tubes without anti-coagulant were collected at days 0, +6, +12 with respect to weaning, in order to evaluate the most common viral infections and IFN-α production. Viral infections were investigated by PCR and antibody assays whereas IFN-α production was tested by a cpe inhibition assay on MDBK cells with Vesicular Stomatitis Virus (VSV) (4). Other blood samples were collected in vacuum tubes with sodium heparin in order to assess intracellular porcine IFN-alpha and the expression of porcine IFN-alpha genes in peripheral blood mononuclear cells (PBMC). IFN-alpha in PBMC was investigated by flow cytometry, and gene expression by RT-Real Time PCR on 9 animals of group 2 according to Cheng (5).

Results

All pigs remained healthy during the whole period of observation. In particular, there was no detectable clinical difference between the two groups under satisfactory hygiene and welfare conditions. There was no evidence of infection by the usual viral agents of swine (PRRSV, PCV2, SIV, PRV) in the first 2 weeks after weaning (PCR and antibody assays). The sera of all piglets in group 2 and of 7 animals only in group 1 were IFN-α positive at day 6 after weaning. This result was confirmed by a neutralization assay of IFN-α on MDBK cells by a monoclonal antibody to porcine IFN-alpha1.

A small percentage of PBMC from several piglets at day +6 were also positive in a flow cytometry assay for intracellular porcine IFN alpha.4 and 10 animals in groups 1 and 2, respectively, were positive, and the prevalence of IFN alpha-positive PBMC showed no evident correlation with that of the sera. The results of RT-Real Time PCR showed at day 0 the expression of the IFN alpha5 and 6 genes in 7 out of 9 piglets and of IFN alpha12, 1, 7, 11 and 2 genes in fewer pigs. All the above genes were not expressed at day +6, and expressed again at day +12.

Discussion/Conclusions

Our results are in agreement with previous reports about constitutive expression and secretion of IFN-alpha; in particular, the need for an IFN-α response to the weaning stress was shown to be much higher in 3, compared with 4-weeks old piglets. Transcriptional control on gene expression in PBMC coincided with peak serum IFN-α titres. These findings highlight the importance of type I IFNs as homeostatic agents in the response to environmental, non-infectious stressors.

Peripheral T lymphocyte changes in neonatal pigs

Glen W. Almond1 Laetitia Bourdieu2 Guy-Pierre Martineau2 Martin Liebstein1
1. College of Vet Med, North Carolina St University, Raleigh, NC, USA; 2. Ecole Nationale Vétérinaire de Toulouse, Toulouse, France

Introduction
Previous studies characterized lymphocyte development and Ig production in fetal pigs (1,2). The porcine immune system is well developed prior to birth, but prenatal factors influence immune function in suckling pigs (3). Furthermore, in utero transmission of pathogens also altered piglet peripheral and tissue T lymphocytes (4). In contrast to controlled experiments under ideal conditions, our understanding of cell-mediated immunity (CMI) is limited for newborn pigs in commercial farms. Therefore, the primary goal of this study was to characterize peripheral T lymphocytes in neonatal pigs on a conventional sow farm.

Materials and Methods
The animal phase of the study was conducted on a PRRSV-stable sow herd. Four sows (parity 1, 2, 3, and 6) were identified prior to farrowing. Farrowing was closely supervised and birth order of the piglets was recorded. Whole blood samples were collected from 12 piglets per sow prior to suckling (day 0), 24 hr after suckling (day 1) and at 7 days of age. Piglets were weighed at the time of each blood collection. Complete blood counts were performed on each sample. Samples were prepared for flow cytometry and the number and percent of CD3+, CD4+ and CD8+ lymphocytes were determined. Spearman rank correlations were used to assess associations among piglet body weights, birth order and immune cell types.

Results
Piglet body weight (BW) did not differ between day 0 (1.3+.05 kg) and day 1 (1.4+.05 kg), but increased (P<.05) at day 7 (2.4+.08 kg). Total lymphocyte counts increased with age; however, the percentage of lymphocytes and neutrophils did not change with age. The number of CD3+, CD4+ and CD8+ lymphocytes increased with age (Fig 2). In contrast, the percentage of CD4+ cells decreased from day 0 to day 7.

Prior to suckling, the % and number of CD8+ cells were positively correlated with birth order (r=0.47, P<.001 and r=0.28, P<.05, respectively) and the percent and number of CD3+ cells were positively correlated with body weight (r=0.32, P<.02 and r=0.48, P<.001, respectively). For the three days of blood samples, there was a positive correlation among the number of CD4+ and CD8+ cells with body weight and day.

Discussion
The percentages and numbers of CD4+ and CD8+ lymphocytes agreed with previous studies of PRRSV-free pigs (3,4). It is expected that the number of CD4+ cells decrease while the number of CD8+ cells continue to increase at weaning or shortly thereafter. The CD4+ TH1 and TH2 subsets bind to macrophages and antigen-specific B cells, respectively, and thus play roles in CMI. The CD8+ lymphocytes (cytotoxic T cells) are programmed to become effecter cells and become more critical to immunity as the pigs mature. As shown in previous studies (1,2), it is evident that newborn pigs in commercial farms are "armed" with the appropriate cells for CMI. However, our results showed that lighter piglets have lower immune cell numbers. These pigs will require additional care and perhaps, they are more susceptible to infections.

Disease Resistance Assay for Animals (DRAA) positively associates T-cell responses with average daily gain (ADG)

John Harding¹ Crissie Auckland¹ Saba Siddiqi² Caroline Billard² Jenny Phipps² Michel Phipps²
¹. University of Saskatchewan, Saskatoon, SK, Canada; ². Metadis Inc., Ottawa, ON, Canada

Introduction
Genetic differences in antibody and cell-mediated immunity have been described, and swine selection programs based on immune responsiveness have been proposed as a means of improving health status and growth performance¹. The objective of this study was to evaluate the relationship between growth performance and an individual pig's general immune competence assessed using a novel mitogen-induced lymphocyte proliferation assay (Disease Resistance Assay for Animals; DRAA). These results are part of a larger study evaluating relationships among general immune competence, post-natal performance, and PCV2 risk.

Materials and Methods
This study was performed in a 600 sow high health farrow-finish farm using 45 PIC Camborough sows blocked by parity. Two male and 2 female piglets, representing small and large birth weight, were selected from each litter at birth and monitored until 15 weeks of age. After weaning at 3 weeks of age, piglets were reared in conventional all-in-all-out nursery and grow-finish rooms and fed commercial diets typical of western Canada. Individual weights were obtained at birth, 3, 9 and 15 weeks of age. The average daily gain (ADG) for each period was calculated. From each piglet, 5 ml heparinized blood was collected at 3, 9 and 15 weeks of age.

DRAA: The individual’s general immune competence was assessed using the DRAA (Metadis Inc.). Lymphocytes were isolated by density gradient centrifugation using 'Lymphoprep', then proliferative responses to a panel of mitogens were assessed as 6 replica of 10⁴ cell aliquots. The mitogens in the panel were chosen in order to mimic a wide array of pathogenic stimuli and each was representative of a specific T-cell molecular signaling pathway and genetic signature. Since some of the elicited receptors respond to multiple mitogens, multivariate-based mathematical analysis was used to eliminate overlaps, leading to a measurable response along 3 fundamental T-cell pathways on which the blastogenic responses relied. For each pathway a TABI score was calculated reflecting the strength of an individual's expected immune response to a pathogen. TABI 1 encompasses general CD3⁺ T-cell responses. TABI 2 reflects the ratio of given T-cell receptors specific to each individual animal. TABI 3 represents the nature of CD4⁺ subsets and the clonal expansion of B lymphoblasts present in the peripheral blood.

Statistical analysis: Generalized linear mixed models (STATA v9, StataCorp, College Station, Tx) were developed to assess potential relationships between the week 15 TABI (1, 2, 3) scores and ADG. Two ADG periods (weeks 9-15 and 0-15) were considered. The TABI 1, 2 and 3 scores measured at week 15 and biologically relevant cofactors that potentially impacted ADG including gender, birth weight and farrowing week were retained in the final model if $P < 0.05$.

Results
Mean birth weight was 1.4 ±0.3 kg. Mean body weight at 15 weeks of age was 62.5 ±9.0 kg. Mean ADG 9-15 was 0.819 ±0.18 and mean ADG 0-15 was 0.581 ±0.01 kg/day. The week 15 TABI 1 scores ranged from -1.37 to 3.54; TABI 2 scores ranged from -2.16 to 3.1; and TABI3 scores ranges from -1.99 to 1.75. The TABI 1 score was significant and positively associated with ADG 9-15 ($r² = 0.43; <\text{em}>P < 0.001)$ and ADG 1-15 ($r² = 0.46; P < 0.001$) (Table 1). TABI 2 and TABI 3 scores were not associated with ADG during either period, nor was gender.

Discussion
Many factors, including health, potentially impact the growth performance in finisher pigs. This study demonstrates that a vigorous and positive T cell response, as quantified by the DRAA, is associated with enhanced growth rate. For each 1 point increase in the TABI 1 score, ADG 9-15 and 0-15 increased 46 and 26 grams/day respectively, or about 4-5%. Of the 3 fundamental T-cell pathways evaluated, only the general CD3⁺ response pathway was significantly associated with growth. Surprisingly, ADG was not associated with gender in this study.

Introduction
The difficulty of sampling swine tonsils ante-mortem makes collection at the time of slaughter an obvious alternative for disease monitoring purposes (1). The funnelling of large number of animals during the slaughter process also provides an opportunity to sample a wide range of animals and animal sources on one premise. The objectives of this 7-month study were to determine the prevalence of porcine pathogens of the tonsil of the soft palate at slaughter, to determine if sampling normal or abnormal hog carcasses provides different microbiological profiles, and to determine if the slaughter plant provides a feasible sampling frame and environment for detecting and monitoring important pathogens in tonsils that have health implications for swine and humans.

Materials and Methods
Twenty (20) tonsil samples were collected every week for 20 consecutive weeks, June to December 2008, from swine carcasses at a federally inspected abattoir in southern Ontario, Canada. The sampling was performed by experienced abattoir staff during normal slaughter operations. Microbiological analyses of the tonsils were conducted by the Animal Health Laboratory (AHL) at the University of Guelph. Guelph, Ontario. Testing included bacteriological culture and identification, real-time PCR testing for PRRS virus and IHC for Porcine Circovirus-2 (PCV-2). The relationship between finding a pathogen from pigs on the hold rail (abnormal carcasses) vs. normal carcasses was examined by logistic regression. A generalized mixed model using farm as a random intercept was utilized to determine whether there was any clustering at the farm level (2).

Results
A total of 395 samples were collected of which 180 were tonsils from normal carcasses and 215 from carcasses that were on the hold rail. 264 different farms were represented and no clustering at the farm level (2). Twenty (20) tonsil samples were collected every week for 20 consecutive weeks, June to December 2008, from swine carcasses at a federally inspected abattoir in southern Ontario, Canada. The sampling was performed by experienced abattoir staff during normal slaughter operations. Microbiological analyses of the tonsils were conducted by the Animal Health Laboratory (AHL) at the University of Guelph. Guelph, Ontario. Testing included bacteriological culture and identification, real-time PCR testing for PRRS virus and IHC for Porcine Circovirus-2 (PCV-2). The relationship between finding a pathogen from pigs on the hold rail (abnormal carcasses) vs. normal carcasses was examined by logistic regression. A generalized mixed model using farm as a random intercept was utilized to determine whether there was any clustering at the farm level (2).

Discussion
The sampling frame and sampling method proved to be an efficacious way to collect swine tonsil tissue. Accurate tissue recovery occurred (99.7%), the sampling protocol was not technically challenging, and plant production was minimally affected during the sampling periods. Tissue collection during the slaughter process was a superior method of tonsil tissue collection compared to reports of ante mortem techniques where only 48.9% of samples were correctly obtained by tonsil biopsy methods (1). Interestingly, tonsils that were positive for PRRSV or PCV-2 were not more likely to be positive for zoonotic pathogens or other swine pathogens with major production limiting implications.

Introduction
Oral fluid specimens have been used extensively in human diagnostic medicine, but only recently has the concept been investigated in the production animal setting (Prickett and Zimmerman, 2010). Two studies were conducted under experimental conditions. The objective of the first study was to determine whether porcine reproductive and respiratory syndrome virus (PRRSV) and/or specific anti-PRRSV antibodies were present in oral fluids. The second study evaluated the detection of porcine circovirus type 2 (PCV2) and anti-PCV2 antibody in oral fluids.

Materials and methods
Experiment 1 (PRRSV): The onset, level, and duration of PRRSV and anti-PRRSV antibodies in serum and oral fluids was evaluated in 3 age groups of pigs (4, 8, and 12 weeks of age). Each age group consisted of 16 pigs (12 PRRSV-inoculated, 4 negative controls) housed in pens of 4 pigs each. Pigs were inoculated IM on DPI 0 with 2 ml of inoculum containing 1 x 10^1.7 TCID50 of PRRSV per ml. After PRRSV inoculation, serum, buccal swabs, and oral fluids were collected at regular intervals for 63 days. Samples were assayed for PRRSV by qRT-PCR and specific anti-PRRSV antibodies by ELISA.

Experiment 2 (PCV2): The onset, level, and duration of qPCR-detectable PCV2 and anti-PCV2 antibody in serum and oral fluid were evaluated over time. Four treatment groups (6 pigs each) were evaluated: Group 1 - negative control; Group 2 - inoculated IM and IN with PCV2a (ISU-40895); Group 3 - inoculated IM and IN with PCV2a (ISU-40895) at 0, 4, 8 and 12 weeks; Group 4 - inoculated IM and IN with PCV2a (ISU-40895), then with PCV2b (PVG4072), and with PCV2a (ISU-4838) at weeks 0, 5, and 10, respectively. Serum from each animal and one oral fluid sample per group were collected every other day through day 14 and weekly through week 14. Serum and oral fluid samples were assayed for PCV2 by qPCR and anti-PCV2 antibody by ELISA. In addition, anti-PCV2 antibody isotypes (IgG, IgA, and IgM) were quantified in oral fluid samples.

Results
Experiment 1 (PRRSV): PRRSV qRT-PCR results in oral fluid samples were correlated with serum levels. 75% of the oral fluid samples collected from PRRSV inoculated pens were positive through day 28. Likewise, PRRSV-specific antibody of the IgG, IgM, and IgA isotypes were detected in oral fluid.

Experiment 2 (PCV2): PCV2 was detected in oral fluids in all inoculated groups by day 2 (first sampling) with peak levels between days 10 and 21. Levels declined thereafter, but persisted through the end of the 98 day study. Analysis of PCV2 qPCR results found no statistically significant differences among inoculated groups either in oral fluid or serum specimens. Likewise, there were no significant differences among inoculated groups in the level of anti-PCV2 antibody in serum. Anti-PCV2 antibody was detected in oral fluids and persisted throughout the 98 day study. Anti-PCV2 IgG, IgA, and IgM were present in oral fluid by DPI 14 and persisted through the end of the study.

Discussion
The results of these two experiments showed that PRRSV and PCV2 infections were detectable in oral fluid specimens using either PCR- or antibody-based assays. These results suggest that oral fluid samples are a viable alternative to serum samples for the surveillance of PRRSV and PCV2. In the field, oral fluid sampling could form the basis of an efficient, cost effective, and practical approach to infectious disease surveillance.

Prevalence of lesions found at slaughter among Swedish fattening pigs

Nils Lundeheim1 Nils Holmgren2

Introduction
Recording of gross lesions at slaughter has for many years been performed in Sweden by the official meat inspectors. This information is stored in a databank run by the Swedish Animal Health Service, and is used to identify herds with health problems, to improve animal welfare, and also for epidemiological studies. In this report, variation in prevalence of, as well as correlations between, gross lesions are analysed.

Material and Methods
The analyses are based on data on all fattening pigs slaughtered during 2009 at the six largest slaughter plants in Sweden (n=2.4 million pigs). Mean prevalence for each herd and slaughter month was calculated for seven pathological lesions (abscesses, arthritis, tail damage, enzootic pneumonia [SEP], pleuropneumonia [PP], pleuritis [Pl] and Ascaris [white spots in livers; WS]). In total, final data comprised information on 729 herds and 7241 herd-month averages (>50 pigs in each average).

Analysis of variance was applied, according to a statistical model including the fixed effects of slaughter plant, month and herd size (4 classes: 500-999; 1000-1999; 2000-3999; 4000- fatteners). The statistical model also included the random effect of herd. Correlations between prevalence of different lesions were estimated as residual correlations, when the effect of slaughter plant was adjusted for.

Results
Slaughter plant had a significant (p<0.001) effect on all prevalences analysed. Herd size had a significant effect on the prevalence of Abscesses (p<0.05) and on PP, Pl and WS (p<0.001), see Tab. 1.

Month had a significant (p<0.001) effect on all traits analysed, except for PP (p<0.5), see Tab. 2.

The following correlations (r>0.1), between the prevalences of the lesions analysed, were highly significant (p<0.001):

- Tail damage – abscesses: +0.33
- Abscesses – arthritis: +0.14
- Pleuropneumonia – Pleuritis: +0.30
- SEP – Pleuritis: +0.19
- SEP- WS: +0.14

Discussion
This investigation identified 4 primary pathological findings at slaughter which should be focused on to improve herd health and animal welfare. According to Swedish legislation, no tail docking of piglets is allowed. Prophylactic measures against tail biting, such as adequate feed and feed allowance and supply of straw, will prevent secondary abscesses (4).

PP, SEP and Pl may be controlled by strict age segregated production (1). Vaccination against Mycoplasma hypopneumoniae reduces SEP and to some extent Pl. These measures are especially important in larger herds as they are associated with high prevalences of respiratory diseases (1,3). Condemnations of livers due to white spots can be prevented by strategic pre-farrowing treatments of sows with anthelmintics in age segregated productions systems (2).

**Prevalence of organ lesions in fattening pigs at slaughter recorded in different slaughterhouses in Switzerland**

Viviane T. de Vries¹ Juliane Funke¹ Roger Stephan² Titus Sydler³ Xaver Sidler¹

¹ Institute of Farm Animals, Division of Swine Medicine, Vetsuisse Faculty, Zürich, Switzerland; ² Institute for Food Safety and Hygiene, Vetsuisse Faculty, Zürich, Switzerland; ³ Institute of Veterinary Pathology, Vetsuisse Faculty, Zürich, Switzerland

**Aim of the Study**

Organ lesions of slaughtered pigs can be used effectively to assess the herd health status on preharvest level. The aim of this study was to record the prevalence of organ lesions in fattening pigs at slaughter in different slaughterhouses in Switzerland, to assess their economic impact and to evaluate the introduction of a system based on codes, which will be used in all Swiss slaughterhouses.

**Materials and Methods**

Data were collected over the period of June 2008 until May 2009 during meat inspection from 34’706 fattening pigs in four different slaughterhouses in Switzerland. Each lesion was recorded within a code system.

**Results**

In total, in 3’101 out of 24’426 organs, which were assessed during meat inspection, lesions were found. The economic loss for the organs was calculated to 15’950 Swiss Francs. The following tables (Table 1-4) summarize the type of lesions in the different organs.

Based on the recorded data during meat inspection, lesions on animal level were statically compared between label and non label pigs and pigs which attend the pig health service (PHS) and those pigs which did not attend. Both label and pig health service slaughtered pigs showed significant less bronchopneumonia (Table 5).

**Conclusion**

Based on this project, a system recording systematically meat inspection data should be implemented in the future in Switzerland. The application of the evaluated system would help to monitor the herd health status on the preharvest level in the pig population and allow assessing the impact of the work of the pig health service.
Introduction
The demand for more organic pigs has increased in Sweden. Production structure has changed from small farrowing-to-finish outdoors organic (OO) herds to larger herds, and also some specialized organic fattening herds. In these herds the pigs are raised indoors (IO) with access to a small area and pasture outside the barn. Thus today a higher proportion of organic pigs in Sweden are kept indoors most of their lives. During 2009 some organic farms started to raise IO pigs in accordance with the EU rules (3). The main difference between these systems is the access to pasture or not. The certified “Swedish” organic pigs must have access to pasture four months of the year, whereas the EU-pigs (EO) must only have access to a small paddock area outside the barn.

The aim with this study was to analyse the prevalence of gross lesions at slaughter over time in organic and in conventional (C) Swedish fattening pigs.

Material and Methods
The analyses are based on data from a databank, comprising information on all fattening pigs slaughtered in Sweden. This databank is run by the Swedish Animal Health Service. Information on all gross lesions found at slaughter is stored in this databank. The Swedish organic pig herds are limited in number, and for 2009, data was available from 23 IO herds (15900 pigs), and 6 EO herds (8000 pigs). Thus, the certified organic pig production in Sweden is <1% of the total pig production.

Results
Prevalence of Swine Enzootic Pneumonia (SEP) decreased continuously in C pigs between 1997 and 2001 (1) and remained at about 4% until 2009. During the same period, prevalence of SEP increased steadily among OO+IO pigs (2) (Fig.1). In 2009, when EO-pigs were introduced, the prevalence of SEP among these pigs where 7.8%. In C-pigs, joint lesions have remained at a constantly low level (1-2%) during the last 10 years. However, these lesions are 3-4 times more prevalent among OO+IO pigs compared to C-pigs (Fig.2). In 2009, the first year of Swedish EO-pigs, the prevalence of joint lesions among them was 4.5%.

Discussion
OO+IO-pig production is seldom age segregated and the barns are seldom emptied or cleaned, and older pigs can infect younger ones. The change in raising system from OO to IO has increased the prevalence of SEP. The prevalence of joint lesions among OO and IO pigs increased 3-6 times during the period studied. The reason why joint lesions are more common in the organic production than in conventional herds is not completely understood. Osteochondrosis and Erysipelas infections are two etiological candidates. In conclusion, prophylactic measures against SEP may be done by applying strict age segregated production and/or vaccination against M.hyo. The etiology of the joint lesions needs to be further investigated.

3. COUNSEL REGULATION (EU) nr 834/2007
Introduction

Pathologic-anatomic findings of lung, pleura, pericard, liver, kidney and carcass in slaughtered pigs can be proper herd health status indicators. The aim of this study was, to determine whether there is a significant relationship between farm management factors, husbandry type and pathologic-anatomic findings in slaughtered pigs.

Materials and Methods

In the first part of this study, the prevalence of pathologic-anatomic lesions of lung, pleura, pericard, liver, kidney, muscle, joint and skin in 34706 pigs was documented on herd level in four Swiss slaughterhouses.

In the second part 82 pig farms were selected to analyze whether certain farm factors can be linked to the findings in slaughtered pigs. On the basis of their pathologic-anatomic findings, the farms were splitted into „case farms“ (more than 30% of the pigs from one farm had a pathologic-anatomic finding) and „control farms“ (less than 10% of the pigs from one farm had a pathologic-anatomic finding). The „case farms“ were separated into farms with lesions at the pluck (S) (lung, liver, pleura, pericard) and at the carcass (T) (kidney). The category „pluck“ had three subcategories: pneumonia (pn), pleuritis/pericarditis (pl/pc) and milkspots (ms). In order to be allotted into one of these subcategories, the finding had to be present in at least 10% of the pigs from one farm. The subcategories were formed to find potential risk factors for pathologic-anatomic findings in the different organs. It was not necessary to form subcategories for the farms with findings at the carcass because all „case farms“ had only lesions in term of „white spotted“ kidneys.

Results

See tables.

Discussion

Pathologic-anatomic findings in slaughterhouses can be used as an objective indicator for diseases throughout the fattening period (Blaha, 1993). In Swiss slaughterhouses is a lot of potential herd health data available which could be of interest for the veterinarian and the pig health service. The data could be an assisting tool to monitor diseases, improve the herd health and to increase the food safety. So far, these data are only used for generation of bills. As it was presented before by different authors, this study was able to show that several farm- and management factor can be linked to pathologic-anatomic findings.

Patterns of condemnation rates in swine from a federally inspected abattoir in relation to disease outbreak information in Ontario (2005 - 2007)

Maria R. Amezcua1, David L. Pearl1, Alejandro Martinez2, Robert M. Friendship1
1. University of Guelph, Guelph, ON, Canada; 2. Maple Leaf Pork, CFIA, Burlington, ON, Canada

Introduction

Data sources for animal syndromic surveillance remain relatively unexplored, and may include veterinary records, and/or animal health laboratory submission files. High correlations between clinical signs on farms and the presence of lesions at slaughter have been reported. The objective of this study was to determine if changes in condemnations rates provide an additional data source for the surveillance of disease outbreaks in finisher pigs. We assessed the epidemiological relevance of these data by determining whether the timing of changes for particular pathological lesions were consistent with a documented outbreak of porcine circovirus associated disease (PCVAD) in Ontario that started in 2005 and was largely controlled by the introduction of effective PCV-2 vaccines in 2007.

Material and Methods

The data were obtained from the database of one large federally inspected packing plant in Ontario from January 2005 to December 2007. Using negative binomial models, we investigated the association between year and quarter with the rate of condemnation for the following lesions that are associated with PCVAD: pneumonia, enteritis and nephritis. Predictive rates for each condemnation category were calculated and graphed by season and year from the final model. Contrasts were performed to determine the difference of rates between season and year. Retrospective temporal scan statistics were performed to identify the most likely temporal clusters for each condemnation category using a Bernoulli model in SaTScan. The patterns of lesions and temporal clusters were compared to PCV-2 diagnostic reports of the Animal Health Laboratory (AHL), at the University of Guelph (2005-2007).

Results

Based on the negative binomial models, a significant decrease in the rates of pneumonia was observed during the study period (Figure 1). In agreement with AHL reports, the pneumonia patterns reflect field infection of PCV-2 in 2005 followed by the increased and widespread use of PCV-2 vaccines in Ontario swine in 2007. In addition, we think that the initial decrease of pneumonia rates in the spring of 2006 may reflect the initiation of PCV-2 vaccines in April of 2006 in Ontario (Figure 1). Similarly, the most likely temporal clusters for pneumonia occurred from January 2005 to March 2006. However, condemnation rates due to nephritis and enteritis increased significantly in 2007 compared to previous years (Figure 1). The most likely temporal clusters for enteritis and nephritis occurred near the end of the study period.

Discussion

These results suggest that abattoir data have potential for the surveillance of emerging pathogens as reflected by the pneumonia patterns. However, abattoir data may also suggest areas for enhanced surveillance for unexplained disease patterns not identified by laboratory submissions. Further prospective studies are required to validate the utility of these data. Abattoir data would be of more value if it could be incorporated into a surveillance program, and validated with multiple sources of swine health data.

Figure 1. Predictive rates of condemnations due to pneumonia, enteritis and nephritis from the negative binomial models.

Introduction
The growing concern of emerging and re-emerging diseases in swine populations in Ontario in 2005, led to the decision to conduct a pilot study to determine the feasibility of an active veterinary-based surveillance system referred to as the Ontario swine veterinary-based surveillance system (OSVS) (1). The OSVS recorded the occurrence/incidence of different syndromes and investigated potential outbreaks during the study period. However, the integration of OSVS data to additional data sources to validate the disease patterns observed was needed. The main objective of this study was to compare the disease patterns observed in the OSVS system with data obtained from case histories that accompanied laboratory submissions to an Ontario regional laboratory, the Animal Health Laboratory (AHL). In addition, the passive data obtained from submissions by OSVS members to the AHL were compared to all passive data submitted to the AHL.

Materials and Methods
Multivariable negative binomial models were used to examine the impact of data stream, season-year and body system affected (i.e., respiratory, digestive and reproductive) on submission rates.

Results
Our results showed that generally higher rates of submissions were reported to the OSVS for the body systems compared to AHL over the study period. However, over the study both OSVS and AHL data captured similar long-term trends of disease (e.g., respiratory) (Figure 1a). Yet, the OSVS data were also able to capture potential outbreaks that were not reflected in the laboratory-based submission data, such as a large increase in digestive cases in Summer 2008 (Figure 1b).

Discussion
Laboratory-based data may be influenced by disease awareness, and more under-reporting compared to active surveillance. In addition, the rates of submissions may be influenced greatly by disease and non-disease factors that influence the total number of submissions to each data stream. The validation of active and passive syndromic surveillance data is necessary, and efforts should be placed on integrating these types of data sources.

A New Swine Veterinary Practice Management and Surveillance System for Western Canada

Gail L. Cunningham¹, Brad Chappell², J. E. Brockhoff³, Pete Pawluk⁴, Chris Misutka³, Blaine Tully¹, Peter Provis¹, Mike Sheridan¹
1. Swine Health Professionals, Steinbach, MB, Canada; 2. Prairie Swine Health Services, Red Deer, AB, Canada; 3. Gail Cunningham Veterinary Services, Kelsey, AB, Canada; 4. Swine Health Centre, Lethbridge, AB, Canada

Introduction
Swine practitioners collect and maintain a large volume of health information as part of daily practice. However, the ability to compile, organize, and use this information is often difficult due to both volume and varied methods of collection and reporting. Swine Database Services (SDS) is a company that arose from a shared vision of private industry veterinarians who recognized the need to organize this information and use it to generate knowledge. Together this group has developed a real time online practice management database that collects and organizes data so it can be readily searched and accessed. This system has also allowed for the collection of real time on farm animal health data that can also be used for emerging disease surveillance.

Materials and Methods
A group of like minded veterinarians from Manitoba and Alberta came together because they shared the need to compile and organize the large volume of health information in their practices. Each group had independently started to develop a data collection database and quickly recognized the synergy to be gained in working together. In merging the two independent databases, the beginning of an innovative information management tool was created. The services of an Information Technology company were contracted to convert it to an online system that could be accessed, used and maintained in real time. The continued development of the database centers on using the data to create knowledge to accomplish the following goals:

• make better decisions for clients
• improve practice management and individual quality of life for swine practitioners
• improve epidemiological data to aid in disease investigation
• create consistent protocols, prescriptions, forms and reporting
• use real time data in the real time surveillance of emerging/re-emerging disease

Results
The SDS database was created primarily to facilitate practice management. Key practice areas were identified and modules created in the database for each area. The current modules in use include:

1. Customer Contact Information
2. Standardized Herd Visit Documentation- veterinary medical records
3. Diagnostic Information – summary of diagnostic information in a searchable format
4. Prescription Generation – injectable and feed which are standardized and error free
5. Producer Medication and Vaccine Usage Plans – provide standardized medication information for clients
6. Quality Assurance Monitoring – notification when CQA need to be done and correction action monitoring.
7. Export Health Certificates to the United States
Numerous reports are also available including electronic signature tracking, invoicing and practice efficiency. The practice efficiency can be used to benchmark customer service and overall practice performance. Health information can also be monitored including syndromic data (e.g. coughing), mortality and on farm diagnostics. Monitoring these parameters over time may provide important signals to changes in the health status of an individual farm and/or geographically or otherwise related farms. This allows the veterinarian to react proactively to these changes. The secondary objective of the database was to provide a real time on farm swine surveillance tool. Each farm is given a unique code known only to the veterinarian so if data is shared, the veterinarian becomes the “gatekeeper” of the information and maintains farm confidentiality. A pilot project with the Alberta Veterinary Surveillance Network (AVSN) was conducted with SDS. Blinded data was analyzed starting in February 2009 including key farm attributes & syndromic information collected during farm visits. The goal of this surveillance is to more rapidly detect and respond to health events in order to protect our industry.

Discussion
The SDS database has been developed to generate knowledge, establish protocols and devise strategies that can help clients and veterinarians thrive in an increasingly challenging industry. The consumer demand to show a commitment to food safety and public health by monitoring the production of our food supply will continue to drive the need for disease surveillance. The SDS database can produce real time health information and reports that help provide assurance to markets about the health of our pigs. Maintaining this information in one comprehensive practice management database provides high quality data while improving practice life for the veterinarian.

Introduction

Livestock disease surveillance systems are necessary for countries to meet their OIE reporting requirements. Trading nations must be able to substantiate their claims about disease status and veterinary infrastructure. Surveillance systems must be able to detect OIE listed diseases as well as newly emerging diseases and changing endemic diseases. The Alberta Veterinary Surveillance Network (AVSN) was developed to meet these needs. AVSN has three parts: disease detection, disease response and communication. Veterinary Practice Surveillance (VPS) provides the system for veterinarians to report disease and non-disease data. Analysis of the data provides valuable demographic information and enhances early detection of important disease events. A VPS for cattle has been operational since 2006 with approximately 30 practices participating (1). This paper describes a Veterinary Practice Surveillance (VPS) for Swine Pilot Project begun in 2009.

Materials and Methods

A contract for data purchase was developed with Swine Database Systems (SDS), a group of swine veterinarians in Western Canada. SDS had recently created an online database system for managing practice and animal health data (2). Three veterinarians from two swine only specialized practices submitted data weekly for one year. Data was provided weekly on all client interactions, including telephone and electronic consultations. Farm name, address, location and phone contacts are present in the SDS database but were not shared. A unique farm and visit identification (ID) code was applied to each farm and only ID codes were included in the data submissions supplied to the AVSN. Definitions for each data field were written in consultation with the SDS veterinarians.

Data were analyzed in Excel and reported to participating veterinarians.

Results

Data were submitted weekly for one year from visits to farms representing approximately 45% of the Alberta sow herd. Herd size and pig type on farm were included, but no other farm identifiers. When unusual disease presentations were noted, the reporting veterinarian was contacted and the case discussed. Definitions were developed for the 13 types of submissions (visit reasons), 12 herd/operation types (e.g. farrow to finish, wean to finish), 11 disease syndromes and four pig types (sows, piglets, nursery and growing pigs). The 11 disease syndromes reported were: coughing, sneezing, scours, neurological, skin, lameness, unthrifty, vices, sudden death, reproductive, and urogenital. Severity was reported by eight percentage ranges of animals affected in each of four pig types in the syndrome categories: 0%, <2%, 2-5%, 5-10%, 10-20%, 20-40%, 40-60%, >60%. Total morbidity and mortality for each class of pigs was also reported. This database allowed the description of veterinary infrastructure for swine in Alberta (i.e. number of visits per farm, size of farms visited, and reasons for visiting farms). Changes in the number of on-farm visits and types of consults were monitored in response to a declining pork price. Consultations for respiratory disease were monitored during the pandemic H1N1 influenza outbreak.

Discussion

Because the database was designed primarily for improving practice efficiency, veterinary practitioner compliance and data quality were good. Reporting information back to practitioners can be valuable in assisting their decision making. The VPS for swine has the potential to generate useful information for several purposes. It may be used to identify animal welfare issues and set baselines for welfare measurement. For international trade and food safety issues, this database may provide information on the presence or absence of certain disease syndromes, detection of emerging health problems, setting of baselines for "normal" disease levels, recording the magnitude of health events and the strength of veterinary infrastructure.

A descriptive study of biosecurity measures in French farrow-to-finish pig herds

Christelle Fablet; Virginie Dorenlor; Fanny Portier; Fabrice Bidan; Florent Eono; Eric Eveno; Jean-Pierre Jolly; François Madec
AFSSA-Site de Ploufragan, Ploufragan, France

Introduction
The term biosecurity in livestock production encompasses a broad spectrum of external and internal farm measures aiming at protecting a herd from infectious agents (viral, bacterial, fungal, parasitic...). Although the importance of effective biosecurity is underlined in numerous studies to reduce disease spread, few data on the implementation of such measures on pig farms are available [1]. The knowledge of currently biosecurity precautions applied in farms might be helpful to determine to what extent appropriate measures are in place. This can in turn provide a baseline of information for veterinarians and producers to build herd health programmes in order to improve the degree of protection. The purpose of the study was to describe the situation vs some biosecurity measures in a sample of farrow-to-finish pig herds.

Materials and Methods
Data from 121 farrow-to-finish pig herds included in a survey designed to identify risk factors for respiratory diseases were used. Information related to the farm characteristics and the biosecurity measures were collected during a visit to each farm. In a first step of the statistical analysis, an univariate analysis was performed. Second, for the variables with sufficient variability (category frequency>20%), a multiple-correspondence analysis method followed by a cluster analysis was used to describe the relationships between the different variables and to reveal groups of pig herds with similar biosecurity practices (SPAD 5.6, DECISIA Inc.).

Results
Three clusters of farms were constituted. The results of the cluster analysis are presented Tables 1, 2 and 3.

Table 1: Pattern of biosecurity practices of the herds belonging to cluster 1

Discussion
As incoming pigs constitute the main source of pathogens introduction into a herd, when dealing with biosecurity, the policies of replacement stock and quarantine management need to be considered. These factors were collected but were not taken into account in this first approach. They will be added in further analysis. However, the results of the study indicate that the importance given to the other aspects of biosecurity varies among farms, the larger herds paying the highest attention. Improvements are specially needed in medium size herds to reduce the risk of disease introduction and spreading. Ribbens et al., [2] found that procedures for persons entering the herds are better applied in larger herds compared to smaller ones. In our study, the lack of control of flies is a main factor characterizing the groups. Since insects may be vectors of swine infectious agents like PRRS virus special attention must be placed to insect control in the different rearing sections [3].

References
Introduction

Biosecurity plays an important role in the pig production units because his close relationship with animal health, by ensuring the pig products quality and improvement of production efficiency. It is important to know the level of biosecurity and technification in pig producing areas to know the risk factors present that will lead to the presence of pathogens that cause disease and implement programs of biosecurity to control them (1); being the northwest of Mexico a high pig production area, we carried out an study to help understand the situation prevalent on biosecurity and use it as a guide to improve the health situation and pork production.

Materials and Methods

Forty-six farms were visited in the municipalities of Cajeme, Navojoa and Hermosillo (15, 14 and 17 respectively). Visual inspection and application of a questionnaire was carried out considering the basic points of biosecurity and technification. Each question was designed with multiple-choice answers with value of 0, 5, 10, 15, 20 & 25 points each; questions closely related between biosecurity and technification were considered for both variables (3). The values of each response on biosecurity and technification were summarized independently, getting a final score for each variable in each farm. Statistical analysis in general and by municipality was carried out and Spearman correlation analysis was applied between Biosecurity (B) and Technification (T).

Results

Farms with low-level of B and T, were not found so four types of farms are identified: MT-MB, MT-HB, HT-MB, HT-HB (M = medium, H = high). The largest number of farms were found to be HT-HB (21). Navojoa has the highest percentage of farms with HB (64%) and HT (93%), Cajeme has the lowest HB (53 %) and Hermosillo in HT (53 %). The average Biosecurity in the study was 2481.71 points (HB) and T values were 708.15 (HT), although by municipality Cajeme has the lowest (2426.67) B points that placed it in a BM level, and Hermosillo has the highest B points (2554.41). A low correlation between B and T (r = 0.0567) was found indicating a relative correlation, but not significant for being away from the confidence level (P>0.05).

Discussion

High homogeneity was found in the pig farms from the north of Mexico, prevailing units with HT (2). Only four types of farms were found because that some state law sets that backyard pig units and all kinds of farms which do not meet the minimum standards of health (4) is prohibited. Correlation between B and T is very low so we can find farms with equal level of technification and biosecurity as farms with higher or lower level of biosecurity, in contrast with their level of technification as found by Zamora (2006), although simple measures of biosecurity, can raise the level of this.

References

Introduction

Insects on pig farms can cause loss in 4 ways.

1. Biting flies such as Stomoxys stable flies and biting midges are known to be capable of causing direct losses due to lesions of direct damage and immuno-allergic reactions. These lesions cause specific losses due to trim loss and extra abattoir processing times, particularly in the summer months.

2. Many common pests of stored products are found in on-site feed storage and feed mill areas on pig farms, such as in storage and hopper locations. Many insects are attracted to feed components and mixed feedstuffs stored on pig farms. These insects may cause direct losses by feed consumption but also reduced quality of feed.1

3. High numbers of summer insects such as flies may exacerbate minor wounds, disturb feed and rest periods and therefore compromise pig welfare. Very high levels of these pests may also disturb farm workers and nearby residential dwellings or businesses.

4. Insects may spread disease within and between farms.2 This may include re-infection of eradication project farms by insects infected with the agent in question.

Materials and Methods

15 representative pig farm study sites within England and Ireland were selected and studied in 2007 and 2008. Invertebrates were collected every 2 weeks at feed storage, breeder and weaner-finisher pig areas with aerial sticky traps, motorised vacuum devices, sweep nets and walk-in floor traps. Traps were placed in constant numbers and locations throughout farms to assist between-farm comparisons. Invertebrates were counted and sorted into genus and species groups by trained entomologists. The total DNA of insects and/or their intestines was extracted and tested for the presence of eubacterial DNA.

Results

Comparison of the populations of invertebrates on each study site, via a dendrogram incorporating component similarity coefficients indicated few major differences in the species evident at each site location across England. Despite the high levels of rainfall and lower than average temperatures in 2007 and 2008, invertebrate group numbers peaked during the summer months. Of the Dipteroid flies, Musca domestica (house fly, n=14 farms) was the most common, but also included Muscina stabulans (false stable fly, n=9), Ophyra spp (garbage fly, n=10), Drosophila (fruit flies, n=8), Stomoxys calcitrans (stable fly, n=2) and Syrphidae containing Eristalis species (hover flies, n=2).

The ground-dwelling beetles found were Carabidae (ground beetles), Curculionoidea (weevils), Staphylinoidea (rove beetles), Tenebrionoidea (darkling beetles) and Bruchidae (bean weevils). A wide variety of Lepidoptera (moths), Acari (mites), Araneae (spiders) and Isopoda (woodlice) species were also present. Other notable findings included Blatta orientalis (oriental cockroach) on 2 farms. Other insect species found on only one or 2 farms included Siphonaptera (fleas) and parasitic wasps from a variety of families including Ichneumonidae and Chalcidae. PCR products typical of eubacterial DNA were confirmed within the gastrointestinal tract of all fresh cockroaches tested and in over 95 % of all fresh smaller whole insects tested.

Discussion

A wide range of Dipteroid fly, beetles, and cockroach activity was evident on many British and Irish pig farms, peaking in summer months as expected. Musca domestica was the most common dominant fly type on the pig farms sampled. These often formed close associations with the farm pigs. We only found the garbage fly Ophyra spp to be the dominant dipteroid fly on one farm – these are considered competitive for Musca spp, in terms of fly feeding ecology. We found Drosophila fruit flies to be the dominant fly species on one farm, but these are not competitive for other flies and are not closely associated with the pigs. A range of expected beetles and weevils associated with feed storage products were found. Cockroaches were noted on two farm – they form large indestructible communities on pig farms when they are introduced – usually via food waste or other waste products. Our trapping methods were not adequate for biting midge evaluations in this initial study. Our results indicated that Stomoxys was a common but low-level presence on many farms. Some of these insects associated closely with pigs had the likely potential to carry and transmit bacterial and viral enteric pathogens, particularly flies and floor-dwelling insects such as cockroaches or Eristalis sp larvae.

References

**Introduction**

UV254 has been a proven method of disinfection since the 1930s (Wells and Brown, 1936). Since then, UV254 inactivation of airborne pathogens has been engineered into areas where people congregate, e.g., by placing UV254 light tube grids into existing ventilation ductwork (Walker and Ko, 2007). Data is available on the inactivation of several human viral pathogens, but little data is available on the UV254 inactivation of viral pathogens of animals.

The goal of this research was to determine the UV254 dose required for inactivation of three common viral pathogens of animals: swine influenza virus (SIV), porcine reproductive and respiratory syndrome virus (PRRSV) and bovine viral diarrhea virus (BVDV). Year One focused on UV254 inactivation of viruses under “static” conditions (virus in liquid medium) using off-the-shelf UV hardware from commercial manufacturers (American Ultraviolet Co., Lebanon IN). Year Two (in progress) will focus on inactivation of airborne pathogens.

**Materials and Methods**

SIV, PRRSV, BVDV, and Reovirus suspended in media were exposed to specific doses of UV254 where dose is defined as (intensity x exposure time) and intensity is expressed as joules per cm². Reovirus, highly resistant to UV254 inactivation, was included for the purpose of process control and comparison.

The effect of UV254 exposure was quantified by comparing virus titers in exposed vs. unexposed controls. Three trials were conducted at 9 exposure doses: 0.3000, 0.2500, 0.2000, 0.1500, 0.1250, 0.1000, 0.0750, 0.0500, and 0.0250 J/cm². Viruses (1.8 ml; 2 mm depth) were placed in separate wells of modified Nunclon® MultiDish™ 8-well plates (Nalge Nunc International, Rochester, NY). Plates were modified by removal of two middle wells to accommodate the placement of a UV254 sensor (Technika, Phoenix, AZ). One well on each plate served as an unexposed control. Following UV254 exposure, the viral suspensions were placed in 2 ml cryovials and frozen at -80°C until assayed for viral infectivity.

Microtitration infectivity assays (TCID50) were conducted on samples in random order. The rate of inactivation was determined by plotting the survival fraction of each viral against the exposure dose.

**Results**

**Discussion**

Larger inactivation constants (K value) indicate greater susceptibility to inactivation by UV254. Thus, in contrast to UV-resistant Reovirus (K value = 0.0118), PRRSV, BVDV and SIV were highly susceptible to inactivation by UV254. Year Two (in progress) will focus on inactivation of airborne pathogens using UV254.

Classification of farrowing sites according to on-farm biosecurity practices and their geographical distribution in two swine production areas of Quebec, Canada

Marie-Ève Lambert1 Zvonimir Poljak2 Sylvie D’Allaire2
1. University of Montreal, Faculty of Veterinary Medicine, St-Hyacinthe, QC, Canada; 2. University of Guelph, Ontario Veterinary College, Guelph, ON, Canada

Introduction
Compartmentalization based on biosecurity could be an important tool to manage disease within a region. The objectives of this study were to describe biosecurity groups and define their distribution over two regions with different pig-herd densities.

Materials and Methods
A high (HD: Estrie) and a low density (LD: Monteregie) areas were purposively targeted and all premises containing sows were included within these areas. A questionnaire was developed to assess the principal potential risks factors reported in literature for introduction of PRRS virus on a site or within a herd. The questionnaire was completed by the owner (independent farm) or by the employee (for farm under contract) and filled out by a single interviewer. Answers were obtained by phone and during a farm visit and included information on more than 40 variables about herd characteristics, geographical coordinates of the site and biosecurity requirements (layout of the site, entrance protocol, transportation of animals, dead pig disposal, pest management, feed and semen deliveries, manure management). Biosecurity was described as measures implemented by producer to limit the introduction of diseases on the site and inside units. Differences between regions were assessed through Mantel-Haenszel chi-square, Fisher’s exact or Wilcoxon statistic as appropriate (p≤0.05). A two-step clustering procedure (SPSS) was performed to classify the farrowing sites in different groups of biosecurity practices. Geographical distribution of sites belonging to the good biosecurity cluster was assessed in both regions using logistic generalized additive model and predicted values were plotted in commercial software (ArcGIS 9.3).

Results
Information was gathered on 71 and 54 sites in HD and LD, respectively. Classification of the 125 sites was performed using 22 variables pertaining to biosecurity and revealed two clusters: A (86 sites) and B (39 sites). Some biosecurity practices related to the entrance protocol are reported in Table 1 according to cluster and region. Significant differences between HD and LD area were observed for the median sow inventory (180 vs. 235) and the median distance from the nearest site (400 vs. 2750 m). Sites belonging to cluster B had a higher proportion of good biosecurity practices and were more frequently located in the LD than in the HD area (62% vs. 38%). Heterogeneity of spatial distribution of sites in cluster B was observed, even in the LD area (Fig. 1).

Table 1: Biosecurity according to region and cluster (%)

*Significant difference between regions (p ≤0.05)  
**Danish entrance: separated contaminated and clean area

Discussion and Conclusion
The higher frequency of good entrance protocol practices, the lower pig-site density and the longer distance from neighbours observed in LD may lower the risk of disease transmission compared to HD. Based on entrance protocol and most other biosecurity variables (not shown), sites in cluster B had overall higher standards than sites in cluster A. A knowledge of the distribution of sites with their respective level of biosecurity is important to implement regional control of diseases.
The use of an online scoring system for the quantification of the biosecurity status in pig herds

Maria Laanen; Stefaan Ribbens; Dominiek Maes; Jeroen Dewulf
Faculty of Veterinary Medicine, Ghent University, Belgium, Merelbeke, Belgium

Introduction
In order to quantify the biosecurity situation on pig farms a biosecurity scoring system was developed by the Veterinary Epidemiology Unit of the faculty of Veterinary Medicine, Ghent University and incorporated in a free online application (www.biocheck.ugent.be).

Materials and Methods
The scoring system takes both external and internal biosecurity measures into account. Both parts are divided into 6 subcategories each consisting of 2 to 13 questions. Each subcategory received a weight based on literature on pathogen transmission and general knowledge of infection risks. A score between 0 and 100 is obtained for both external and internal biosecurity. The scoring system is adapted to be appropriate for every type of pig unit (fattening herd, breeding herd, mixed herd, etc).

Results and Discussion
The scoring system has been available for pig farmers in Belgium for one year and 138 herds (i.e. 13 breeding herds, 6 fattening herds and 119 mixed herds) have filled in the questionnaire until January 2010. The average score for external biosecurity is 64 (min 29; max 95). The score for internal biosecurity is lower in most farms (91%) with an average of 51 (min 18; max 89). There is a strong positive correlation (r=0.63) between the scores for external and internal biosecurity (see figure below).

Figure 1 The correlation between the scores for external and internal biosecurity on Belgian pig farms.

Some selected results relating to external biosecurity show that 81% of the herds purchasing new breeding animals use quarantine facilities for an average period of 36 days. 96% provides farm-specific clothing and footwear to visitors, but only 29% ask visitors to wash and disinfect their hands. Nevertheless, only in 58% of the herds, the farmer and personnel also carry out these hygienic measures themselves before entering the stables.

Concerning internal biosecurity, only 38% of the farmers house diseased animals in separate hospital pens and 48% manipulates the diseased animals after the healthy ones. Suckling piglets are transferred between sows on 98% of the herds, of which 43% performs this operation after 4 days post partum. All-in all-out management is practiced in 82% of the herds in the nursery unit, 70% of the herds in the fattening unit. Nevertheless, 21% puts smaller but older pigs together with the younger ones in the nursery and/or fattening unit. From all the herds, 62% cleans and disinfects every stable after a production round, but only very few (5) verifies the efficiency of these measures. 54% always applies a sanitary stand empty period after each production round.

The large variation in scores of different farms shows that there is room for improvement in many participating herds. On average, the scores for external biosecurity, which are mainly measures related to infrastructure or measures imposable on other parties, are higher than the scores on internal biosecurity which are more related to the work and management strategies of the farmers themselves. As the results show, there are many biosecurity measures that have become common practice for farmers in Belgium; on the other hand, some effective biosecurity measures should be more frequently practiced. It needs to be emphasized that these 138 farms voluntarily participated in this study and may therefore not be representative for all pig herds. Therefore it is likely that the general results are lower than the results presented here.

The biosecurity scoring system is used in another study (Laanen et al., 2010) to relate biosecurity in a quantitative way with health and production parameters.

Preliminary results on the link between biosecurity status and herd characteristics, daily weight gain and mortality

Maria Laanen; Stefaan Ribbens; Dominiek Maes; Jeroen Dewulf
Faculty of Veterinary Medicine, Ghent University, Belgium, Merelbeke, Belgium

Introduction
It is believed biosecurity influences production results, nevertheless, few studies succeed in demonstrating this link. In order to quantify the biosecurity situation on pig farms a biosecurity scoring system was developed (Laanen et al., 2010). This scoring system was used to study the relation between the biosecurity on a farm and herd characteristics, daily weight gain and mortality.

Materials and Methods
Thirty one randomly selected Belgian pig herds were visited. The herds had at least 80 sows and 500 fattening pigs. During a herd visit, the biosecurity status of the herd was quantified by means of a biosecurity scoring system (Laanen et al., 2010). At the same time additional data concerning the herd and production characteristics (number of sows, number of piglets, number of fattening pigs, age of the buildings, years of experience of the farmer, daily weight gain and mortality of fattening pigs) were collected.

Results
Herd characteristics:
A positive correlation was found between the number of sows on a herd and both the external (r = 0.43, p = 0.02) and internal (r = 0.34, p = 0.06) biosecurity. Also the number of piglets (< 25kg) and the external biosecurity were positively correlated (r = 0.39, p = 0.03). The correlation with the internal biosecurity was only weakly positive (r = 0.19, p = 0.30). No correlation was found between the number of fattening pigs on a herd and the external or internal biosecurity.

Both the age of the buildings and the years of experience of the farmer were negatively correlated with the internal (r = -0.41, p = 0.02; r = -0.21, p = 0.27 respectively) and external (r = -0.14, p = 0.46; r = -0.09, p = 0.64 respectively) biosecurity.

Performance of fattening pigs:
The daily weight gain of the fattening pigs was positively correlated with the external biosecurity (r = 0.28, p = 0.15), but no effect of the internal biosecurity (r = 0.03, p = 0.86) on the daily weight gain was found. No clear effects of the biosecurity status of the herd on the mortality of the fattening pigs were found.

Discussion
These results clearly indicate the existence of a positive correlation between the number of sows or piglets on a herd and the level of biosecurity, indicating that farmers with larger herds pay more attention to biosecurity than those with smaller herds. The larger a herd becomes, it is more likely to be more professional and well managed. No comparable effect was seen for the number of fattening pigs on the herd. It should also be noticed that the found correlations are moderate to low.

It is also noticeable that the biosecurity increases with a decreasing age of the buildings. This illustrates that in more modern infrastructure more attention is paid to biosecurity. The same holds for the years of experience of the farmer suggesting that younger farmers are more interested in, and willing to apply biosecurity measures.

When evaluating the link with the daily weight gain of the fattening pigs it appears that this increases with an increasing external biosecurity, whereas for mortality no clear link could be identified. This was also seen in a study by Maes et al. (2004).

Several of the found correlations are not statistically significant and therefore need to be interpreted with care. Yet in this study only the results of the first 31 herds out of an ongoing study on 100 herds are presented. Therefore it is believed that with increasing sample size several of the observed trends will become statistically significant. Moreover, the data will be further explored to identify the parts of biosecurity that are the most influential on health and production parameters.

**Evaluation of mortality rate in fattening pig herds and respective correlation on biosecurity measures**

Giuseppe Martano  
ASI TO3, Vigone, Italy

### Introduction

The aim of this study is to evaluate the mortality rate and correlation with biosecurity level in 26 finishing pig herds and to obtain more knowledge about major risk factors.

Biosecurity is very important in the health management of intensive pig farms, to avoid introduction of pathogenic germs and to reduce microbial circulation in the herd.

Many swine herds could to improve their health standard through improved external and internal biosecurity measures.

### Material and Methods

A survey was performed on 26 fattening pig herds located in Pinerolo District, Northwest Italy to describe their biosecurity status and mortality data, expressed as the number of dead pigs divided by the number of pigs placed in the growing-finishing unit. The herds size ranged from 420 to 4050, for a total of 31,000 pigs. All herds introduced pigs at age 70-90 days and the same were slaughtered not before 270 days old.

In order to collect data it has been used a questionnaire divided in different sections regarding internal and external biosecurity, feeding and sanitary treatments.

It was collected data about mortality rate in the last four years (from 2006 to 2009).

### Results

Mortality rate has been evaluated for each farms.

The overall average mortality rate from 2006 to 2009 resulted 4.41 per cent.

</tr>
</tbody>
</table>

No statistical significant difference from year to year for the totality of farms: nevertheless in some herds this index is very variable.

Mortality percentage in the single herds ranged from 1.28 % to 9.12 %.

### Discussion

Some potential risk factors were evaluated about high mortality percentage.

In this work we found farms that introduced piglets from more than two origin herds were associated with higher mortality. Also biosecurity level could influence the mortality.

Biosecurity on farm should be considered a dynamic process, which require recurrent improvements.

In this study, we found that some important strategic practices were not implemented in most of the pig herds.

In all farms the biosecurity level is susceptible of improvements. Reduce mortality in the herds is a target to reach.

A study of cleaning methods on number of bacterial count on farrowing crates in pig farms

Pariwat Poolperm; Suwicha Kasemsuwan; Prapha Songjiinda; Kanokkan Nunta; Peerakorn Jittrarak; Nisarat Iamnoi; Sakarin Praprut; Soraya Na-ranong
Kasetsart University, Nakornpathom, Thailand

Introduction
The important risk factor of infection for farrowing sows and piglets is direct exposure to infectious microorganisms. The farrowing crate floor is the main source of bacteria contamination and it is the first surface piglets are directly exposed to after birth (1). Hence, the cleanliness of farrowing crate is vital to reduce the risk of MMA/PHS in farrowing sows and diarrhea in piglets. It is therefore of interest to assess the efficacy of cleaning methods that are used generally in pig farms in Thailand.

The aim of this study was to evaluate the efficacy of different cleaning methods on farrowing crates in pig farm considering the mean of total bacterial count (TC), coliform count (CF) and percentage of E. coli (EC) positive on the floor after cleaning.

Materials and Methods
A comparison of four different cleaning methods; 1) using high pressure and washing with detergent (CT, n=4), 2) same as CT additional with pouring disinfectant one-time (T1, n=10), 3) same as CT additional with pouring disinfectant two-times (T2, n=10), and 4) same as CT additional with pouring disinfectant one-time and flaming floor thoroughly (T3, n=10) were evaluated. The disinfectant (Beta-Q®) used in the study was glutaraldehyde base.

Five positions that towards each corner and one in the middle on the farrowing crate for each cleaning method were swabbed using wet and dry technique before cleaning (d-1), at 1-2 hours (d0), 1 (d1), 2 (d2) and 3 days (d3) after cleaning. Pooled samples for each crate were cultured onto PCA agar (Criterian®, Santa Maria, CA, USA) and coliform agar (Chromocult®, Merck KGaA, Darmstadt, Germany). Colonies of total bacteria and coliform were counted. E.coli was counted and reported as percentage of positive crate. Average of log10 bacterial counts of each cleaning methods were compared using repeated measure ANOVA.

Results
The results showed that total bacterial count (fig.1) in CT group significantly differed from T1, T2 and T3 (p=0.02). There were no significant differences in the TC and CF among the T1, T2 and T3 methods. Coliform was lowest on day 2 and increased significantly on day 3 after cleaning, which was the same as % of E.coli positive crate that increased on day 3. The longer period after cleaning, the higher number of coliform and percentage of E. coli positive crate were found in this study. The percentage of E. coli positive samples in T1, T2, T3 and CT cleaning method were 40%, 30%, 15% and 50%, respectively. T3 method showed the lowest percentage of E.coli.

Discussions
This study demonstrated the benefits of cleaning practices with applying additional disinfectant and/ or flaming step. Without disinfectant the floor was not efficiently clean using only high pressure and detergent washing. The proper cleaning method on farrowing crate could reduce bacterial contamination on the floor and reduce risk of sow being MMA/PHS during farrowing period. The longer period after cleaning was at risk of re-contamination from moving sows in or out of the barn.

Introduction
Frequent transmission of PRRS virus from one premises to another has hampered control and elimination efforts and suggests that current biosecurity practices are often ineffective. Published information on current biosecurity practices in the U.S. is limited. One of the few organizations which does publish such information is the USDA’s National Animal Health Monitoring System (NAHMS). The most recent study published by NAHMS, the Swine 2006 study, provided some information on biosecurity practices. Additional information would help producers and veterinarians benchmark biosecurity practices against others in the U.S. and help define industry needs for biosecurity education.

The purpose of this paper is to describe biosecurity practices related to mortality disposal in U.S. swine breeding herds using the database of assessments from the American Association of Swine Veterinarians (AASV) Production Animal Disease Risk Assessment Program (PADRAP). PADRAP is an epidemiologically-based initiative to help producers and veterinarians manage disease risks. PADRAP is used by veterinarians as a tool to evaluate current biosecurity protocols and/or develop new biosecurity protocols to avoid risk. There are currently two risk assessments available within PADRAP: the PRRS Risk Assessment for the Breeding Herd and PRRS Risk Assessment for Growing Pig Herd.

Methodology
The PRRS Risk Assessment for the Breeding Herd contains questions regarding introduction of a non-resident PRRS virus (external biosecurity) and management of a resident PRRS virus within a herd (internal biosecurity). Mortality disposal is one of 14 categories of external biosecurity factors in the assessment. As of October 2009, the PRRS Risk Assessment for the Breeding Herd (v2) database had 1749 risk assessments from 1017 premises. Of the 1017 premises, 68.0% are in the U.S., 18.3% in Canada, and 13.7% in Mexico. Only assessments on breeding herd premises in the U.S. completed between May 2005 and October 2009 were included in this analysis.

Results
The 689 premises included in the analysis were completed for premises in 25 different states and represent 1,567,889 sows, which is approximately 26.8% of the national inventory (5,850,000). A majority (77.5%) of the premises are commercial breeding herds, including those with internal multiplication, and 22.5% are genetic breeding herds producing replacement animals for breeding purposes. Nineteen percent of the premises have fewer than 800 sows, 29% have 800 to 1999 sows, 31% have 2000 to 2999 sows, and 21% have greater than 3000 sows. Sixty percent of the premises are reported to be PRRS positive while 40% of the premises are PRRS negative.

Discussion
The authors are not aware of any studies that have shown that off-site disposal of mortality is associated with greater biosecurity risks but rendering trucks picking up mortality for off-site disposal creates many opportunities for introduction of virus into a herd. If properly managed, on-site disposal by burial, incineration, or composting very likely creates fewer biosecurity risks. For the 32.5% of the premises in this analysis still using off-site disposal there is an opportunity to improve their biosecurity by switching to on-site disposal. The opportunity is greatest for the largest herds where 36.5% of premises are using on-site disposal. Adoption of on-site disposal in large herds is complicated by the larger volume of mortalities making it increasingly more difficult to manage. For those premises that cannot justify on-site disposal for management or economic reasons, there are still opportunities to reduce biosecurity risks by using enclosed, or in some areas refrigerated, boxes to store mortalities awaiting pickup. This study suggests that there are still significant needs for educational efforts that emphasize the importance of managing biosecurity risks related to mortality disposal practices in U.S. swine production.

Serology-based classification of pig herds into “zoonoses risk categories” and “herd health categories” by using meat juice as specimen

Diana Meemken; Juliane Nobmann; Thomas Blaha
Field Station for Epidemiology, University of Veterinary Medicine Hannover, Bakum, Germany

Introduction
The high number of foodborne diseases in humans such as salmonellosis and yersinioses, which leave no apparent or palpable alterations, proves that the traditional meat inspection as end product inspection is not able to control the risks of today (1). Therefore the European Commission has issued a new food safety legislation which regulates the transition of the traditional meat inspection, which demands inspecting each individual carcass in the same way, to a risk-based meat inspection, where the method and the intensity of the inspection are to depend on a risk assessment for human as well as for animal health. This risk assessment is based on the so called food chain information which contains data such as the housing conditions, the use of antibiotics, the results of previous slaughter checks and the results of serological monitoring systems to detect zoonotic pathogens (2). The objective of this paper is to evaluate a set of serological tests, which provides a classification of pig herds into “zoonoses risk categories” as demanded in the regulations and, into “herd health categories” by using meat juice. Collecting meat juice from carcasses at the slaughter line instead of taking blood serum from pigs in the barn by veterinarians implies an increased cost benefit, especially by applying the once taken sample for various ELISA tests.

Material and Methods
To evaluate the general usability of meat juice as specimen for such ELISA tests, which are solely licensed for blood serum, several test runs with lower dilutions than prescribed for blood serum were conducted. Subsequently, a set of serological tests was selected, which provides results with relevance for human health (measuring antibodies of zoonotic pathogens) as well as for pig herd health (measuring antibodies of infectious pathogens for pigs). Altogether, blood sera and meat juices from 328 pigs were collected at the slaughter line and tested with seven different ELISA-tests, whereas meat juice was ten times fewer diluted than the prescribed dilution for blood serum, respectively.

Results
The proportion of positive samples and the degree of correlation between the results with serum and meat juice as specimen are shown in Table 1.

Table 1: Correlation between ELISA test results with blood serum and meat juice of 328 slaughter pigs

Discussion
The demonstrated high degree of correlation between the test results with sera and meat juice shows that it is possible to use meat juice for serologically evaluating the health status of a herd in the framework of the risk-based meat inspection. As for Yersinia enterocolitica a serology-based classification of pig herds may, despite the high seroprevalence of 70% become the start of a targeted search for risk factors. All in all, this ELISA-based approach with meat juice as specimen is feasible to detect herds with pig health and zoonotic problems. Targeted intervention measures can be established on the farms. The availability of standardised and validated herd health assessment tools is of an increasing importance, since there is a worldwide move from curing disease to prevention.

**Presence of zoonotic interest bacteria in slaughter pigs**

Laura Hernandez-Andrade¹ Paulino Elizalde-Castañeda¹ Rosa Urrutia¹ Luis Moles y Cervantes² Efren Díaz-Aparicio¹

1. INIFAP, México, DF, Mexico; 2. Universidad Autónoma Metropolitana-Xochimilco, México, DF, Mexico

**Introduction**

Animal slaughter is one of the professional activities with a higher degree of risk, with a very significant role in the transmission of zoonotic diseases. Slaughterhouse operators, that are in direct contact with carcasses or viscera are the ones that are more at risk (1, 2, 3). Among the main bacterial zoonosis in swine are salmonellosis, brucellosis, yersiniosis and leptospirosis.

**Material and Methods**

Since the frequency of these organisms in swine in Mexico is not known, a pilot study with 20 samples was done to estimate infection frequency and based on this estimate the sample size (n) was established with the equation n=v²(p)(1-p)/T².

The minimum sample size was estimated in 62 pigs, nevertheless it was increased to 100.

The origin of the animals was the States of Jalisco, Guanajuato, Sonora and Michoacán. From each one of the slaughtered and apparently healthy animals samples were taken from blood, tonsils, ileum, kidney and spleen.

Samples were individually deposited in sterile glass flasks and plastic bags, properly identified and preserved at refrigerator temperature (4°C). For brucellosis diagnosis, card test and bacteriology from spleen were performed. For leptospirosis a microscopy agglutination technique was used employing 13 serovars of Leptospira interrogans and bacteriology from kidney. Bacteriology study was performed for Salmonella diagnosis using samples from ileum and tonsil samples were used for diagnosis of Yersinia enterocolitica.

**Results and Discussion**

Salmonella study results were negative for all animals. Five reactors were found for Brucella by serology (5%) but no isolation was achieved. Twenty-five (25%) positive reactors to two serovars of Leptospiro were found: L. bratislava 19 animals (19%) and L. panama 6 (6%) with no isolation of the bacteria. Twenty-two (22%) isolations of Yersinia enterocolitica biotype 1 serotypes 0:3 and 0:9 were obtained; no crossed reaction was detected in the serology for brucella in the sera of the pigs where Yersinia enterocolitica was isolated. Positive animals came from the States of Jalisco and Guanajuato. It is concluded that of the four diseases that were studied, the one that had more relevance was Y. enterocolitica with 22% of isolations in slaughter swine that are apparently healthy.

**References**

Introduction
Animal health and public health are key issues in pig production for both economical and social reasons. Health management needs the implication of all stakeholders. The latter are more likely to feel involved if they are aware of the importance of the issues they have to control.

The aim of this study was to determine through a survey which issues were regarded as matter of concern by agents involved in pig raising and health control in pig production.

Materials and Methods
The study took place between June and October 2009 in France. Seventy-three semi-structured interviews were carried out by a single investigator who met 45 veterinarians or scientists, 14 farmers and 14 technicians. Veterinarians/scientists were selected on a geographical basis (all over the north west of France, i.e. the main pig production area in the country). Some of them were asked to select one farmer and one technician they work with. During the interview, the agents were asked to identify what they consider as the main issues for animal health and public health in the pig production chain. They were additionally demanded to explain why a given issue was regarded as a matter of concern.

Results
Seven items were the most frequently cited by agents. Diseases of pigs were the first issue that they cited, among which the main items were PRRS, Porcine Circovirus Associated Diseases, colibacillosis (mainly oedema disease whose occurrence seems to be increasing), actinobacillosis and enzootic pneumonia. The matter of concern is the improvement of control measures. Salmonella is regarded as a public health concern in the control of which the all production chain should be involved. Many agents insist on the need to reduce the use of antimicrobials for both economical and social reasons. Influenza was categorised as a “mediatic” issue although agents notice that diagnostic tools and vaccines could be improved for this infection. Herd management and biosecurity are cited as key tools for improvement of animal and public health.

Discussion
We were interested in questioning agents involved in animal and public health management at several levels: advisors, supervisors or implementers i.e. vets, technicians and producers respectively.

Apart from pig diseases and their impact on animal health and welfare as well as on farm productivity, many stakeholders highlighted the lack of communication on animal and public health in the pig production chain. Consequently although stakeholders feel more and more involved in the improvement of animal and public health, consumers seem not to be aware that these issues are taken into account. This point was raised as a specific item and was cited for Salmonella, use of antimicrobials, influenza, welfare regulations.

Introduction

Despite public opinion to minimize the use of antibiotics in food-producing animals, use of antibiotics in pigs, veal calves and poultry has been increasing during the last decennia (1). The aim of this study was to quantify the use of antibiotics in Dutch nucleus herds in 2007 and 2008.

Materials and Methods

Thirty-seven nucleus farms of the Dutch breeding association TOPIGS were visited to collect data of the total quantity of antibiotics purchased in 2007 and 2008, and of the number of animals for each category (sows, weaned piglets, nursing piglets, gilts, finishing pigs). Additional data about management and medication regime were included in this survey. The quantity of antibiotics used was expressed in DD/ay (daily doses per animal year), which indicates with how many daily doses an ‘average’ animal of the farm is treated each year. The farms were divided into categories depending on health status: conventional (n=33) or SPF (n=4). DD/ay was analysed using a linear mixed model (2) allowing for repeated measurements and random effects of farm (nested within health status). Effects of year, health status and farm size were included in the model. Data were not normally distributed and therefore log transformed.

Results

Average DD/ay did not differ between 2007 and 2008. SPF farms have a lower mean DD/ay (2.21 ± 2.29) than conventional farms (14.04 ± 15.90) (r = 0.68, p<0.001). DD/ay was positively correlated with the herd size (Figure 1).

Figure 1 Herd size in relation to DD/ay. The dashed line represents the regression line for data from 2007 (y = 0.0601x − 6.118 (R² = 0.4422)), the solid line for the data from 2008 (y = 0.0512x − 5.8528 (R² = 0.5256)). White triangle = 2007, black dot = 2008

Discussion

There are huge differences in DD/ay between farms. These can partly be explained by health status and herd size.

As expected, SPF farms have lower DD/ay compared to conventional farms. This might be due to the absence of specific pathogens, and a strict hygiene. Strict hygiene itself may be a reason for lower prevalence of endemic infectious diseases, even in SPF herds. On conventional farms the difference in DD/ay between farms is striking. There is a more than 300-fold difference between the lowest and highest DD/ay.

The number of sows present on the farm is associated with the DD/ay. Data collected from individual farms showed that farmers of large herds more often medicate pig groups routinely. Further analysis will be conducted to study the decision making with respect to group medication and its effect upon total DD/ay.

The large differences between herds and the assumed large influence of group medication on the total DD/ay indicates that a strategy is feasible to minimize the use of antibiotics in the future.

Restrictive use of antibiotics: who decides?

Leo van Leengoed1 Ellen Meijer1 Inge van Geijlswijk2 Geertjan van Groenland3 Merel Postma1 Hanneke Feitsma4 Dik Mevius5

Department of Veterinary Pharmacy, Faculty of Veterinary Medicine, Utrecht University, Utrecht, Netherlands; 3. TOPIGS, Vught, Netherlands; 4. Institute for Pig Genetics, Beuningen, Netherlands; 5. Department of Infectious Diseases and Immunology, Faculty of Veterinary Medicine, Utrecht University, Utrecht, Netherlands

Antibiotics in food-producing animals are often used to allow logistic efficacy in husbandry. This dictates a labor-saving strategy of group-medication to prevent disease. Risk upon infectious diseases, that are endemic, is managed by routine medication, and this preventive use of antibiotics has become a public health threat. The increase in prevalence of multi-resistant bacteria in swine herds that may affect both animals and humans (1,2), urges to reduce the use of antibiotics. In contrast to the awareness of these risks the use of antibiotics in pigs, veal calves and poultry has been increasing during the last decennia (3). Therefore, a decision matrix was designed to get a transparent use of antibiotics in pig herds.

By definition, bacteria are selected for resistance when exposed to an antibiotic. Increase has been found in prevalence of animal-related Methicillin-Resistant Staphylococcus aureus (vMRSA) and Clostridium difficile ribotype 078, that both have a resistant profile that mimics antibiotics used in humans.

Therefore, a convenant between the Royal Dutch Veterinary Association and the Ministry of Agriculture is signed in 2009, and aims to reduce the use of antibiotics in farm animals (5). Veterinarians have economic interest in selling antibiotics to farmers. Farmers have economic interest in preventive use of antibiotics as it can cover up shortcomings of their husbandry system.

Ten TOPIGS nucleus herds were analyzed with respect to antibiotic use. Antibiotic use was expressed as DD/ay, which indicates with how many daily doses an ‘average’ animal of the farm is treated each year. The daily doses were calculated on label use of the antibiotics purchased at each farm. A huge variation was observed between herds: 0.7 -57 DD/ay. High antibiotic use was based upon preventive use in oral medications in feed or drinking water. Routine medication of weaned piglets strongly contributed to the excessive use. However, 4 out of 10 of these nucleus herds had a DD/ay < 7. Use of cephalosporin or fluoroquinolone, antibiotics that should be restricted to human use, was limited or absent in most of these herds. The observed variation in antibiotic use indicates that reduction in use is feasible. National and EU regulations with respect to antibiotic registration, hygiene conduct and animal welfare intend to limit antibiotic use and to optimize husbandry conditions.

A decision matrix for antibiotic prescription by veterinarians was designed, based upon national Dutch as well as EU regulations. Routine medications in feed or drinking water account for the major quantity of antibiotics used and routine medication is always preventive. National regulations, however, state that farm animals should be kept in an environment that does not harm their health. This legal obligation is used in the decision matrix as an incentive to improve animal husbandry conditions. Each preventive medication of pig groups is coupled with an assessment of risk factors for infectious diseases present at the herd. Benchmarking of antibiotic use makes comparison of herds possible and transparent. Assessments with respect to working standards and education of farm workers are a consequence of use of the matrix, and essential to achieve reduction of antibiotic use.

Introduction

The use of antibiotics in food-producing animals has been increasing during the last decades in regions with intensive livestock production. The increase in prevalence of multi-resistant bacteria in swine herds that may affect both animals and humans, urges to reduce the use of antibiotics. In the Netherlands this has lead to an agreement between the most important players in the field of livestock production. This will lead to a national registration of the use of antibiotics per farm expressed in the so called DD/ay (Daily Doses per animal year). These registrations will be followed by analyses and advises to come to a substantial reduction and a better awareness of proper use of antibiotics as a tool to treat diseased animals.

The extensive use of antibiotics can partly be explained by a number of factors among others:

- Use out of habit – “we have always done so” - often not realizing that the original cause of using the treatment has vanished already for a long time.
- Masking management failures. In using antibiotics often necessary changes in the farm and the management are delayed.
- Treatments have been shifted from curative to preventive where often such treatments are given without a real effect or even sometimes with negative side effects.

Registration of the use of antibiotics on farms

On 45 of the TOPIGS breeding farms in The Netherlands (almost 50 % of the breeding stock) registration of the DD/ay has been done for the years 2007 and 2008. The same will be done for the year 2009. It is done in such a way that more extensive analyses per farm can be done:

- Registration per category of animals present (i.e. sows, suckling and weaned piglets, rearing pigs and if present finishers).
- Registration of the administration route of the medication (i.e. in or over feed via drinking water in case of group medication, routine needle medication, individual treatments based on farm specific formulae).
- Registration of the used groups of type of medication.

Interventions and further actions

In close co-operation with farmers and their farm veterinarians, a decision matrix will be implemented in order to omit all preventive treatments and mass medications and to exclusively use antibiotics for curative purposes that complies with Good Veterinary Practice. This will be achieved by:

- accurate instruction and training of herdsmen and farm workers with respect to risks, precautions, side effects and administration techniques.
- the before mentioned intensive analysis, bench marking between the various breeding farms,
- a thorough analysis of the causes of disease problems that exist on the farm (with support of laboratory analyses),
- an intensive analysis of managerial improvement items. In this field one can think of:
  - internal bio-security improvements like age separation, prevention of mixing animals, working order, prevention of unnecessary contact structures, etc.
  - changes in farm lay-out and housing aspects
- a critical evaluation and possibly adaptation of the vaccination program running on the farm

We realize that more factors will be taken into account in adapting the farms to a strategy that must lead to a change of mind in using antibiotics and preventive interventions by antibiotics will be avoided.

As a breeding company, being on top of the pyramid of producing meat for human consumption, we take our responsibility. We have to be ahead on the growing awareness in the Netherlands that social acceptance of meat production goes along with restricted use of antibiotics.

Future developments

It will be clear that at this very moment of submitting the abstract, implementing of the above described procedures is going on. In June 2010 new data of this project will be available and incorporated in our presentation at IPVS.

Isolation of Methicillin-Resistant *Staphylococcus aureus* from nasal swabs and Broncho Alveolar Lavage Fluid from flatdeck and fattening pigs in Northwest Germany

Christoph Keller¹ Christian Brüggemann² Rolf Nathaus² Heinrich Wilkes² Ohlinger F. Volker¹

1. BioScreen EVDMC GmbH, Münster, Germany; 2. VETeam Reken, Reken, Germany

**Introduction**

*Staphylococcus aureus* is a Gram-positive Bacterium, that occurs in man and practically all species of animals. Apart from clinically latent colonization of skin and mucous membranes, it is a potentially pathogenic bacterium, that causes a broad range of diseases. Methicillin resistant *S. aureus* (MRSA) isolates causes severe nosocomial infections in humans.¹ Recent studies demonstrate, that MRSA has a very high prevalence in pigs.²,³ As so far no clinical disease can be linked to MRSA or methicillin sensible *S. aureus* (MSSA) in pigs, the pathological importance of the high prevalence of *S. aureus* in pigs is not clear. The aim of this study was to investigate the occurrence of MRSA and MSSA in lower respiratory tract of pigs.

**Materials and Methods**

230 BALF samples and nasal swabs were taken by the same veterinarian on 20 piglet producing farms and 6 connected finisher units. All samples were inoculated on Columbia blood agar plates, Columbia blood agar plates with CNA and a chromogenic selective agar for the isolation of MRSA (MRSA-Ident agar) (heipha Dr. Müller GmbH, Eppelheim, Germany) within 24 h after sampling. Plates were incubated at 37 °C. Bacterial growth was evaluated after 24 and 48 h of incubation. All suspicious Staphylococci were isolated. Biochemical identified was done by the use of API ID 32 Staph (bioMérieux Deutschland GmbH, Nürtingen, Germany). *S. aureus* isolates were additionally identified by a *S. aureus* specific PCR and tested for the presence of the mecA gene.⁴

**Results**

A total of 180 *S. aureus* were isolated in this study. The majority of these isolates were MRSA (158 out of 180; 87,78%). MRSA could be isolated from 126 out of 230 nasal swabs (54.8%), whereas only 32 BALF samples from the same animals were positive for MRSA. A comparable number of both sample types were positive for MSSA: 12 (5.2%) of the nasal swabs and 10 (4.4 %) of the BALF samples. Seven nasal swabs were positive for MRSA and MSSA (3.0%), but only in two BALF samples (0.9%) MRSA and MSSA were detected in parallel. One pig was positive for MRSA and MSSA in the nasal swab and the BALF sample. No *S. aureus* were detected in 99 nasal swabs (43.0%) and in 190 (82.6%) of the BALF samples. In nasal swabs from 23 farms MRSA were detected (88.5%), whereas only 12 farms (46.1%) were positive for MRSA when examining the BALF samples. MSSA were detected in the nasal swabs from seven farms (26.5%) and in the BALF from five farms (19.2%).

**Discussion**

The majority of the *S. aureus* isolates found in this study were resistant to methicillin. Interestingly MRSA and MSSA were not present at the same ratio in nasal swabs (12.6:1) and BALF (3.2:1) samples from the same animals. This indicates that MRSA colonizes preferably in the nasal cavity and has no tendency to colonize the lung alveola. Most of the nasal swabs, that were positive for MSSA in the nasal swab were also positive for MRSA (7 out of 12; 58.33%). This indicates, that antibiotic pressure is not the major cause for the high prevalence of MRSA in pigs. Although the prevalence of MRSA on pig farms and in pigs is very high, in this study 88.5 % and 54.8 % respectively, so far no clinical disease could be linked to MRSA in pigs. Further investigations will be necessary to understand the significance of MRSA in pigs.

Occurrence of MRSA isolated from pathologically altered porcine tissues from 2004 to 2007

Diana Meemken² Regina Tegeler² Berd-Alois Tenhagen¹ Beatriz Guerra¹ Alexandra Fetsch¹ Thomas Blaha²

1. Federal Institute for Risk Assessment, Department of Biological Safety, Berlin, Germany; 2. Field Station for Epidemiology, University of Veterinary Medicine Hannover, Bakum, Germany

**Introduction**

Since 2005 data on Methicillin-resistant *Staphylococcus aureus* (MRSA) isolated from farm animals have been published in various countries (1,2,3). Most of these MRSA are of the spa-types which are associated with the Multilocus Sequence Type (MLST) ST398. This type was also found as nasal colonizer in farmers, veterinarians and slaughterhouse staff (1,2). As in humans, the nasal colonization of MRSA in pigs is in most cases without clinical symptoms. However, there are reports on MRSA as causative agent with clinical symptoms such as exudative dermatitis (4).

Triggered by the fact that most researchers assume an emerging occurrence of MRSA ST398 since 2005 in farm animals, our study focuses on two questions:

a) Has MRSA ST398 only started to occur in pigs in 2005?
b) Can MRSA be isolated from pathologically altered tissues in pigs?

This paper reports the results of reculturing *S. aureus* strains isolated from inflammatory lesions of pigs submitted for diagnostic purposes to the Field Station for Epidemiology of the University for Veterinary Medicine Hannover, Germany.

**Material and Methods**

In this study, 138 stored *S. aureus* isolates, collected between 2004 and 2007 from various pathological lesions of pigs at necropsy, were recultured and potential MRSA were identified by growth on selective chromogenic media. At the Federal Institute for Risk Assessment, Berlin, Germany, all presumptive MRSA isolates were analysed for confirmation by a triplex PCR (5). Furthermore, spa-typing (6) of all confirmed MRSA isolates was performed to determine whether the isolates belong to spa-types associated with the MLST-type ST398. Additionally, all 138 cases were analysed whether *S. aureus* was found in pure or in mixed cultures.

**Results**

Out of the 138 *S. aureus* strains, isolated from pathologically altered porcine tissues between 2004 and 2007, 60 isolates (43%) turned out to be MRSA (Tab. 1). The majority (57/60) of the MRSA-isolates found were spa-types associated with MRSA ST398. Three MRSA were ST97, a type that has not been described as an MRSA in pigs before. The proportion of MRSA in the tissues are shown in Table 2.

**Discussion**

Since MRSA ST398 isolates were found in similar frequency in all four years, we assume that MRSA in pigs may have occurred earlier than 2004 and might not be really emerging, but rather have been overlooked until recently. Furthermore, MRSA ST398 is not only a nasal colonizer, but needs to be discussed as contributor (or even cause) of various lesions in pigs.

Screening pig farms for MRSA in the Euregio-Region of Lower Saxony part of the MRSA-Safeguard-Project

Josef Schulte-Wuelwer¹ Robin Koeck³ Alexander W. Friedrich³ Susanne Gundlach² Juergen Apel² Hendrik Nienhoff²
¹. Swine Health Service, Chamber of Agriculture Lower Saxony, Oldenburg, Germany; ². LUFA NRW, Muenster, Germany; ³. Institute of Hygiene, University Hospital Muenster, Muenster, Germany

Introduction
Resistant pathogens, especially coagulase-positive staphylococci are a major challenge in both human- and veterinary medicine. The importance of MRSA in swine production for human medicine has grown in the last years (1,2). The aim of this study was to estimate the prevalence of MRSA in German pig farms in the Dutch-German border region (Euregio) of Lower Saxony, Germany.

Materials and Methods
From May to Oct. 2009 54 pig farms were tested for the presence of MRSA. Five barn dust samples or ten nasal swabs were taken per farm. After 24-h enrichment culture in selective broth, all cultures were streaked onto Columbia-blood agar and a chromogenic medium for the detection of MRSA (bioMérieux, Marcy l’Etoile, France). Methicillin-resistance was tested by cefoxitin disc agar diffusion and was confirmed by mecA-specific PCR (5) and all MRSA isolates were typed by S. aureus protein A (spa) sequence-based typing (6).

Results
31农场 were positive (57.4 %). Among these, 26 farms were detected positive by barn dust, 5 by nasal swabs. 22.2% of the barn dust samples were positive and 43.6% of the nasal swabs were positive. The geographic distribution of MRSA positive and negative farms is shown in Fig. 1.

Fig. 1: Location of the sampled and positive pig farms

Discussion
Up to now no correlation between different farms or types of farms could be found. Breeding herds as well as fattening farms had positive results. Also new built farms and high health herds were positive. No regional accumulation in relation to pig density could be found. Our findings, including the spa-typing results, correspond well, to data of other authors (2,3,4).

A longitudinal study on MRSA colonization on gilts in supplier farms

Jürgen Harlizius1 Uwe Heinbach1 Susanne Gundlach2 Alexander Friedrich3 Robin Köck3
1. Animal Health Services, Landwirtschaftskammer NRW, Bonn, Germany; 2. LUFA, Landwirtschaftskammer NRW, Münster, Germany; 3. Universitätsklinikum, Münster, Germany

Introduction
Recently, Methicillin-resistant Staphylococcus aureus (MRSA) have emerged in pigs in most European countries (1,3). Pigs colonized with MRSA are found on 70% of pig farms in North Rhine-Westphalia, Germany (2). However, the dynamics of colonization among the animals is unclear and strategies for avoiding the spread of MRSA between pig holdings are lacking.

We raised the question when gilts from a nucleus herd documented to be specifically “free” of MRSA get colonized, if they are introduced into MRSA positive farms.

Methods
Within the framework of the Euregio project SafeGuard VetMedNet we identified 2 MRSA free nucleus farms. We chose 3 farms on which MRSA had been detected before in animals or the environment and one farm which was free of MRSA when tested consecutively by pooled samples (n=5). One nucleus herd was build up PaR, PRRS and M.hyo. free after repop/depop in 2007. Since this time the farm is also free of MRSA. We analysed the colonization status of MRSA free gilts introduced into breeding herds known to harbour MRSA colonized pigs and herds which were tested negative for MRSA.

A total of 65 gilts tested negative for MRSA colonization, were introduced into three MRSA positive and one MRSA negative pig holdings. Immediately after the introduction of the gilts into the new herds, nasal swabs were derived from all 65 gilts. During a ten-week-period, swabs were taken 7 times with a sampling interval of 1-3 weeks. MRSA diagnostic was performed using a double enrichment in selective broth (Phenol Red Mannitol Broth with 5 mg/L ceftizoxime, 75 mg/L aztreonam) and plating on a chromogenic medium (Brilliance MRSA, Oxoid, Wesel, Germany). MRSA was confirmed using coagulase tube test and meCA-PCR All MRSA isolates were typed using the Staphylococcus aureus protein A (spa) approach (4).

Results
All gilts tested negative for MRSA colonization in the nucleus farms and introduced into the breeding herd in which MRSA had not been detected before, remained negative.

MRSA negative gilts introduced into MRSA positive herds, the gilts remained MRSA free again into the isolation pens. But immediately after introducing the gilts into the sows of the breeding stock, MRSA was detected. In the first week an overall colonization rate of 61% was observed, followed by 49% after 2 weeks, and 73% after 3 weeks, respectively.

Although colonization rate was fluctuant, overall 88% of all MRSA negative gilts introduced into positive MRSA holdings were found to acquire MRSA at least intermittently. Clinical symptoms were not seen in any sow. Characterization of spa types identified MRSA t011, t034 and t5838.

Discussion
We found that there are still MRSA negative pig production chains. Introduction of MRSA free gilts in positive herds led to frequent, but fluctuating colonization of the individual gilts. Therefore, it is unclear to what extent the colonization is transient or persistent. Since there was no clear difference in the use of antimicrobials between the MRSA negative and positive farms, preventive efforts will have to be set up for cleaning and disinfection schemes.

Longitudinal study on the colonisation dynamics of MRSA ST398 in two German pig herds

Diana Meemken1 Thomas Blaha1 Rolf Nathaus2
1. Field Station for Epidemiology, University of Veterinary Medicine Hannover, Bakum, Germany; 2. Veterinary Clinic Reken, Vet-Team-Reken, Reken, Germany

Introduction
The occurrence of one special clonal line of Methicillin-resistant S. aureus (MRSA) in farm animals, the so called livestock-associated MRSA ST398, is reported in several countries such as The Netherlands (1), Canada (2) and Germany (3). However, there are only few data illustrating the in-herd patterns of colonisation during the pigs’ lifetime. Our study presents information about the colonisation dynamics of MRSA in pigs from birth to the end of the nursery in two German pig herds.

Material and Methods
Data collection took place between November 2008 and May 2009 on two independent pig farms in the Northwest of Germany. Farm A is a two-site production system with 80 sows and farm B is a farrow-to-finish herd with 170 sows. On farm A, 58 piglets (two piglets each from 29 sows) and on farm B 40 piglets (two piglets each from 20 sows) were earmarked and tested repeatedly at a three week interval for MRSA by pharyngeal or nasal swab from birth until the end of nursery. Additionally, nasal swabs were taken from the 29 sows in herd A and from the 20 sows in herd B to learn more about the transmission of MRSA between the sow and its offspring.

Results
The proportion of MRSA-positive animals differed between the two farms remarkably (Tab. 1, Tab. 2).

Table 1: Microbiological results of nasal swabs of 29 sows and 58 piglets (two piglets each per sow) in farm A

While on farm A MRSA was detected in sows and piglets at the first sampling date, positive results on farm B in piglets did not occur before three weeks of life. However, findings of Methicillin-sensitive S. aureus (MSSA) in combination with Methicillin-resistant S. aureus at the same time are possible and can occur in quite high proportions as ascertained on farm A. Although S. aureus belongs to the normal porcine skin flora, an absence of S. aureus in the nasal cavity of sows and piglets is detectable in both farms, especially in farm B.

Discussion
The colonisation dynamics of MRSA and MSSA varies remarkably between farms. The MRSA colonisation status of pigs can change during the animals’ lifetime. The MRSA-status of the sow has a strong impact on the MRSA-status of the newborn piglet, and a weaker impact on the colonisation at later points in time during the animals’ lifetime. Furthermore, our results support the assumption that an early colonisation with MSSA might have a protective effect due to a phenomenon similar to a competitive exclusion between MSSA and MRSA. To be free from S. aureus early in life seems to lead to more MRSA findings at older ages.

Introduction
Methicillin-resistant Staphylococcus aureus (MRSA) is a leading cause of hospital-associated infections, and has emerged as a significant pathogen in the community. In the last decade, community-acquired MRSA (CA-MRSA) clones have been increasingly detected in companion animals and livestock. Recently, isolates belonging to MRSA Clonal Complex (CC) 398 have emerged in pig farming and it is now prevalent in farm animals in some countries of Central and Northern Europe (de Neeling et al., 2007). MRSA CC398 has also emerged as a cause of colonization and infection in humans and it is responsible for >20% of all human MRSA in the Netherlands. The aim of the study was to estimate the herd prevalence of MRSA in finishing pig holdings in Italy, to provide phenotypic and molecular characterization of isolates for epidemiological purposes, and to gather information about their relationships and their possible origin.

Materials and Methods
Herds were selected by a random sampling procedure (20% exp. prev.; 95% CL; 7.5% accuracy) from the national registry of holdings rearing pigs for slaughter, at the base of the pig production pyramid. For among-herd prevalence estimates, 118 holdings from 29 provinces and 10 different regions (Northern, Central and Southern, accounting for >90% of the Italian pig population) were enrolled for the survey. Sixty nasal swabs per holding were sampled at slaughter; they were pooled (10 per pool) and cultured through a multiple step procedure (pre-enrichment, selective enrichment and selective plating).

Results
A total of 45 out of 118 (38.1%, 95% CI 29.4%-46.9%) holdings were positive for MRSA. Nearly 50% (22/45) of positive holdings had only one positive pool. Eleven different spa-types were detected, three of which never described before (t4794, t4795, t4838), and belonging to five different MLST profiles, ST398, ST1, ST9, ST97, ST1476. 7.6% of holdings had their animals positive for 2, 3 or 4 unrelated spa-types belonging to ST1, ST97, ST1476 or ST398 in different combinations. Twenty-eight percent of holdings were positive for other lineages, one for ST9 (t4794), three for t4795, ST97 and ten for t1730. The most prevalent spa-type was t899, ST398, detected in 22/45 (49%) positive holdings, with an overall holding prevalence of 18.6%. Cattle- and human-associated CCs (CC97 and CC1) were found in 40% of positive holdings. The most frequent SCCmec ccr and mec combination was Type V, detected in 77% of isolates. All isolates were resistant to tetracyclines, and high resistance rates to trimethoprim, erythromycin and ciprofloxacin were detected. A pattern of tetracycline-erythromycin-ciprofloxacin resistance was a common feature among ST1 and ST(CC)97 lineages.

Discussion
This is the first description of: MRSA among pig population in Italy; three novel spa-types (t4794, ST9; t4795, ST97; t4838, ST398); MRSA of ST1 ST1476 and ST97 lineages among pigs, and the first report of MRSA ST9 in Europe. Spa type t899, ST398, was the most prevalent spa-type, although it had been considered a rare type in pigs until recent description in the Netherlands (van Duijkeren et al. 2008). The presence of unrelated spa-types within the same holdings (up to four spa-types), either belonging to ST398, CC97 or to ST1, suggests subsequent introduction of new strains over time as the most common pattern of colonization and diffusion among animals and holdings. This population study shows that pigs may be a possible reservoir for MRSA of the cattle-associated CC97 lineages, and for the human-associated ST1 (found in 6% of Italian holdings), and a source of exposure for the community from a zoonotic pathogen that may need little or no adaptation to humans. The antimicrobial resistance profiles suggest that beside the use of beta-lactams, the amount and pattern of usage of other drugs should be investigated as a further important predictor in the spread of MRSA within and among Italian pig holdings.

**Occurrence of MRSA in air and exhaust air of pig barns**

Anika Friese1 Jochen Schulz2 Laura Höhle1 Alexandra Fetsch3 Joerg Hartung2 Uwe Roesler1

**Introduction**

In recent years a distinction was made between community acquired [1] and animal associated MRSA (methicillin-resistant Staphylococcus aureus), that are also spread in pig production [2]. However, the knowledge on occurrence and transmission are still scarce.

From 2009 to 2011 a nationwide joint research project on MRSA in livestock production in Germany is currently funded by the Federal Ministry of Food, Agriculture and Consumer Protection. This paper gives preliminary results on the incidence of MRSA in animal house air and in exhaust air from pig barns.

**Materials and Methods**

**Sampled flocks**

A representative number of pig barns of different sizes and management schemes were investigated. MRSA positive and –negative barns were selected by initial screening of dust samples. Most barns were investigated once, some were chosen for long-term studies and will be continuously observed for one year.

**Sampling methods**

Environmental samples such as air samples, sock swabs, pooled samples from dust, faces and feed were collected. In addition swab samples of nose and skin of 60 pigs were taken in each barn. Air samples were collected in 1.50 m height above ground floor at three different locations in the animal house. For sampling All-Glas-Impingers (AGI-30) and IOM samplers (polycarbonate filter) were used simultaneously.

In barns chosen for the long-term-studies air samples of the exhaust air as well as sock swab samples from the ground outside the barn were taken. Air and sock swab samples were taken in different distances from the barn (100 m Luv, as well as 50 m, 150 m and 300 m Lee, respectively).

**Laboratory methods**

All samples were analysed qualitatively for MRSA. Additionally, quantitative analyses of the nose swabs and all air samples were performed. Swab samples of nose and skin were investigated individually and pooled.

Selective agar (CHROMagar) in combination with a triplex-PCR is used for the identification of MRSA.

**Results**

Until now, MRSA was found in dust samples in 51.2 % of 43 initial investigated flocks.

92.5 % of the individual investigated nasal swabs of all observed flocks (n = 132) were MRSA positive, with a mean bacteria count of 860 Cfu per swab. However 99.3 % of the pooled samples of nasal swabs (n = 132), yield positive results. Concerning the skin swabs 88 % of individual analyzed samples (n = 132) and 99.3 % of pooled samples (n = 132) were MRSA positive.

MRSA could be found in at least one of three air samples of every stable. In general, MRSA could be found in 78 % of the impinger and 47 % of the filter samples from stable air. The mean counts of MRSA were about 435 Cfu / m3 for impinger and 452 Cfu / m3 for filter samples.

MRSA was detected in each dust sample with a mean count of 7.6 x 104 / g. 64 % of fecal samples and 55 % of the feed samples were tested positive for MRSA.

All samples taken of the exhaust air were MRSA negative. However, in sock swab samples outside the barn the detection of MRSA was regularly possible.

**Discussion**

The present data show that a high rate of contamination of MRSA in pig barns exists. Detection of MRSA in the air was possible in each investigated barn. Impingement turned out to be more efficient to detect MRSA than filtration. In the environment around the barn no MRSA could be detected in air samples, however most sock swab samples were positive. It seems that MRSA are emitted from the investigated barns by way of the air and deposited in the environment, however the currently used techniques were unable to sample MRSA directly from the air.

The project continues and future investigations will also include techniques such as typing of MRSA strains which will lead to more information.

Prevalence of Methicillin-Resistant Staphylococcus aureus (MRSA) in different swine production systems and swine groups

Johannes Frick1 Stefan Hörmansdorfer2 Matthias Eddicks1 Susanne Zöls1 Andreas Palzer1 Mathias Ritzmann3 Karl Heinritzi1
1. Clinic for Swine LMU Munich, Oberschleißheim, Germany; 2. Bavarian Health and Food Authority, Oberschleißheim, Germany; 3. Clinic for Swine Vetmeduni Vienna, Vienna, Austria

Introduction
For several years, MRSA are well known for nosocomial infections in hospitals and nursing homes. MRSA can cause wound infections, post operative complications or severe general illness including death. So far, only a few cases of livestock associated MRSA transmission to humans has been reported (1,2). The present study is an epidemiological risk assessment of current MRSA prevalence in Bavarian swine farms, swine producers and their extended family.

Material and Methods
Animals of Bavarian swine farms, the farm owners and their families were examined for MRSA prevalence. For this purpose, 634 nasal swabs from pigs of 60 farms with different swine production systems as well as nasal swabs from 116 individuals from 57 of these farms were bacteriologically examined. All Staphylococcus aureus isolates were subjected to real time PCR for detecting the mecA-gene and orfX-gene, identifying methicillin-resistance and confirming the species Staphylococcus aureus (3). Strains which were identified by PCR were later characterized using spa-typing (4). A total of 63 strains were subjected to MLST (multilocus sequence typing). Furthermore, the presence of the Panton-Valentine leucocidin-gene (PVL) as a virulence factor for community-acquired MRSA was also examined.

Results
In the present study the MRSA herd prevalence of bavarian farms was 45.0% (see tab.1)

According to spa-typing of the isolated MRSA in pigs, spa-type t011 and spa-type t034 were identified in 86.7% and 10.0% of the samples respectively. Similarly, spa-type t011 (88.2%) and spa-type t034 (9.0%) were predominantly isolated from farmers. 62 of 63 strains belonged to MLST-type ST398. The Panton-Valentine leucocidin-gene was not identified in any of the isolates. None of the examined animals and persons except for one person with folliculitis showed clinical symptoms indicative of MRSA related diseases.

Conclusion
The prevalence of 45.0% in bavarian pig farms and 33.3% in pigs shows the widespread and the frequent occurrence of MRSA. Due to the examination of the owners, this study confirms that a MRSA transfer between pigs and humans within the production chain is not a rare occurrence. The spa-types t011 and t034 dominate in swine population as well as among farm owners. However, in comparison to hospital-acquired and community-acquired MRSA, low virulence is assumed due to the absence of the Panton-Valentine leucocidin-gene. But individuals should still consider undergoing a pre-operative MRSA screening before planning an operation to prevent MRSA introduction into hospitals and to minimize the risk of falling ill to a MRSA infection themselves while in hospital.

References
Introduction

Staphylococcus aureus including Meticillin-resistant S. aureus (MRSA) is frequently present on the skin, in the nose or in the mouth of human hosts without causing illness (Peacock et al., 2001). However, in some instances, S. aureus can cause disease when it enters wounds or damaged skin leading eventually to abscesses, pneumonia, meningitis, endocarditis and septicemia preferably in immune suppressed patients. Recently a specific clone (CC398) was identified in nearly all production animals, particularly in pigs, across Europe and world wide that colonises also farmers and veterinarians, and concerns rise that it may enter hospitals and the food chain (EFSA, 2008). Clear abatement strategies are not yet in place in animal production. This paper will describe control options on farms suitable to avoid or reduce transmission of these micro-organisms.

Short characterization of S. aureus

Staphylococcus is a genus of Gram-positive bacteria that are coccoid (spherical) and approximately 1 micrometer in diameter, have thick peptidoglycan cell walls, have a low G + C content, and grow in clusters similar to grapes (staphyl = grape). They are commensals colonising as normal bacterial flora nose, throat, axilla, rectum, perineum and gastrointestinal tract of mammals, but can also survive in a variety of environments and survive vastly desiccation. There are over 30 species of staphylococci, the most pathogenic species for humans is S. aureus. Infections, carriage or colonisation and contamination have to be carefully distinguished (EFSA, 2008).

Transmission routes

S. aureus is transmitted from human to human, animals to human and vice versa and through other viable or inanimate vectors (Roberson, 1999) such as flies or ticks ( Förster et al., 2007). Mechanical transmission occurs by means of body parts without a multiplication of the infectious agent (Last, 2000). Inanimate vectors could be medical devices, contaminated material or objects, food, milk and dust (Youngster et al., 2008). The transmission routes of methicillin-resistant S. aureus (MRSA) are probably similar to those of methicillin-sensitive S. aureus (MSSA) (Kawada et al., 2003) but there may be differences in the efficiency of host colonization due to genetic diversity. Examples of vector related transmission of MRSA strains will be given.

Prevention measures

In spite of the presently still limited understanding of the transmission routes it is even more important to apply and constantly improve bio-security measures in order to avoid spread of MRSA. Such general measures on farm level can help to reduce the entrance and the spread of infectious agents in general both within and between herds (Hartung, 2005) and can be described as follows:

- Restriction of traffic of cars and trucks and people transporting in and bringing out animals, feed stuff, equipment, slurry or manure.
- Avoid direct contact with animals. Provide protective clothing, gloves and breathing masks.
- New animals have to undergo veterinary inspection, testing and a quarantine time before entering the herd.
- Store fallen animals in separate and safe containers until removed as soon as possible by specialised companies.
- Reduce contact with rodents, insects and wild birds on the premises in order to avoid transfer of infectious agents and MRSA from farm to farm and between herds in a farm. Prevent pets of the farm to have access to the pigs.
- Check regularly the health status of personnel with regard to MRSA and other zoonotic diseases.
- Apply continuously strict cleaning and disinfecting regimes to all pig houses on the farm.
- In order to avoid airborne transmission of MRSA new farm buildings should be placed in sufficient distance to the next farm or residential dwelling ("safe distances").
- Air cleaners could be applied such as biofilters or bioscrubbers (VDI guidelines) to reduce or to eliminate bacterial emissions from farms (Seedorf and Hartung, 1999). However, experiences with these techniques are still underway for MRSA control.

There is an urgent need for more research to better understand the transmission pathways and hence be able to develop prevention and control strategies.

Use of serological monitoring to detect infection with *Salmonella* spp. in flatdeck piglets in Germany

Christoph Keller; Ohlinger F. Volker
bioScreen EVDMC GmbH, Münster, Germany

**Introduction**

Salmonella infections are still one of the most important food-born diseases in humans. Pig meat is one of the sources for salmonella infections in humans. In many European countries programs are established to monitor and reduce infections with salmonella in pig herds. So far these programs focus on slaughter pigs. In this study pigs about 10 weeks of age were examined, to get more information about the status of Salmonella infections in the production system prior to the fattening units.

**Materials and Methods**

The blood samples were tested for the presence of antibodies against *Salmonella* spp. using a commercial ELISA kit (HerdChek Swine Salmonella, IDEXX). The ELISA was performed according to the manufactures manual. In brief a 1:20 dilution of the serum sample with sample diluent was incubated at room temperature (18 – 25 °C) for 30 min in the antigen coated wells. After washing away of unbound material by three washing steps, 100 μl of anti-porcine horseradish peroxidase conjugate were added to each well. After a second incubation for 30 min at room temperature and additional three washing steps, 100 μl TMB were added to each well. Colour development was terminated by the addition of 100 μl stop solution to each well after 15 min incubation. The absorbance at 620 nm was measured for each well. Results were calculated as OD% in relation to the positive control samples on each plate. Interpretation of results war according to the manual and the German registration of the kit by the FLI (Zul. Nr.- BGVV-B305). Samples with OD% value less than 10 % were considered negative. Samples with OD% values equal to or greater than 10% were considered positive.

**Results**

A total of 4269 samples were taken from piglets end of flatdeck (about 10 weeks of age). The samples originate from 427 German pig farms. Antibodies against *Salmonella* spp. were detected in 317 blood samples (7.43%). The positive blood samples originate from 118 farms (27.63% of the tested farms). Within the positive farms 26.86 % of the samples (317 out of 1180) were positive. In 44 farms (37,3% of positive farms) only low positive results (OD% 10%-20%) were detected. High positive samples (OD% > 40%) were found in 42 farms (35.59 % of positive farms; 9.84 of all tested farms).

**Discussion**

The ELISA kit used in this survey allows to detect antibodies to a broad range of Salmonella serogroups indicating the exposure of a swine herd to the bacterium. The reliability and comparability of this ELISA has been verified in an international ring test. The data presented in this study demonstrate the presence of antibodies specific to *Salmonella* spp. in German piglets at 10 weeks of age. About 30% of the herds tested were positive for antibodies against *Salmonella* spp. at 10 weeks of age. This indicates that infection with *Salmonella* spp. does not only occur in slaughter pigs, but also earlier in production. So piglets should be considered as potential source of Salmonella intake in finisher units. However this result cannot be compared to the results from monitoring of slaughter pigs, which aim to categorize the health status of the herds. In this study the diagnostic cut off value of the ELISA was used to demonstrate exposure of the pigs to *Salmonella* spp. early in the production chain.

It can be concluded from this study, that control of Salmonella infection in pigs needs highly sensitive diagnostic tools and has to cover the complete production chain from piglets to slaughter pigs. Serological examination provides a powerful tool to monitor infections with Salmonella, when the diagnostic cut-off value of the ELISA (≥ 10 OD%) is used. Serological monitoring of herds using diagnostic cut-off values will not only raise awareness of infections with *Salmonella* spp. in pigs, but also provide a basis for effective disease control.

Antimicrobial resistance related to class 1 integrons in porcine Salmonella enterica serotype Typhimurium isolates

Aeran Kim; Ji Youn Lee; Hee Soo Lee; Suk Kyung Lim; Chun Tae Lim; Suk Chan Jung
National Veterinary Research & Quarantine Service, Anyang, Korea

Introduction
Salmonella enterica serotype Typhimurium is one of the leading causes of food-borne disease in developed countries. Multidrug resistance is generally linked to the presence of integrons and is often related to antibiotic use in food animals. In this work, we investigated the frequency, features and molecular epidemiology of class 1 integron-carrying porcine S. Typhimurium isolates.

Materials and Methods
A total of 128 S. Typhimurium isolates was collected from pigs and ducks during 2006-2007 in South Korea. Seventeen antimicrobial resistances were determined by disk diffusion method. The isolates were screened for the presence of class 1 integrons by polymerase chain reaction (PCR) amplification using specific primers aimed to detect the int1 gene. The number of integrons and the size of their variable region (VR) were analysed by PCR employing the 5’CS and 3’CS set of primers. Genotyping and phage typing of 19 typical class 1 integron-carrying isolates were performed by Pulsed field gel electrophoresis (PFGE) and phage typing.

Results
The highest rate of resistance was tetracycline (77.3%), followed by streptomycin (77.3%), nalidixic acid (76.6%), ampicillin (50.8%) and sulfamethoxazole/trimethoprim (46.9%). A low frequency of resistance was found towards cefazolin (4.7%) and cefoxitin whereas all isolates were susceptible to amikacin, ceftaxidime, ciprofloxacin and colistin. Only two different VR and two different integron profiles were identified among the 19 strains (14.5%) exhibiting class 1 integrons. Gene cassettes encoding resistance to streptomycin (3 isolates, aadA1), and trimethoprim (16 isolates, dhfr12) were observed. The PFGE patterns of 19 isolates revealed three different genotypes and irrespective of their integron profile and phage type.

Conclusions
The results show a high percentage of resistance for some antimicrobials and the presence of integrons in strains of S. Typhimurium isolated from pigs. The prevalence of multidrug resistance in porcine S. Typhimurium isolates is associated with the presence of class 1 integrons, particularly with the integron containing aadA1 and dhfr12 VR, and is attributable to the spread of a clone.

Contamination of *Salmonella* in retail raw meat in Hanoi, Vietnam

Thuy N. Do¹ Huong T. Van¹ Hang T. Le¹ Takeshi Koichi² Yamasaki Eiki² Makino Sou-ichi³

1. National Institute of Veterinary Research, Hanoi, Vietnam; 2. Department of Applied Veterinary Science and Public Health, Obihiro University of Agriculture and Veterinary Medicine, Obihiro, Japan; 3. Laboratory of Food Microbiology and Immunology, Research Center for Animal Hygiene and Food Safety, Obihiro University, Obihiro, Japan

Introduction

*Salmonella* spp. is one of the most important foodborne pathogens and the causative agent of salmonellosis in humans and animals. Most serotypes can cause gastroenteritis when ingested by eating contaminated foods. Currently, much attention has been focused to improved food safety in Vietnam where most retail meats is sourced directly from abattoirs with no refrigeration, ie the kill during the night and the meat is sold the following morning. Here, we investigated standards of food hygiene in raw meat products as a first step, and based on results, we will investigate hygienic levels of backyard marketplaces and identify epidemiological factors of foodborne salmonellosis due to ingestion of contaminated meat products. The objectives of the present study were therefore to determine the rate of contamination and some characteristics of *Salmonella* spp. isolated from retail raw meat samples in Hanoi.

Materials and Methods

Samples (n=100) of retail raw meat (beef, pork and chicken) were collected directly from open markets and supermarkets in Hanoi. The procedures for sample preparations, isolation and identification of *Salmonella* spp. were based on the FDA method with some modifications according to Department of Applied Veterinary Science and Public Health, Obihiro University of Agriculture and Veterinary Medicine, Japan. PCR tests for rapid screening were performed to amplify DNAs coding for some virulence factors including enterotoxin gene (*stn*), invasion gene (*inv*A) and 16S and 23S spacer region of ribosomal RNA (rRNA) of *S. Typhimurium* DT104 (104SR) according to Kishima et al. (2008)

*: O4:- (1 isolate); O8: g:- (1 isolate); and O7, 8:- (1 isolate), **: O8: g:- (2 isolates)

Discussion

The present study demonstrated that meats commonly retailed in marketplaces in Hanoi were heavily contaminated with *Salmonella* spp., of which these bacteria were isolated significantly more often pork (56%) than from chicken (28%) and beef (12%) (P<0.05). All isolates (100%) carry *stn* gene and only 2/27 isolates (7.4%) harbour 104SR gene. The number of isolates which were positive for *inv*A gene varied among type of samples, in which 57.1% isolates from chicken, 71.4% from pork and 83.3% from beef possessed this gene, though these differences are not significant (P=0.58>0.05). Seven serovars were isolated from samples that were generic potential hazards in meat hygiene.

Adding of Novobiocin in non-selective pre-enrichment step provide a more suitable starting material for real-time-ttr-PCR assay for the detection of Salmonella enterica spp

Talal S. Salih
University of Mosul, Mosul, Iraq

Since the production of meat and meat product based foods are multistage processes, the need for on farm food safety risk assessment and quality assurance has greatly increased. Thus, for food safety, the availability of reliable, rapid sensitive and accurate accepted test protocol to detect of Salmonella in examines samples became increasingly important for the agricultural and food industry, as well as the legislative quality control and public.

In this work, 4 Salmonella specific isolation protocols: real-time ttr-PCR, ISO 6579:2002, MSRV and FD CEN/TR 15215-3 were evaluated for their abilities to detect the presence or absence of Salmonella in 275 naturally contaminated animal feed, feces and environmental samples that were collected monthly from two pig farms around the city of Stuttgart, Germany. The main aim was to investigate the effect of addition of 40 mg/l Novobiocin (NOV) to non-selective buffered peptone water (BPW) for pre-enrichment of Salmonella in combination with selective enrichment in Rappaport-Vassiliadis soy broth (RVS).

The result showed that all of the 7 samples that were Salmonella-positive by conventional methods were also Salmonella-positive by the ttr-PCR-RVS-NOV method, which also detected 19 additional Salmonella-positive samples. Comparison with the conventional culture methods, the new ttr-PCR-RVS-NOV protocol has a sensitivity of 100% and no Salmonella false-negative was observed moreover, the McNemar test has showed a significant different . Thus, this method might be used as a meaningful tool in monitoring Salmonella-positive samples at farm level and thus, keeping them out of the food chain. The McNemar test did not show any significant different among the conventional culture methods, also it was no significant different and different agreement values (kappa test) within the samples tested.

Overall, the MSRV method proved to be the most reliable and sensitive method for detecting Salmonella in fecal samples. It detected 2 (50%) of the positive samples, whereas one (25%) detected by the both ISO 6579:2002 the FD CEN/TR. The addition of Novobiocin in FD CEN/TR method to BPW gave small but significant increase in the total number of Salmonella isolates from environmental samples. In conclusion, the high sensitivity and the more Salmonella detected in this study maybe caused by the inhibitory influence of Novobiocin on a number of competitive microorganisms in the samples leading to a higher ratio of Salmonella/non-Salmonella, which is likely to provide a more suitable starting material for real-time-ttr-PCR assay.
Effect of K-diformate in fattening diets on Salmonella carriage in high prevalence pig herds

Isabelle Corrège¹, Anne Hémonic¹, Eric Royer¹, Marc Le Roux²

1. IFIP – French Pig Technical Institute, LeRheu, France; 2. BNA Nutrition Animale, Château-Gontier, France

Introduction
The control of Salmonella carriage by pigs is one strategy for reducing the contamination of pig carcasses at slaughter. Several risk factors of high prevalence herds, mainly related to biosecurity and management have been identified. The addition of acids or acid salts in water or feed also appears as a protective factor (5). A study was conducted in farms with high prevalence, to assess the influence of the inclusion of an organic acid salt in fattening feeds on the carriage of Salmonella at the slaughterhouses.

Materials and Methods
Five farms with high Salmonella prevalence in fatteners were selected to evaluate the influence of 0.6% K-diformate (Formi®) addition in growing-finishing pelleted feeds. The Salmonella antibodies were analyzed with the IDEXX serological test on 50 meat juice samples collected from pigs at slaughterhouse during 9 months. An optical density reading of 40% or above was classified as positive.

Then, the prevalence of three successive batches of pigs fed with the acidified diet during fattening was calculated on 20 samples per batch. After that, the incorporation of K-diformate was stopped and the contamination of 2 new batches was evaluated, respectively 5 and 7 months after stopping. A monitoring was carried out on farms in order to take into account any change of health status, management or housing practices during the treatments.

Results and Discussion
Three patterns of the evolution of the Salmonella prevalence were obtained (Figure 1).

In the 1st pattern (herd A): prevalence significantly decreased during treatment, but increased after cessation and reached a level which was identical to the original one. The survey revealed no change in management that could explain these variations.

In the 2nd profile (herds B and C): prevalence significantly decreased during treatment but did not increase after cessation of treatment. Two assumptions are made:
1) The acidification limits the shedding and transmission of salmonellae during treatment but also after stopping the treatment.
2) The status improvement may be independent of treatment. Indeed, the Salmonella infection in some farms may vary significantly from one period to another, without any evidence of housing or management changes explaining these variations (1).

In the 3rd pattern (herds D and E), the prevalence was not modified during the treatment. It remained unchanged after the treatment for herd D, whereas it significantly decreased after cessation of the treatment for farm E.

The addition of 0.6% K-diformate to the feed during the fattening period results, in some farms, in a reduction in Salmonella carriage during treatment, and sometimes in a reduced infection after the treatment. In other farms, we do not measure any effect on incidence. These facts confirm previous studies: Papenbrock et al. (3) reported that the inclusion of 1.2% K-diformate in feed can reduce the faecal excretion ratio and shedding duration of infected piglets. However, other trials show that acidifying drinking water or feed has inconsistent effects (4) or sometimes no beneficial effect (2). This study nevertheless illustrates the need for an integrated strategy in which acidification should be included.

Detection and characterization of Salmonella in lairage, intestines and on pig carcasses in five slaughterhouses using serotyping and macrorestriction genotyping

Emily V. De Busser; Dominiek Maes; Jeroen Dewulf; Kurt Houf; Lieven De Zutter
Faculty of Veterinary Medicine, Ghent, Merelbeke, Belgium

Introduction
In 2008, 3944 Salmonella infections in humans had been registered in Belgium, of which Salmonella Typhimurium (57%) was the most common serotype (1). As the consumption of pork meat is a major source for human infection, more insight is needed into the epidemiology and spread of this bacterium throughout the production chain.

The aims of this study were to investigate the prevalence of Salmonella contamination along the slaughter line and to identify possible critical control points by performing serotyping and macrorestriction genotyping of the isolates.

Materials and Methods
Five Belgian slaughterhouses (slaughter rate of 170-580 pigs/hour) were visited twice. Faecal samples from pigs of different batches were taken at the lairage area using overshoes. At exsanguination, 30 pigs were individually identified (total: 30 pigs * 5 slaughterhouses * 2 = 300 pigs) and swab samples of the oral cavity were taken. These 30 pigs were further investigated at the slaughter line. Carcass swabs were taken after polishing, after splitting and after first chill as well as content of duodenum, ileum and rectum and mesenteric lymph nodes of the corresponding pigs. All the samples were submitted to Salmonella isolation using standard procedures (ISO 6579:2002 FDA). Prior to serotyping according to the Kaufmann-White scheme, isolates were clustered by the enterobacterial repetitive intergenic consensus PCR. Characterization at strain level was performed by pulsed-field gel electrophoresis with the restriction endonucleases XbaI (and BlnI for the serotype Rissen).

Results
In total, 276 samples (14.4%) were Salmonella positive, with 48.2% of the pigs positive in at least one sample. The lairage area was highly contaminated, with a large variation (0-100%) among the slaughterhouses. In total, 13 different serotypes were identified with differences in occurrence between slaughterhouses and slaughterhouse visits. Salmonella Typhimurium (58.7%) and Salmonella Rissen (17.4%) were the most common serotypes. The largest variation in serotypes was noticed in lymph nodes, rectum and ileum content. Genotyping of the 273 isolates revealed 46 different strains of which 32 for Salmonella Typhimurium, 4 for Salmonella Derby and 2 for Salmonella Rissen (by using BlnI). The same genotypes could be detected in the lairage as well as in the oral cavity (94.7%), in the lairage and in the gut content (65.5%), in the lairage and on the carcass (57.9%), but never in the lairage and the lymph nodes of animals held in these pens. In 82.7% the same genotype was found in the lymph nodes and gut contents of the same animal, whereas the same genotype was only found in 30% of the different carcass samples (the other 70% harbored different serotypes). In 55.5% the same genotype was found in the gut content and on the carcass. In 47.6% the same genotype was detected in the oral cavity as on the carcass. In 44.4% the same genotype was identified in the lymph nodes as on the carcass.

Discussion and conclusions
Salmonella was commonly present in the lairage area, in the pigs' intestines and on the carcasses along the slaughter line. No positive overshoe samples could be detected in one slaughterhouse where the lairage area consisted of a slatted floor allowing a minimum of contact with the feces. The results showed that the same pig could harbor different serotypes and amongst the same serotype different genotypes in the lymph nodes and gut content. Furthermore the study shows that pigs do take up Salmonella in the lairage area, where Salmonella was already present in the environment or shed by pen-mates. There was however no association between the genotypes found in the lymph nodes and in the lairage. On the other hand more than the half of the genotypes found on the carcass were also detected in the gut content and in the lairage area. A good fasting procedure, prevention of accidental cutting of intestines and improved cleaning and disinfection of the lairage area are important factors to prevent contamination. As in 30% of the different carcass samples, the same genotype was detected, cross contamination and contamination out of the slaughterhouse environment does occur and are of major importance to reduce the Salmonella level of the end product.

Serologic monitoring of salmonella in pigs of different productive systems from Argentina

Julián Parada1 Alicia I. Carranza1 Bibiana R. Pelliza1 Pablo J. Tamiozzo1 Ismael Dolso2 Arnaldo Ambrogi1
1. Universidad Nacional de Río Cuarto, Río Cuarto, Argentina; 2. UNRC, Río Cuarto, Argentina

Introduction
The annual increase of human salmonelosis cases related to the consumption of pork has led countries worldwide to implement control programs of Salmonella spp in pork production (Hugas, 2007). The Danish surveillance program for Salmonella in pigs uses a serologic monitoring system with classification of herds in 3 levels: level 1, of low seroprevalence (index<40%), level 2, moderate (40%≤index≤70%), and 3, high (index>70%), using an ELISA evaluated at a cut-off 20% Optical Density (OD) (Alban, 2002). In Argentina official data about levels of Salmonella infection in herds do not exist.

Due to its importance, this work tries to evaluate the sanitary situation of herds in the zone of greater pig production in Argentina, through serologic monitoring to different ages, in different production systems.

Materials and Methods
This work was carried out in 5 provinces of Argentina. Nineteen farrow-to-finish pig herds with indoor production systems (SC) (X=810 sows) and 11 with outdoors systems (SAL) (X=266 sows) were selected. All herds were bred on an intensive basis, with weaning between 21 and 23 days of life, and averages of 22.44 finished pigs/sow/year in SC and 18.05 pigs/sow/year in SAL. From each farm, samples were taken randomly to pigs of 8, 15 and 21 weeks of age. A number of samples was taken necessary to detect the presence of antibodies against Salmonella spp, with 40% of expected prevalence, 95% of Confidence and 5% of error. 40% represents the minimum prevalence to detect levels 2 and 3 of the Danish system (Alban, 2002).

The serums were analysed using an ELISA Herdcheck Swine Salmonella (IDEXX), for detection of antibodies against LPS antigen (serogroup B, C1 and D) of Salmonella spp, measuring values at 650 nm of absorption. The results were evaluated at 3 cut-off values, namely 10, 20 and 40%OD.

Results
A total of 504 serums were analyzed. The results of positive farms are shown in table 1.

Table 1: Percentage of farms with positive pigs to ELISA for each system, according to age and cut-off value.

<tr>
<td>SC</td>
<td>26.3%</td>
<td>5%</td>
<td>5%</td>
</tr>
</tbody>
</table>

The number of positive pigs by production systems is shown in graphic 1.

According to Danish classification system, 27% of SAL were level 1; 18% level 2 and 55% level 3. As to SC, 53% were level 1; 16% level 2 and 32% level 3.

Discussion
Considering a cut-off value of 20%DO, 68.4% of herds SC (13) and 91% of herds SAL (10) had positive pigs to Salmonella spp at 21 weeks of age. This seems to indicate an wide distribution of Salmonella in herds of the country. In addition, 40% (12), of the total herds were classified as level 3 (high risk).

Analyzing the number of positive pigs by herd (non published data), there were no significant differences between systems at 8 and 16 weeks of age. Nevertheless, at 21 weeks of age there was a greater number of positive pigs in SAL than in SC (p<0.05). As Baptista indicates (2009), this could be due to the presence of serotypes of Salmonella enterica of greater virulence in these systems or to a major number of re infections in SAL. The high intra-premises infection levels indicate the necessity to implement control strategies against Salmonella spp in herds from Argentina. Nevertheless, more accurate future works will be necessary to determine the serotypes circulating in the country and the risk factors involved in the dynamics of infection within each system.

Introduction

The pig industry is affected by diseases caused by bacteria, virus, parasites and rickettsias. Among the organisms that cause those diseases are the bacteria of the genus Salmonella. Salmonella spp also affect the Public Health. In order to design programs for the control of this pathology, it is necessary to know the presence, distribution, and serotypes. The objectives of this study were: 1) to detect the presence of Salmonella spp in fattening pigs; 2) to identify the most frequent serotypes; 3) to determine the pattern of resistance to antibiotics.

Materials and Methods

A cross-sectional epidemiological study was carried out on five pig farms. The farms were located at the central region of Yucatan, Mexico. The sample size to detect the presence of Salmonella spp was calculated considering 5% prevalence and 95% confidence level. Feces (1 g/animal) were collected directly for the animal rectum. The samples were analyzed at FMVZ-UADY using the technique described by Rappapor-Vasiliadis cited by Fedorka et al. (1). The serotyping was carried out at the National Institute for Diagnosis and Epidemiological of Mexico. The antibiogram was conducted at the FMVZ-UADY.

Results

Sixty percent of the farms in this study result positive (fig. 1). The week of higher risk to detect Salmonella spp was eighteen (fig 2).

The serotypes most frequent were S. Havana, S.Give y S. Typhymurium. These serotypes showed a different resistant pattern. Only the Amikacin, showed efficacy against the isolates serotypes (Table 1).

I= Intermediate; S= Sensible; R= Resistant

Discussion

The farms that result positive in this study are indicating that the prevalence of Salmonella spp is 20% or higher. Those that result negative are indicating that, if Salmonella spp, is present, the prevalence will be below of 20%. Also the serotype S. Thyphymurium has been reported previously en this region (2). On the other hand it is the first time that S. give and S. Havana are reported in this area. These have been reported in other areas and speciecs (3)(4). Finally, it can observe the high percent of resistant of serotypes to varies antibiotics. It can be conclude that salmonellosis is present in the swine industry in this area.

Introduction

Probiotics are viable microorganisms that once ingested by humans and animals, produce beneficial physiological effects by assisting in the establishment of an intestinal population. The aim of this study was to assess the effect of two probiotics in different inclusion periods during nursery, growing and finishing on the performance of swine.

Materials and Methods

One hundred sixty pigs from 23 to 138 days of age were used to evaluate two probiotics, one of them was composed by Bacillus subtilis, Bifidobacterium bifidum, Enterococcus faecium, Lactobacillus acidophilus, Lactobacillus casei and Lactobacillus lactis (PA), and the other by Bacillus subtilis and Bacillus toyoi (PB). Both were tested with an inclusion in the diet in 3 different periods characterizing 8 treatments: PA44 (PA until 44 days of age and control diet after), PA65 (PA until 65 days of age and control diet after), PA138 (PA until 138 days of age), PB44 (PB until 44 days of age and control diet after), PB65 (PB until 65 days of age and control diet after), PB138 (PB until 138 days of age), CTR (diet control without additives) and ATB (diet control with an antibiotic as growth promoter). At 51 days of age the programmed challenge with Salmonella Typhimurium (LSS – SR41) was given orally. Body weight (BW) at 23, 30, 37, 44, 51, 58, 65, 79, 106, 112, 126 and 138 days of age and feed conversion (FC) corresponding these periods were evaluated. At weaning (23 days of age), pigs were blocked by body weight and sex, and placed in a nursery pen (4 pigs/pen). Data were analyzed by SAS2, and treatments were compared by orthogonal contrast method. The level of significance considered was 5%.

Results

The contrast 1 (C1), PA44, PA65 and PA138 vs ATB showed from 37 (8,33Kg vs 9,54Kg, respectively) to 112 days of age (64,01 Kg vs 70,75Kg, respectively), the highest values for ATB regarding BW. Similar results were obtained for the contrast 2 (C2), PB44, PB65 e PB138 vs ATB from 37 (8,71Kg vs 9,54Kg, respectively) to 106 days of age (60Kg vs 65,53Kg, respectively), demonstrating the superiority of ATB against probiotics. There were no significant differences from the age of 112 days for C1 and 106 days for C2 until 138 days of age for neither of the groups. The FC showed significant difference in C1 (7,78 vs 1,55, respectively) and C2 (1,79 vs 1,55, respectively) at nursery period (23 to 65 days of age), with lowest values for ATB. During growing-finishing periods (66 to 138 days of age) the lowest values were found for probiotics on C1 (2,49 vs 2,63, respectively) and C2 (2,53 vs 2,63, respectively) with P=0.06 and P=0.16, respectively. These values emphasize a numerical advantage (140 and 100 grams for C1 and C2, respectively) in favor of probiotics.

Discussion

Although there was a significant difference from nursery period until days 106-112 (C2 and C1 respectively) regarding BW, this variable did not show significance until 138 days of age when probiotics and ATB were compared. Similar3 and contradictory4 results were reported in literature, considering the nursery period while during growing-finishing few evidences were described. The treatments PA65 and PB44 (98,87Kg and 97,33Kg respectively) showed equivalent body weights in comparison with the ATB (99,63Kg), indicating distinct actions depending on the probiotic’s inclusion time. In the programmed challenge at 51 days of age, significant effects were observed regarding performance for C1 (21,74Kg VS 25,99Kg, respectively) and C2 (21,91Kg vs 25,99Kg, respectively), showing the probiotic treatments were affected by the challenge. The modification observed in BW and FC in the growing-finishing suggested a recovery by unknown factors that could be connected to the microflora complex modification. Considering the equivalence of the results on the performance and the economic aspects involving the inclusion of the probiotics, its use until 44 or 65 days was better than until 138 days of age.

Evaluation of risk factors and proposals for control of infection of Salmonella sp. in different production systems of Brazilian swine

Jalusa D. Kich2, Patricia Schwarz1, Arlei Coldebella2, Luis Gustavo Corbellini1, Marisa Cardoso1

1. Universidade Federal do Rio Grande do Sul, Porto Alegre, RS, Brazil; 2. Embrapa Suínos e Aves, Concórdia, SC, Brazil

Introduction
Studies of risk for contamination of meat along the production chain as well as the quantitative representation of their impacts have been conducted around the world (Dahl et al. 2000; Giovaninni et al. 2003). This study was carried out in order to identify factors associated with infection of herds and to suggest alternatives to control the main pig producing regions of Brazil and in different production systems.

Materials and Methods
In this study, 5 different Brazilian pork production systems were chosen. They were evaluated for Salmonella prevalence. An epidemiological investigation and evaluation of risk factors were inferred in 189 farms. The results of seroprevalence and risk factors of each farm were analyzed by logistic regression. The risk factors that were identified were also inserted into a simulation model of intervention in swine.

Results
The main risk factors associated with high prevalence of Salmonella were pre-pit dirty, other animals on the farm in addition to pigs, the presence of intensive production of broilers in the same farm, post-weaning multisystemic wasting syndrome (PMWS) with high scores of mortality and culling and number of origins of animals housed in the same farm. The simulation models with values considered protective for the risk variables that were found reached 11.20 to 44.89% prevalence of the mathematical model used.

Discussion
The predisposing factors for infection of pig herds were determinants variable of biosafety in the evaluated companies. Through simulation models, the combination of risk factors for the intervention of control of Salmonella sp. in farms producing pigs is proposed. In this study, the early phase of Salmonella infection was the finishing one, as previous studies conducted in Brazil by Müller (2007) and Schwarz et al. (2009), therefore this stage was the focus of the epidemiological assessment. The risk factor with the highest probability of infection was the presence of intensive production of broilers, indicating the possible contamination of one species to another in the same environment. The Pre-dirty pit was another source of infection for pigs, because the feces in the environment can be directed into the stalls by fomites.

In these cases, the presence of other animals on the farm represents a threat to the swine herds, because the Salmonella sp. is widespread among most animal species (Popoff et al., 2003). PMWS has been identified as an important risk variable in 2 of 5 companies analyzed. This interaction between this risk variable and high seroprevalence may be associated with biosecurity issues common to Salmonella infection and PMWS.

Another risk factor identified in this study was the number of sources of animals housed in the same farm. In Brazil, Kich et al. (2005) found that the number of sources of pigs and other animals on the farm as risk factors for infection with Salmonella sp. The number of sources of piglets can increase the chances of introducing new pathogens in the swine herds (Morés, 2003).

According to Davies et al. (1997), the limited number of days of fallowing (less than 7) was identified as a risk factor in 2 companies, as well as mixing animals from different sources, also described by Quessy et al. (1999), and size of herds, cited by Carstensen & Christensen (1998).

A comparative analysis of the seroprevalence of Salmonella among the companies in this study showed the differences between production systems (P <0.05), as well as differences in the distribution of identified risk factors.

*Embrapa Suínos e Aves, Concórdia, SC, Brazil*

**Introduction**

The post-weaning multisystemic wasting syndrome (PMWS) has caused considerable losses due to mortality and wasting of pigs, and has been often associated with co-infections with other viral or bacterial agents (2, 3). The aim of this study was to evaluate the Salmonella seroprevalence in swine herds that are affected by PMWS to different severities.

**Materials and Methods**

Productive performance data and most prevalent symptoms were investigated in herds associated to 11 Brazilian swine companies that reported the occurrence of PMWS (1). Herds (n=188) were classified according to the mortality and wasting frequency, and these data were considered as PMWS severity degrees (table 1). Blood samples were taken from slaughter pigs of each herd and submitted to an indirect ELISA test against Salmonella sp. Statistical analysis was performed using chi-square test for linear trend to test the hypothesis of increased Salmonella seroprevalence with levels of PMWS severity. The farms were divided in two groups according with the seroprevalence, ≤ 70% and > 70%. These groups were compared between the levels of PMWS severity. The analysis was performed using the software EpiInfo 6.0 (4).

**Table 1:** Classification of farms in the intensity levels of involvement by PMWS

<td>2 to 3%</td>
<td>2 to 4%</td>
</tr>
<tr>
<td>Level 3</td>
<td>above 3%</td>
<td>above 4%</td>
</tr>
</tbody>
</table>

**Results**

In all herds the appearance of PMWS was associated with a decrease in animal performance and a tendency of a higher frequency of enteric symptoms. Seroprevalence >70% against Salmonella was associated to higher PMWS severity (P=0.0001) (table 2).

**Discussion**

This result may be related to the immune impairment caused by PMWS that may predispose to Salmonella infection, as well as to the occurrence of common risk factors to both infections in affected herds (5). These factors include the size of the batch, the mixture of animals of different origins and hygiene facilities (1). In conclusion, a high frequency of Salmonella carrier pigs may be an additional problem in farms severely affected by PMWS.

Introduction
Salmonella control programs have been developed in swine farms from several European countries [1]. Those farms with a high level of contamination will have to establish control measures to reduce the number of Salmonella infected animals [2]. We have carried out an interventional study in a pig fattening unit to assess the effectiveness of an acid treatment administered in drinking water for the control of salmonellosis.

Materials and Methods
The study was performed in a pig fattening unit infected by Salmonella Typhimurium housing 3,000 pigs distributed in two barns (1,500 pigs each). One of them was chosen as control group and received no treatment while the other was chosen as experimental group. Animals from experimental group were administered a commercial acid, Acidvall®, composed of lactic acid (56%), formic acid (23%), propionic acid (13%), and acetic acid (5%), that was added to drinking water during the last 40 days of the fattening period at a concentration of 0.035%. Within each group, 40 animals were randomly selected and sampled throughout the experiment. Fecal samples and serum were collected the first days of the fattening period, at the beginning of the treatment, 20 days after (only blood samples) as well as at the last day of treatment (previous day to slaughter). Moreover, cecal content and ileocecal lymph nodes were collected from pigs of both experimental groups at the slaughter. Samples were submitted to the infectious animal diseases laboratory and processed. Bacteriological analyses were made using EN-ISO 6579:2002/Amd 1:2007. Serological samples were tested with Idexx herdchek Swine Salmonella kit® according to manufacturer’s instructions.

Results
Results showed significant differences in bacteriology ($\chi^2=21.4, p<0.001$) and serology ($\chi^2=71.45, p<0.001$) between groups at the end of the fattening period (17.5% shedders and 27.5% seropositive pigs in treatment group compared to 50% shedders and 87.5% seropositive pigs in control group). Similar results, near to significance, were found out at the abattoir where Salmonella was detected in cecal content in 47.5% of the treated pigs versus 65% of the control animals. Differences were also found in the prevalence of positive animals in ileocecal lymph nodes 55% of positive in the treatment group to 70% in control group.

Discussion
Several studies have demonstrated that organic acids can be useful to reduce Salmonella contamination in swine farms [2,3]. In the present study the treatment, which was designed taking into account treatment economic feasibility (0.035%, during forty days) has been able to demonstrate a reduction of the number of Salmonella shedders. Moreover, the number of Salmonella seropositive animals was also reduced. Despite that this results are promising further studies are required to confirm them.

Salmonella Typhimurium and Derby infection in weaned pigs

Jan Matiasovic; Hana Stepanova; Lenka Leva; Hana Havlickova; Frantisek Sisak; Ivan Rychlik; Martin Faldyna
Veterinary Research Institute, Brno, Czech Republic

Introduction
Salmonella Typhimurium (STM) and Derby (SD) are most common serovars in pig herds in Europe (EFSA 2008). Studies of STM shedding and serological response to Salmonella infection at herd and individual level were performed (Scherer et al. 2008), but little is known about the course of SD infection. Moreover, no information about competition between STM and SD is available. Here we show the kinetics of Salmonella fecal shedding and development of specific antibody response to SD, STM as well as mixed infection in weaned pigs.

Materials and Methods
Strains used were isolated from infected sows. STM was of DT104 phagotype. Weaned salmonella-free pigs were divided into groups of five animals for STM, SD and non-infected control. Another group consisting of 10 animals was infected with a mixture of STM and SD. Animals were infected per os with 10^8 bacteria per animal. Experiment was carried-out for 28 days. Salmonella shedding was investigated in fecal samples by a standard culture method (EN ISO 6579:2002). Presence of antibodies against LPS O antigens (STM and SD share the same O antigens) in blood serum was evaluated by ELISA Salmotype® LDL (Germany). Sampling of feces and blood was done twice a week.

Results
Shedding of STM was observed in group infected with STM up to 14 DPI, in group with mixed infection up to 17 DPI. Shedding of SD was observed during all experiment in both groups infected with SD (SD group and group with mixed infection). From 14 DPI, the titers of SD in both groups were very similar or the same. Percentage of STM in isolates from mixed infection varied from 0% (14 DPI) to 50% (17 DPI).

Antibodies against O antigens were detected at 14 DPI in three of five animals in group infected with STM. At 28 DPI, four animals reached high antibody titer, but one animal from this group did not develop antibody response. In SD group, a low titer of antibodies was detected only at 28 DPI in three of five animals. In group with mixed infection, antibody titer was measured only at 28 DPI; six of ten animals developed antibody response.

Discussion
Short fecal shedding of STM (up to 14 DPI) and early developing of antibody response (14 DPI) in group infected with STM was similar as it was previously shown (Scherer et al. 2008). Contrary to STM, the period of SD shedding was prolonged. SD was detected in feces during the entire experiment, but only in a low titer from 21 DPI. Contrary to that, antibody response to SD infection was slow and only three of five animals developed low antibody titers at 28 DPI. In group with mixed infection, fecal shedding of STM was similar to group infected with STM only. Shedding of SD was nearly the same as in group infected only with SD and was also prolonged during all experiment. From this data we can conclude there is no competition between STM and SD.

Efficiency of vaccination with an inactivated vaccine to reduce salmonella prevalence in a pig fattening unit

Héctor Argüello; Sonia Álvarez; Álvaro Hidalgo; Jesús Osorio; Mario Arcos; German Naharro; Ana Carvajal; Pedro Rubio
University of León, León, Spain

Introduction

Immune response stimulation by vaccines has been a useful mechanism stand up to pathogens [1]. Vaccination can be a useful tool for the control of swine salmonellosis and live vaccines are the first choice, but they have several disadvantages like biosecurity, oral administration and higher prices. In the present study we have evaluated an inactivated vaccine of Salmonella Typhimurium, easy to produce and cheaper than live vaccines.

Materials and Methods

The vaccine was prepared from a culture of Salmonella Typhimurium DT104 (109 UFC/ml) inactivated by formol and using hydroxide aluminum Al(OH)3 as adjuvant. A pig fattening unit infected by S. Typhimurium and S. 4,5,12:i:- was chosen for the experiment. Farm housed 2960 pigs distributed in two barns (1480 pigs each). One of them was chosen as control group and was not vaccinated while the other was chosen as experimental group (vaccinated animals). Within the farm, animals were housed in two different barns. Pigs from one of the barns, vaccinated group, were injected intramuscularly 2 ml of the inactivated vaccine at the beginning of the fattening period (70 days of life approximately) and 25 days later. Pigs from the second barn served as control group and receive no treatment. Both groups were monitored during the fattening period by collecting serum and fecal samples that were used for serological and bacteriological detection of Salmonella infection. Moreover, cecal content, mesenteric lymph nodes and blood samples were collected after slaughter from both groups. In each sampling forty animals per group were included. Bacteriological analyses were made using EN-ISO 6579:2002/Amd 1:2007: Microbiology of food and animal feeding stuffs– Horizontal method for the detection of Salmonella spp. In animal feces and in environmental samples from the primary production stage. Serological samples were tested with Idexx herdcheck Swine Salmonella kit® according to manufacturers’ instructions.

Results

The percentage of Salmonella shedders was significantly lower (Chi²=67.5 p<0.001) among vaccinated animals as compared with control pigs (18 % - 65 % in control group versus 0 % - 7.5 % in vaccinated group). Abattoir study also revealed significant differences in the prevalence of Salmonella positive samples among cecal content (Chi²=33.43, p<0.001) (55 % versus 15 %) and mesenteric lymph nodes (Chi²=20,2, p<0.001) (55 % to 22.5 %). Results of serological analysis were no so consistent although significant differences (Chi²=49.6 p<0.001) in the percentage of seropositive animals were also detected at the end of the study (88 % of seropositive animals in control group versus 44 % in vaccinated group).

Discussion

Despite of live vaccines and its cell mediated response provide a better protection [2,3], our study demonstrates that inactivated vaccines can be useful in the control of swine salmonellosis. Further investigations are needed to corroborate these results and particularly in farms infected by other serotypes different to S. Typhimurium.

Resistence patterns of Salmonella isolated from pigs and porc in Germany
Andreas Schroeter; Annemarie Kaesbohrer; Reiner Helmuth; Christina Dorn; Kirsten Heckenbach; Bernd-Alois Tenhagen
Federal Institute for Risk Assessment (BfR), Berlin, Germany

Introduction
Antimicrobial resistance in Salmonella spp. is a major public health concern in Europe and worldwide. Although in the majority of cases Salmonella is not associated with clinical disease in pigs, studies have shown that they are prevalent at slaughter and enter the food chain. S. Typhimurium from pigs is estimated to be a major source of human salmonella infections. It was the purpose of this study to compare the resistance patterns of Salmonella spp. isolated from porc with those isolated from pigs.

Materials and Methods
Salmonella isolates from pigs and porc submitted to the National Reference Laboratory for Salmonella between 2000 and 2008 were analysed for their susceptibility to antimicrobials using the broth microdilution method according to NCCLS/CLSI standards. Minimum inhibitory concentrations (MIC) were evaluated according to epidemiological cut off values (www.eucast.org). Isolates with MIC above the cut offs were considered resistant, otherwise susceptible.

Results
Overall 1595 isolates from porc and 3820 isolates from pigs were tested. The majority of isolates from pigs were from three serovars, namely S. Typhimurium (67 %), S. 1,4[5,12:i:- (9 %) and S. Derby (8 %). The proportion of S. Typhimurium decreased from above 80 % in 2000-2002 to 44 % in 2008. In the same period, the proportion of S. 1,4[5,12:i:- increased from 0 to 21 %. S. Derby on the other hand was constant in its share of the submitted isolates.

In porc, the same serovars dominated. S. Typhimurium had a proportion of above 60 % in 2000-2002 that decreased to 43 % in 2008. Overall, 53 % of all isolates from porc were S. Typhimurium. S. 1,4[5,12:i:- (9 % of the isolates) was practically not observed in 2000 but had a share of above 20 % in 2007 and 2008. S. Derby (10 % of the isolates was fairly constant between 5 and 12 % of the isolates over the years.

The proportion of isolates that were susceptible to all antimicrobials tested increased over the years in animals (10 % in 2000-2002 to 22 % in 2006-2008) and the proportion of isolates resistant against more than one group of antimicrobials decreased slightly (78 vs. 71 %) in the same time period.

In isolates from porc the changes were less pronounced. The number of isolates that were susceptible against all antimicrobials tested increased only slightly (from 25 to 31 %). In contrast to the situation in animals, the proportion of isolates resistant against more than one group of substances increased slightly over the years (from 56.6 to 60.2 %).

In S. Typhimurium from pigs, the resistance situation did not change very much over the years. From 2000-2002 to 2006-2008 the proportion of susceptible strains increased slightly from 6.0 to 10.5 % in pigs, but the high proportion of multiresistant strains remained unchanged (86.6 vs 85.2 %). In food, a different situation was observed. The proportion of susceptible strains decreased from 21.5 to 14.8 % and the proportion of multiresistant strains increased slightly (69.5 to 73.3 %).

Trends in resistance for S. 1,4[5,12:i:- cannot be described as there were practically no isolates in the first years. However the vast majority of strains from pigs (86 %) and porc (83 %) were multiresistant and only few isolates (3 and 4 %) were susceptible to all antimicrobials tested.

S. Derby was less resistant to antimicrobials. Overall, 47 % of the isolates from pigs and 57 % of the isolates from porc were susceptible against all tested antimicrobials. The proportion of multiresistant strains was substantially lower than in S. Typhimurium and S. 1,4[5,12:i:- (28% in pigs, 22 % in porc).

The highest resistance rates were observed for ampicillin, streptomycin, sulfamethoxazole and tetracycline. The resistance rates to these antimicrobials were higher in isolates from pigs (60 to 90 %) than in isolates from porc (40 to 60 %). The lowest resistance rates were observed against gentamicin, colistin, and 3rd generation of cephalosporins (0 to 5 %).

Discussion
The results underline that colonized or infected pigs are a likely source of contamination for porc indicating the need to control Salmonella pre- and at harvest to reduce this contamination. S. Typhimurium and S. 1,4[5,12:i:- show multiresistance in the majority of the isolates which hampers treatment of infections in humans. Resistance to antimicrobials that are administered via animal feed, such as tetracycline and amoxicillin is widespread. It has been pointed out, that the use of these antimicrobials is associated with a higher risk of slaughter pigs to harbour S. Typhimurium in their ileocaecal lymph nodes (Tenhagen et al. 2009).
Identification of *Salmonella* Typhimurium genes induced in porcine tonsils and lymph nodes during long-term persistence using in vivo expression technology (IVET)

Department of Pathology, Bacteriology and Avian Diseases, Faculty of Veterinary Medicine, Ghent University, Merelbeke, Belgium

**Introduction**

Persistent *Salmonella* Typhimurium infections in pigs often result in asymptomatic carrier pigs and are a major concern for food safety and human health. Tonsils and lymph nodes play a key role in the persistence of *Salmonella* Typhimurium in pigs, but very little is known about the underlying mechanisms. For the identification of *Salmonella* Typhimurium genes specifically induced in these organs, a genome-wide screening method was performed using in vivo expression technology (IVET) (Mahan et al, 1993).

**Materials and Methods**

We used a spontaneous nalidixic acid resistant derivative of a wild type *Salmonella* Typhimurium strain isolated from a pig stool sample. A Δ*purA* deletion mutant was constructed in this strain using the Datsenko and Wanner method (2000). For proper use in the IVET protocol, we verified that this mutant was significantly impaired in comparison to the wild type strain in a preliminary *in vivo* mixed infection experiment. We constructed an IVET library as described earlier for *Salmonella* Enteritidis (Gantois et al., 2008), composed of approximately 12,000 different transformants, representing the major part of the *Salmonella* Typhimurium genome.

For IVET selection in pigs, 9 pigs were orally inoculated with approximately 10^8 CFU of our IVET library. Three weeks after inoculation, pigs were euthanized and tonsil and lymph node samples were collected, processed and plated on selective MacConkey agar. White colonies, representing *in vivo* but not *in vitro* induced genes, were collected and the IVET fusions were sequenced as described before (Gantois et al., 2008). Identification of the sequence of the cloned promoter was done by BLAST analysis.

**Results**

From the IVET selection experiment, 19 and 24 different genes were identified in the tonsils and lymph nodes, respectively (see Table 1 for a summary). The majority of these genes plays a role in *Salmonella* metabolism. One known virulence gene (*sifB*) was identified, playing a role in formation and maintenance of the *Salmonella*-containing vacuole. AsmA, a gene important for the invasion of nonphagocytic cells, was upregulated in the lymph nodes. Furthermore, 2 genes were identified that act in stress responses (*htpG* and *dnaK*). The flagellin-producing operon *floC/floJ* was induced in the tonsils, while *rafE*, involved in LPS-biosynthesis, was identified in the lymph nodes. Finally, several genes with a yet unknown function were identified in tonsils and lymph nodes.

**Discussion**

Using IVET, Huang et al. (2007) already identified several *Salmonella* Typhimurium genes expressed in porcine tonsils at 2 days post inoculation. These genes differ from the genes that we were able to identify at 3 weeks post inoculation (except for *rpoN*). This suggests that different sets of *Salmonella* genes play a role in short- and long-term persistence in pigs.

Although we identified several *Salmonella* genes that might be important for long-term persistence in pigs, further research is needed to confirm their exact function.

Class 1 integrons of “Salmonella enterica” isolated from white or Iberian swine in the Southwest of Europe

Gonzalo Palomo1 María J. Campos2,1 Alberto Quesada3 Santiago Vadillo1 Anselmo Perea1 Carmen Borge4 Segundo Píriz1
1. Animal Health Department, Extremadura University, Cáceres, SA, Spain; 2. Grupo de Investigação em Recursos Marinhos (GIRM), Instituto Politécnico de Leiria (IPL), Peniche, Portugal; 3. Biochemistry Department, Extremadura University, Cáceres, Spain; 4. Animal Health Department, Cordoba University, Córdoba, Spain

Introduction
Salmonellosis is the most important food borne disease in the North Hemisphere. There is a mortality of 0.1% in the European Union, mainly in children, elderly and immunodepressed patients, where antimicrobial therapy was no efficient enough. The main sources of infection are pork, eggs and poultry alimentation (EFSA, 2009).

Material and Methods
Our strain collection consists in 144 “Salmonella enterica” strains isolated from slaughter house samples and clinical cases in Spain and Portugal. Minimum inhibitory concentrations (MICs) for ampicillin (Amp), amoxicillin (Amx), streptomycin (Str), spectinomycin (Spt), florphenicol (Fhl), chloramphenicol (Chl), tetracycline (Tet) and sulfametoazol (Sul) were determined by microdilution broth. The screening for class 1 integrase gene (int1) was performed by PCR (Leverstein-Van Hall et al, 2002). A second PCR was used to amplify the conserved-cassettes (CS) inside the integrons which contains the antibiotic resistance genes. Finally, CS regions were characterized by RFLP analysis and sequencing (Levesque et al, 1995).

Results
Half of the collection (65 strains) was int1 positive. Majority of them (92%) were multidrug resistance (MDR) strains and only three were totally sensible. Among these strains, the most common MDR profiles were: AmpAmxStrSptChlSulTet (n=20) found in white swine (WS) and (n=10) in Iberian ones (IS); AmpAmxStrSptSulTet (n=6) and AmpAmxStrSptChlSulTet (n=5) in WS and AmpAmxStrChlSulTet (n=5) in IS. A total of 36 strains has both the penta-resistant phenotype (AmpStrChlSulTet) and the class 1 integron. Nine CS profiles were described (from A to I). The conservative-cassettes contain the genes: blaOXA-30, blaPSE1 (amoxicillin and ampicillin resistance); aadA1, aadA2 y aadA12 (streptomycin and spectinomycin); dfrA1, dfrA12, dfr17 y dhfrVII (trimetoprim, a sulfonamides synergic antimicrobial).

Discussion
Most class 1 integrons profiles are exclusively distributed among the two swine subpopulations studied, since only profiles D (5 WS and 6 IS) and A (13 WS and 1 IS) are shared between them. The genes associated to the class 1 integrons indicates that these genetic elements might support almost all phenotypical resistance. The finding of new genotype/serovar combinations, as far as (to our knowledge) the identification of dhfrVII in Montevideo; dfr17 in Anatum and Bredeney; and dfrA1 in Hindmarsh, had never been reported.

Serological Salmonella prevalence in breeding farms

Luminita Costinar; Corina Pascu; Viorel Herman
Faculty of Veterinary Medicine, Timisoara, Romania

Introduction

Serology is use in the last years to determine the prevalence of Salmonella on pig farms and has been adopted by several countries into national control programs. These programs designed to reduce occurrence of Salmonella on the farm and in pork (4, 6). A national serologic surveillance program has been in place in Denmark since 1993 for breeding stock herds and since 1995 for herds producing slaughter pigs. The prevalence of salmonella in Danish pork is reported to have declined from 3.5% in 1993 to 0.7% in 2000 (2).

The aim of the present study was to monitoring serological prevalence of Salmonella in four sows farms.

Material and Methods

A longitudinal study was carried out in 4 sows farms. There were tested a number of 304 samples and were made 3 samplings at different times.

Serological monitoring was made October 2008 – May 2009. Samples were analyzed for the presence of antibodies against Salmonella by commercially available ELISA: HerdChek® Swine Salmonella, IDEXX (USA). Samples with OD% values equal to or greater than 10% (S/P=0.25) are considered positive. Interpretation results was made with xChek IDEXX software.

Results

The HerdChek® Swine Salmonella allows rapid screening for the presence of antibodies to a broad range of Salmonella serogroups indicating swine herd’s exposure to the bacteria (1).

Monitoring of the immune status of a herd can be an important tool in the control of the disease. Serological monitoring of Salmonella infection of swine by standardized commercial ELISA is a fast, simple and economical.

Several studies have reported the variability of serologic responses in different groups of animals sampled at the same time and at different times. In the table is presents the samplings results.

The prevalence in each herd at the different time sampling is shown in

It could be observed that in all four sows farms are presents the Salmonella antibodies. Between collection of the second and third samples in the farms A the proportions of positive serologic increased.

Epidemiological screening about Salmonella antibodies in sows farms using HerdChek® Swine Salmonella ELISA kit, revealed that all 4 monitorised sows farms were high positive.

Serological tests for Salmonella antibodies in swine are interpreted by associating test results with a reduction in prevalence of subclinical infection in pigs (2, 6) and reduced risk of carcass contamination at slaughter rather than with the presence or absence of disease.

The concept of serologic testing is most useful as an ongoing monitoring surveillance exercise (2). The sensitivity of the test increases with multiple sampling. The serologic response to subclinical Salmonella infection may vary between farms of sows or even within the same group sampled at different times.

Serological study on hepatitis E infection in Croatian pig herds

Zoran Lipej; Besi Roic'; Dinko Novosel; Zeljko Mihaljevic
Croatian Veterinary Institute, Zagreb, Croatia

Introduction
Hepatitis E virus (HEV) is one of the most important causes of acute clinical hepatitis in human population. Swine HEV has a cross-reaction with human anti-HEV antibodies. Therefore pigs could be an animal reservoir, rendering hepatitis E as a zoonosis (3). HEV is an important public health problem specially in developing countries (1). The first HEV strain genetically closed to human was described in swine (2). Serological studies reported that swine HEV infection is widespread in many European countries (4,5). The aim of the present study was to determine the prevalence of HEV in domestic pig population at different ages in Croatia.

Material and Methods
During 2009 serum samples of 200 pigs were collected from four farrow-to-finishling farms located in continental part of Croatia. Blood samples were taken from 50 animals for each farm. Groups of animals were selected in 5 group by age and sex. Group 1 (n=10) gilts, group 2 (n=10) sows, group 3 (n=10) boars, group 4 (n=10) pigs <12 weeks of age and group 5 (n=10) pigs >12 weeks of age. All blood samples were delivered to Virology laboratory of the Croatian Veterinary Institute and were stored at -20 °C before testing. Serum specimens were tested for the presence of specific anti-HEV IgG antibodies by enzyme linked immunosorbent assay (ELISA) according to the method decribed by (7) using a commercially available reagents (MP Diagnostics HEV ELISA, MP Biomedicals Suisse S.A., Switzerland) according to manufacturers instructions. The protocol used is designed for detecting HEV antibodies in human sera but adapted to animals using anti-pig IgG horsreadish peroxidase instead of anti-human conjugates.

All swine sera were tested in duplicate at a dilution of 1:21. Serum samples were added to each well and incubated for 30 min at 37 0C. Plates were washed 6 times with washing buffer and conjugated with goat anti-swine IgG (H+L) (Jackson ImmunoResearch) was added of 100 μl/well. The optimal working dilution of conjugate was 1:1000. After incubation at 37 0C for 30 min and six washes 100 μl of substrate solution was added. The reaction was stopped after 15 min by adding 50 μl stop solution. The optical densiti of each serum sample was read at 492 nm with a photometer and comparasion of the absorbance between test and control wells (Microplate Autoreader TECAN Sunrise –Magellan, Austria). Samples with OD values greater than or equal to the Cut-off Value are considered reactive by the criteria of this HEV antibody ELISA kit.

Results and Discussion
Among 200 serum samples collected from four pig farms overall sero prevalence was 89.5% (200/179). Positive rate of HEV-specific IgG in all farms ranging from 86% to 92%. All four farrow-to-finishling units located in different geographical regions were HEV positive. The highest proportion of 100 % IgG positive animals comprised gilts and finishers. Seroprevalence was 85% in sows, 90% in boars and 72.5% in pigs <12 weeks of age.

Our results show that HEV is present and widespread among pig population in Croatia at high HEV antibody prevalence (89.5%). These findings correlate with the results of other studies (4,5,7). This is the first evidence of HEV infection in Croatian domestic swine population.

Comparison of five enzyme immunoassays (EIAs) for detection of anti-hepatitis E virus (HEV) immunoglobulin G (IgG) in swine

Introduction

Hepatitis E virus (HEV) is a major cause of acute hepatitis in humans but the virus is also widespread in the pig population and HEV is considered a zoonotic agent (1,4). There are currently at least four known genotypes of HEV with one recognized serotype (5). Serological studies in swine are often conducted with in-house assays based on peptides and recombinant proteins of different HEV genotypes and are mainly limited to research laboratories (2,3). The objective of the current study was to determine the diagnostic accuracy of one commercially available and four in-house EIAs on samples from pigs experimentally-infected with genotype 3 human or swine HEV and genotype 4 human HEV.

Materials and Methods

A total of 72 serum samples (18 obtained from gnotobiotic pigs and 54 obtained from conventional pigs) were tested by five different assays. Twenty-six of the 72 samples were control samples from non-inoculated pigs, 16/72 samples were obtained from pigs experimentally inoculated with genotype 3 human HEV (US-2 strain), 14/72 samples were obtained from pigs experimentally inoculated with genotype 3 swine HEV (Meng strain), and 16/72 samples were obtained from pigs experimentally inoculated with genotype 4 human HEV (Taiwan strain TW6196E). All serum samples were stored at -80˚C until processing. For the comparison, all samples above were tested with four enzyme-linked immunosorbent assays (ELISAs) and one strip line immunoassay. The antigen used in the different assays varied but all were derived from human HEV genotype 1 or genotype 3 recombinant proteins. Plate-specific cutoffs were used for ELISAs 1-3 and samples in ELISA 4 were considered positive if their optical density (OD) value was equal to or greater than 0.4. The strip line immunoassay results were read both visually by eyes and digital-interpretation. For the statistical analysis, the optimal cutoff was determined using Receiver operator characteristic (ROC) analysis. The ROC analysis was based on known infection status of each pig and included data from days post inoculation (dpi) 35-56. This analysis provided ROC optimized cut-off values that maximized diagnostic sensitivity and specificity of each assay.

Results

For the strip line assay samples that were considered positive by visual reading were also found positive when digital analysis was run. All 26 control samples were negative with all five assays. In all experimentally-inoculated pigs, seroconversion was detected at the same dpi for each individual pig across all EIAs. All five EIAs used in this study were found to be able to identify anti-HEV antibodies in pigs experimentally-inoculated with genotype 3 and 4 HEV strains with varying sensitivity and specificity according to ROC analysis. The ROC analysis showed that the assay with the greatest sensitivity and specificity was ELISA 4 when the optimized cutoff was used; however, a small subset of samples was used and results may vary with a greater sample set. The ROC analysis also revealed that from dpi 35 to dpi 56 all four ELISAs had a sensitivity and specificity of 100%.

Discussion

The similar seroconversion profiles obtained with the five EIAs when used to test sera from the experimentally-infected pigs indicates that (1) each assay could reliably discriminate between the absence and presence of anti-HEV and (2) each antigen reacted with similar levels of sensitivity with different genotypes (genotypes 1, 3 and 4). Since the capture recombinant antigens were from human HEV genotypes 1 and 3, the data suggests that these five EIAs are effective for detecting antibodies against HEV viruses representing the 4 main genotypes. This is in agreement with previous data indicating that only one HEV serotype exists (2,3).

Presence of hepatitis E virus in slaughter pigs

Maribel Casas1 Raquel Cortés2 Sonia Pina3,4 Bibiana Peralta3 Martí Cortey3 Enric Mateu2,3 Jordi Casal2,3 Marga Martin2,3
1. CREAL (Centre for Research in Animal Health), Barcelona, Spain; 2. Departament de Sanitat i Anatomia Animals, Barcelona, Spain; 3. Centre de Recerca en Sanitat Animal (CReSA), Barcelona, Spain; 4. Institut de Recerca i Tecnologia Agroalimentàries (IRTA), Barcelona, Spain

Introduction
In Europe, imported human cases of hepatitis E virus (HEV) infection are declining while autochthonous cases although sporadic in nature have become more frequent (1). These autochthonous cases are most often caused by genotypes 3 and 4 of HEV whereas in endemic countries genotypes 1 and 2 are the commonest and cause epidemics transmitted through drinking water. In industrialized countries, the ubiquitous nature of the virus in domestic pigs and the genetic similarity between porcine and human HEV isolates support the notion of a potential zoonotic transmission of the infection. Thus, some human cases have been associated with the consumption of inadequately cooked meat products (2). In Spain, >90% of pig farms have HEV-seropositive pigs and the infection is suspected to be present from at least the decade of 1980 (3). The objective of the present study was to determine the percentage of pigs that could reach the abattoir being infected.

Materials and Methods
A longitudinal survey was conducted in six farrow-to-finish swine herds. Farms had been previously diagnosed as HEV positive. Twenty piglets per farm were serologically monitored from nursery to slaughter age (3, 7, 13, 18 and 25 weeks (wk) of age). Sera were analyzed for anti-HEV IgM and IgG antibodies using an in-house ELISA. At slaughter, liver (n=96) and bile (n=80) were taken and tested by RT-PCR. In order to compare HEV sequences, serum and faeces collected at 13wk of age from positive animals at slaughter, were also analyzed by RT-PCR.

Results
Anti-HEV IgM were firstly detected in pigs of 7wk of age in five farms whereas in the remaining farm, animals did not show anti HEV IgM until 13wk of age (farm 6). At slaughter age, for the first five farms between 50%-100% of pigs had seroconverted for anti-HEV IgG whereas in farm 6 only 5% of pigs were IgG seropositive. Six out of 96 livers (6%) and five out of 80 biles (6%) were HEV positive by RT-PCR. None of the pigs was simultaneously positive in liver and bile and therefore, the total percentage of infected animals was the sum of both cases (12%).

Discussion
Interestingly, positive animals from five farms had already seroconverted at slaughter, whereas positive animals from farm 6-the one seroconverting late- had not seroconverted yet. All RT-PCR product sequences corresponded to HEV genotype 3 and shared 83.5-98.7% nucleotide similarity among them or with other human or porcine HEV isolates. Three infected pigs (farms 3 & 4) were also positive in faeces or in serum at 13wk of age. The sequences from one of them had 85.8% nucleotide identity between 13wk and slaughter sequences, whereas another pig had 93.3% nucleotide identity between them.

In Spain, consumption of viscera is very low (0-2.9 grams/person/day) and thus, the risk of acquiring HEV by consumption of infected pig livers should be extremely low. However, manipulation or cross-contamination of HEV infected livers could be a potential route of transmission.

Surveillance of Shiga toxin-Producing Escherichia coli O157 and non-O157 from a breeding pig farm in China

Yaxian Yan1 Dongmei Cao1 Luming Xia1 Huiying Zhang2 Liangke Su2 Jianhe Sun2
1. Shanghai Jiaotong University, Shanghai, China; 2. School of Agriculture and Biology, Shanghai, China

The prevalence and characterization of Shiga toxin-producing Escherichia coli and Stx-converting phage isolated from a pig farm near Shanghai, China was reported. From randomly collected swine fecal samples (60 per month for 1 year), we isolated O157 and non-O157 STEC strains and Stx phage, and identified bacterial virulence genes and Stx phage morphologies.

In total, we found 8 STEC O157 (1.1%), 33 STEC non-O157 (4.6%), and 2 stx-negative O157 (0.3%) strains. Three virulence gene patterns were observed in the STEC O157 isolates—stx1-stx2-eae (1), stx2-eae-hlyA (4), and stx1-stx2-eae-hlyA (3)—while 6 virulence gene patterns were found in non-O157 STEC, most frequently stx1-stx2. Stx2-eae was in all STEC O157, whereas stx1 was in most of the non-O157 isolates.

We isolated 15 Stx1 and 57 Stx2 phages from fecal samples, and induced 1 Stx1 and 8 Stx2 phages from STEC O157 strains. Interestingly, all Stx1 phages had hexagonal heads with long tails, while Stx2 phages had 3 different structures. Most STEC O157 strains released more phage and Stx toxin after ciprofloxacin induction. Upon infection with the recombinant phage ØMin27(Δstx::cat) for gene mapping, laboratory strains produced lysogenic and lytic phage, while 2 of the 8 O157 STEC strains only produced lysogens.

The lysogens from laboratory strains produced infectious particles similar to ØMin27 after norfloxacin induction. The lysogens from STEC O157 isolates released Stx phage, although free ØMin27(Δstx::cat) particles were not detected.

Our results showed that breeding pig farms are important reservoirs for O157 and non-O157 STEC, as well as Stx phage. Residual antibacterial agents may enhance the release of Stx phage and the expression of Stx, while higher virulence of new pathogen may be produced in clinical and experimental strains by phages lysogenic conversion.

Therefore, in STEC monitoring of animal farms, attention must be given to antibiotic residues and Stx phage to improve the safety of animal related products.
Confirmation of the presence of Mycobacterium avium infections in two pig herds which had a high risk profile for M. avium as assessed by serologically monitoring

Anne Hiller1 Henk J. Wisselink2 Conny B. van Solt-Smuts2 Derk Oorburg3 Gereon Schulze Althoff4 Günter Klein1
1. University of Veterinary Medicine Hannover, Hannover, Germany; 2. Central Veterinary Institute of Wageningen UR, Lelystad, Netherlands; 3. VION Fresh Meat West, Postbus, Boxtel, Netherlands; 4. VION GmbH, Franz-Rennefeld-Weg, Düsseldorf, Germany

Introduction
Diagnosis of Mycobacterium avium (MA) infection in pigs is based on detection of granulomatous lesions in lymph nodes by incision and visual inspection by traditional meat inspection at slaughter. In certain cases MA bacteria can be detected whereas granulomatous lesions are absent (1). On the other hand also Rhodococcus equi has been frequently isolated from lymph nodes with lesions (2). In 2009 a serological monitoring has been implemented within a “risk based meat inspection” pilot in a german slaughterhouse as an alternative for detection of MA infections by traditional meat inspection. From each delivery of pigs from a pig producer to the slaughterhouse, a specific number of blood samples are examined for MA antibody titers (4). Test results from current and several previous deliveries were used to determine the MA risk level for each pig producer. On the basis of this serological monitoring 17 pig herds with a high risk for an MA infection were identified. Here we describe experiments on two of these pig herds to confirm their high risk status for MA infections.

Materials and Methods
Two farms (A and B) with a high risk profile for MA infections were selected. Pigs from both farms (A: n=58, B: n=19) underwent an intradermal tuberculin test with 0,1 ml Avian Tuberculin PPD (25.000 I.U., ASG, Lelystad, The Netherlands). The presence of induration and erythema at the injection site was read 72 h after injection. After slaughtering, blood serum samples were taken and analysed by MA-ELISA (4). Test results from current and several previous deliveries were used to determine the MA risk level for each pig producer. On the basis of this serological monitoring 17 pig herds with a high risk for an MA infection were identified. Here we describe experiments on two of these pig herds to confirm their high risk status for MA infections.

Results
In the tuberculin skin tests 72 h after injection approximately 44 pigs from farm A 29 and 15 pigs from farm B reacted positive. The skin showed swelling, erythema and partial central necrosis and exsudation. Bacteriological examination of the lymph nodes showed that 66% (38/58) and 32% (6/19) of the pigs were positive for MA (Table 1). In farm A 26% (15/58) of the pigs tested positive in MA-ELISA and 28% (16/58) by pathological examination. In farm B pigs tested with 16% (3/19) positivity by serological and pathological examination. The sensitivity of the MA-ELISA in farm A was 21,6% and the specificity 61,1%, whereas the sensitivity of the pathological examination was 40,5% and the specificity 94,4%. In farm B the sensitivity of the MA-ELISA and the pathological examination was 66,6% and the specificity of both examinations was 92,3%.

1 Positive when M. avium bacteria were detected by bacteriological examination on submaxillary lymph nodes and mesenteric lymph nodes. 2 Positive when granulomatous lesions were seen in the submaxillary lymph nodes. ND not determined.

Discussion
Two pig herds with a high risk profile for MA infections based on the serological monitoring had indeed an MA infection. Results of avian tuberculin testing on both farms showed already the presence of an MA infection, bacteriological examination of lymph nodes confirmed it definitely. Specificity and sensitivity of the pathological examination for MA infections at slaughter is questioned (2, 4). Here we show that serological monitoring for MA infections showed good perspectives to identify succesfully MA positive pig herds.

Examination of *Rhodococcus equi* strains isolated from lymph nodes of Dutch slaughter pigs

Henk J. Wisselink1 Frans F. Putirulan1 Riri Hashimoto3 Yayoi Honda3 Ryoko Ohno3 Hajime Okano3 Bert A. Urlings2 Shinji Takai3

1. Central Veterinary Institute of Wageningen UR, Lelystad, Netherlands; 2. VION N.V., Best, Netherlands; 3. School of Veterinary Medicine and Animal Sciences, Kitasato University, Towada, Japan

**Introduction**

*Rhodococcus equi* can cause disease in horses, especially in young foals. In humans, it mainly causes disease in those infected with HIV (Prescott et al., 1991). *R. equi* is also frequently isolated from granulomatous lesions in submaxillary lymph nodes of pigs (Komijn et al., 2007). *R. equi* strains differ in virulence. Virulent *R. equi* strains are isolated from horses and are characterized by the presence of virulence-associated 15- to 17-kDa antigens (VapA). *R. equi* strains of intermediate virulence are identified by a virulence-associated 20-kDa antigen (VapB) and are found in lymph nodes of pigs (Takai et al., 1996). Avirulent *R. equi* strains show no evidence of virulence-associated antigens or plasmid DNA and are widespread in soil. Humans can be infected with *R. equi* strains of the three virulence levels. The reservoir for infection in humans is not clear. Earlier, the isolation of *R. equi* from lymph nodes of Dutch slaughter pigs was reported (Komijn et al., 2007). Here we describe the typing of these strains for virulence plasmids.

**Materials and Methods**

*R. equi* strains (n=46) isolated from lymph nodes of slaughter pigs originating from nine farms were used in this study (Komijn et al., 2007). Strain ATCC 33701 (virulent strain) and 27 representative strains of intermediate virulence were used as reference strains (Makrai et al., 2008). Plasmid DNA was extracted by an alkaline lysis method with some modifications and digested with the restriction endonucleases BamHI, EcoRI, EcoT22I and HindIII for detailed comparison and estimation of plasmid sizes (Takai et al., 1993, 1999). Samples of the plasmid preparations were separated in 0.7% or 1.0% agarose gels at approx. 5 V/cm for 2 h.

**Results**

None of the 46 *R. equi* isolates contained the vapA gene, 43 isolates (93%) were positive for the vapB gene showing a 827-bp PCR product of the expected size. The 43 isolates of intermediate virulence contained seven different virulence plasmids including three new plasmid variants (Table 1). On the basis of restriction digestion patterns of plasmid DNAs, we tentatively designated these new variants as type 29, 30 and 31 (Table 1). *R. equi* strains with virulence plasmid 5 was most widespread, in strains isolated from pigs of eight of the nine farms this plasmid was found. In contrast, strains with plasmid type 1, 9, 29, 30 and 31 were exclusively found in lymph nodes of pigs from single farms.

**Discussion**

In agreement with earlier findings the *R. equi* strains isolated from lymph nodes of pigs appeared to be from intermediate virulence (Takai et al., 1996). In addition, compared to other studies, plasmid type 5 is the predominating one (Makrai et al., 2008).

Reports on *R. equi* infections in humans in the Netherlands are scarce. A further surveillance study among Dutch human *R. equi* strains is needed to answer the question to the risk of *R. equi* transmission from pigs to humans.

Introduction
Toxoplasmosis is a worldwide zoonotic disease caused by Toxoplasma gondii, which infects most warm-blooded animals. In fact, human prevalence has been found worldwide in nearly one-third of the population (Tenter et al., 2000). The consumption of raw or undercooked pork meat containing tissue cysts is considered among the principal source for human infection (Dubey, 2009). Pigs can get infected with T. gondii through ingestion of sporulated oocysts in soil, vegetation or water, by ingestion of cysts in tissues of infected animals such as rodents, birds and other pigs, or congenitally (Dubey, 2009).

The aim of the present study was to provide recent information on epidemiology and prevalence of T. gondii and the risk factors associated to this protozoan parasite in domestic pigs from the main swine producing regions of Spain.

Material and Methods
A cross-sectional study was conducted in 100 swine farms (83 farrow-to-finish and 17 piglet production farms) located all over Spain between 2007 and 2009.

Blood samples were collected from a total of 2,970 pigs. Fourteen sows and 20 fattening pigs were randomly selected in each farrow-to-finish farm and samples from 14 sows were obtained from the piglet production farms.

Presence of antibodies to T. gondii was tested by modification agglutination test (MAT). The serum from each pig was tested at dilutions from 1:25, 1:50 and 1:500. Epidemiological data were collected through a structured filled-in questionnaire in order to provide information on exposure levels to potential risk factors.

The effect of the exploratory variables on the response variable (seropositivity to T. gondii) was investigated by the method of generalized estimating equations (GEE). The statistical analyses were performed using SPSS v15.0.

Results
Antibodies (MAT 1:25 or higher) against T. gondii were detected in 492 (16.6%; CI95%: 15 2-18.0) of 2,970 pigs tested, with titers 1:25 in 287 (58.3%), 1:50 in 171 (34.8%) and ≥ 1:500 in 34 (6.9%). Farm prevalence was 85.0% (CI95%= 78-92) and within-farm prevalence ranged from 2.9% to 92.8% (median= 17.6%). Significantly higher seroprevalences were detected in Valencia Community (27.3%), Extremadura (23.3%) and Catalonia (21.2%) with respect to the other sampled regions. Sows with parity number higher than three had significantly higher seropositivity to T. gondii compared to younger sows. The GEE showed that age sows compared to fattening pigs (OR= 2.9; CI95%=1.8 – 4.5), no rodent control (OR= 1.9; CI95%= 1.04 – 3.60) and presence of cats (OR= 1.6; CI95%= 1.12 - 2.34) were risk factors potentially associated to T. gondii seroprevalence.

Discussion
The results showed widespread exposure to T. gondii among domestic pigs in Spain, with highly variable prevalence levels among farms and regions. The high seroprevalence rates indicate that raw or undercooked pork could be a source for human infections in Spain and the need of consumption of properly cook pork, especially in pregnant women.

Higher exposure was related to age of pigs, with the highest levels observed in sows, and to poor management practices related to lack of rodent control and to the presence of cats in the farms. Therefore, in order to reduce the risk of infection by T. gondii in pig farms in Spain, adequate rodent control programs and restriction of cats in the farms should be advised, and especial emphasis of avoiding infection should be taken care in the sows.

Occurrence and antimicrobial susceptibility of *Yersinia enterocolitica* on liver surfaces of slaughtered pigs

Alexandra von Altrock, Uwe Roesler, Roswitha Merle, Karl-Heinz Waldmann

WHO-Collaborating Centre for Research and Training in Veterinary Public Health, University of Veterinary Medicine, Hannover, Germany; 4. Clinic for Swine, Small Ruminants, Forensic Medicine and Ambulatory Service, University of Veterinary Medicine, Hannover, Germany

**Introduction**

Yersiniosis is the third most frequently reported human food-borne gastroenteritis in Europe caused by *Yersinia (Y.) enterocolitica*. Bioserotype 4/O:3 is the predominant type, which can be found especially in pigs' tonsils and to a lesser degree in the intestine, the faeces and lymph nodes of slaughtering pigs (4). After evisceration, rinse water enables the spread of *Y. enterocolitica* to the organs of the pluck set, hanging on a hook beneath the tonsils (2).

The purpose of the study was to evaluate the prevalence and the resistant pattern of *Y. enterocolitica* isolated from liver surfaces of slaughtered pigs in order to estimate the risk of the consumer being infected with this zoonotic agent by offal of porcine origin.

**Materials and Methods**

In a slaughterhouse in Lower Saxony, 1,500 liver surfaces of pigs from 50 herds (30 livers from each herd) were swabbed during slaughtering process. *Y. enterocolitica* were grown in irgasan-irgasan-potassium chlorate (ITC) broth, isolated on cefsoludin-irgasan-novobiocin (CIN) agar, identified with the API 20E system (bioMérieux, Nuertingen, Germany) and serotyped by slide agglutination (Sifin, Berlin, Germany). Antimicrobial susceptibility was investigated by the broth dilution method following the instructions of the supplier (VetMICTMGN-mo-Plates, SVA, Uppsala, Sweden). Breakpoints to establish resistance were selected, based on CLSI recommendations for *Enterobacteriaceae*.

**Results**

Out of 1,500 swabs from liver surfaces, 70 (4.7 %) were positive for *Y. enterocolitica* O:3. No other serotype was identified. At herd level, up to seven liver surfaces per herd were positive. From 22 herds (44.0 %), *Y. enterocolitica* could not be isolated.

All isolates were resistant to ampicillin and sulfamethoxazole. Multi-resistance to four antimicrobials was observed in four strains (6.8 %).

**Discussion**

Isolation of *Y. enterocolitica* O:3 was successful from liver surfaces of pigs from 56 % of the tested herds. However, sampling of liver surfaces does not consequently reflect the prevalence on the farm, since cross-contamination in abattoirs may occur. Altogether, not even five per cent of the livers were contaminated, which does not seem to represent a high risk for consumers. But the psychotropic agent is able to grow at temperatures close to 0°C. Therefore, low contaminated pork might reach a contamination rate of clinically significant levels during the course of storage period (3).

Monitoring of antimicrobial resistance became compulsory for the EU member states by the directive 2003/99/EC, because resistance of zoonotic pathogens may potentially reduce the effectiveness of antimicrobial treatment of foodborne disease if contracted by humans (1). Altogether, 27.3 % of the strains were resistant to three or more antimicrobials. Nevertheless, antimicrobials used for the therapy of extraintestinal *Yersinia* infections in humans, where third-generation cephalosporine or fluoroquinolones are recommended, were not affected.

Antibiotic sensitivities of fecal E. coli isolates from Austrian pigs
Sabine Elicker2 Louis Fischer3 Daniela Philadelphy1 Wolfgang Sipos1
1. University of Veterinary Medicine Vienna, Vienna, Austria; 2. Veterinary Practice Entenfellner, Stössing, Austria; 3. LaboVet GmbH, Vienna, Austria

Introduction
E. coli are the most frequent pathogens causing diarrhea in pigs. Besides diarrhea, they can also cause septicemias and cystitides. Suckling and weaned piglets most often suffer from diarrhea, whereas colitoxin shock is most often found in piglets short after weaning.

E. coli are gram-negative bacteria belonging to the family of Enterobacteriaceae. Classification is based on O-, K-, H-, and F-antigens. Additionally, E. coli are classified as enterotoxic (ETEC), entero-pathogenic (EPEC), necrotoxic (NTEC), and shigatoxin-like producing (STEC) strains due to their pathogenic factors. STECs are further divided into enterohemorrhagic (EHEC) and edema disease causing (EDEC) strains (1).

Due to the clinical importance of these bacteria, large scale usage of antibiotics is the consequence. As antibiotic usage is an effective measure in the fight against bacterial infections if administered correctly on the one hand, but may lead to unfavourable side-effects such as increasing antibiotic resistance if given careless on the other hand (2), the following data aim at helping the practitioner in his decision which antibiotic to use.

Materials and Methods
E. coli isolates out of 444 pigs (24 suckling piglets, 314 weaners, 88 fattening pigs, and 13 sows) suffering from diarrhea were tested for their antibiotic sensitivities by routine agar diffusion test. Following antibiotic substances were included: amoxicillin, cefquinome, colistin, enrofloxacin, gentamicin, linco-spectin, and sulfamethoxazole-trimethoprim.

Results
Isolates were most sensitive to cefquinome and enrofloxacin. Thus, bacterial growth could be inhibited at 98.8 % by cefquinome and at 89.9 % by enrofloxacin. Sensitivities to the other antibiotics were less pronounced (linco-spectin: 60.7 %, sulfamethoxazole-trimethoprim: 54.9 %, gentamicin: 40.9 %, colistin: 36.2 %, amoxicillin: 21.0 %). Single isolates, which were additionally tested for their sensitivities against neomycin and tylosine, were completely resistant against these substances.

Additionally, differences in the susceptibilities were found concerning the source, i.e. the different age groups. 100 % of isolates derived from fattening and breeding animals were susceptible to cefquinome and 95.7 % of isolates from fattening pigs alone to enrofloxacin. Nevertheless, susceptibilities to gentamicin and amoxicillin were reduced (25.5 %, 14.9 %) in these animals. Isolates of sows were comparably highly susceptible to linco-spectin (76.9 %) and those of suckling piglets to linco-spectin, sulfamethoxazole-trimethoprim, and gentamicin (91.7 %, 87.5 %, 65.0 %). However, these age-dependent data are considered preliminary due to the small number of animals in the age groups of suckling piglets and sows.

Discussion
This study exhibited marked differences in the antibiotic susceptibility of fecal E. coli isolates. Importantly, isolates showed reduced sensitivities against the frequently applied substance colistin and also against the broad-spectrum antibiotic amoxicillin. Cefquinome and enrofloxacin were shown to be most effective against fecal E. coli isolates.

References
**Introduction**

Immunmodulatory effect of the combination butafosfan and vitamin B12 (Catosal®) in sheep (1), calves (2) and mice (3) was already reported. Beneficial effect of Catosal® on metabolic function in the farrowing sows was also reported (4). The purpose of the present study was to investigate the effect of the metaphylactic treatment with Catosal® in pregnant sows on the immunoglobulines in colostrum and blood of sows and on newborn piglets. Furthermore, production parameters were also investigated.

**Material and method**

Thirty randomly selected pregnant crossbred sows were allocated in one of two study groups equally. All sows were managed and treated with same standard routine applications during the pregnancy. Catosal® group was treated with 20 ml of Catosal® (100 mg butafosfan and 0.05 vitamin B12/ml) at 3 weeks, 2 weeks and 1 week before farrowing start intramuscularly. And control group did not receive Catosal® but 20 ml saline. Colostrum and blood samples from all sows were collected at the start of farrowing to test the immunoglobulines (IgG, IgM, IgA). Blood was collected from new born piglets at 3 days of age to test above mentioned immunoglobulines (n=15 for each group). Farrowing and weaning performance of sows and piglets was evaluated. Commercial Indirect ELISA test kit (Bethyl Laboratories Inc., Montgomery, TX) for analysis of the total immunoglobulins (IgG, IgM, IgA) in the colostrums and blood was used. Plasma and colostral samples were diluted at 1:10,000 for the analysis. All piglets in the study groups had standard routine treatments. Data were analyzed statistically based on Wilcoxon-Mann-Whitney-U Test, two sided, 95% CI.

**Results**

Mean number of alive born piglets in Catosal and control group litters was 10.8 and 10.9 respectively. Metaphylaxis with Catosal® had significant beneficial effect for the immunity (Table 1) and weaning weight of liveborn piglets (Figure 1). There was an increase by 6% (534 g) in the weaning weight of liveborn piglets in the Catosal group compared to control group (p<0.05). An increase (2.6%) in the survivability of alive born piglets up to weaning was observed in the Catosal group (91.4%), but this increase could not be proven statistically. In the first week of life, piglets in Catosal® group had better fecal consistency, low diarrhoea incidence.

**Conclusion**

Metaphylaxis with Catosal® at prepartum period stimulated the immunity of sows that resulted in increased immunoglobulines in colostrum and consequently in piglets. An increased weaning weight was a significant economic benefit of the treatment.

**Pharmacokinetic / Pharmacodynamic Relationships of Valnemulin (Econor®) and Lawsonia intracellularis the Cause of ‘ileitis’**

David G. Burch¹ Ulrich Klein²

1. Octagon Services Ltd, Old Windsor, Berkshire, UK; 2. Novartis Animal Health Inc., Basel, Switzerland

### Introduction

Valnemulin (Econor® - Novartis Animal Health Inc.), a pleuromutilin with exceptional activity against the gut pathogens Brachyspira hyodysenteriae and B. pilosicoli was reported to have good activity against Lawsonia intracellularis (Li), (1) the causal agent of Porcine Proliferative Enteropathy or ‘ileitis’. Valnemulin (VAL) has been shown to be highly effective in the treatment of ileitis (1) when given in feed. It was the purpose of this paper to look at the pharmacokinetics (PK) of VAL in the gut contents and relate these to the pharmacodynamics (PD) of VAL and its clinical effect against Li.

### Materials and Methods

**A) Pharmacokinetics (PK)**

VAL concentrations were described in colon contents (2) following in feed medication at approximately 75 and 200 ppm for 28 days at 1.6 and 5.2μg/g. The relationship between colon and ileum contents was modelled (3) and it was estimated that an effective steady state concentration of approximately 29% of the colon contents was found in the ileum. These figures were used to determine the ileum contents concentration of VAL at 0.49 and 1.5μg/ml, respectively.

**B) Pharmacodynamics (PD)**

A recent report (4) showed that VAL had a very low intracellular MIC 90 against 10 isolates of Li from the United States (n=6) and Europe (n=4), at ≤0.125μg/ml. This level was much lower than previously reported (1) at ≤2μg/ml. The in vitro method was slightly different and used McCoy cells rather than rat enterocytes (IEC-18 cells) to grow the Li. They also used a wider range of different concentrations (0.125-128μg/ml) than the original study, making a titration of low and high MICs possible.

**C) Clinical effect**

In an artificial challenge trial (1), VAL was given in feed at 25, 37.5 & 50 ppm, from 2 days before challenge with Li strain LR189/5/83, with an intracellular MIC of <0.125μg/ml, until termination 21 days after infection. In the treatment challenge study (1), VAL was given 7 days after infection for 14 days until termination (see Table 1).

Lesions in the ileum were examined grossly and histologically.

### Results and Discussion

Effective concentrations of VAL are achieved in the ileum contents, which inhibited the development of gross lesions of ileitis at 50 ppm. At 75 ppm VAL and above, no gross or microscopic lesions were observed (see Figure 1 & 2) following treatment.

**Effect of Catosal® on appetite and body weight of sows during lactation**

Eliana O. Dantas¹ Rogério B. Petri¹ Stefan A. Rohr²
1. Bayer S.A., São Paulo, Brazil; 2. Integrall Consulting, Belo Horizonte, MG, Brazil

**Introduction**

Weight loss by the sow should not be more than 12% during lactating period, which will support good piglet assistance, a fast return to heat after weaning and a good reproductive performance in the subsequent parturition (1). The aim of this trial was to evaluate the impact of Catosal® (Butaphosphan 100mg and Cyanocobalamin 0,05mg/mL; Bayer Animal Health; in some countries available as Catosal®B12, Coforta® or Phosphorum®B12) in lactating sows on different parameters, including feed intake and weight loss during lactation period.

**Materials and Methods**

The experiment was conducted in a Brazilian commercial farm including 360 sows which were equally distributed in blocks according to the parturition order: first parturition, second parturition, and between third and sixth parturition. These blocks were distributed into four treatments, with 90 repetitions, and each animal was considered an experimental unit. Around 110 days of gestation the sows were transferred to the farrowing facility and received the lactation diet in the restricted amount of 2.0 kg/day. After farrowing, feed was distributed twice in a day, ad libitum. The wet feed consisted of 58% feed and 42% water. Sows were weighted in the entrance and in the exit of the farrowing unit, and the feed intake was measured daily. The weaning was proceeded when piglets were 21 days old. The treatment groups were classified as: T1 (negative control), T2 (10mL of Catosal®), T3 (15mL of Catosal®) and T4 (20mL of Catosal®). The product was administered intramuscularly after detection of the first signals of parturition.

**Results**

Average weekly feed intake was high for all treatments in the first lactation week. However, the T4 group had statistically higher average feed intake (p<0.05) than the control group T1 on lactation week 1, 2 and 4 (Table 1) as well as total feed consumption during lactation of T4 was significantly higher than T1. For absolute values of weight loss, it was observed that the T4 group had a lower weight loss with statistical significance (p<0.05) than the groups T1 and T2. The T3 group also had a lower weight loss with statistical significance than the group T1.

For the percentages of weight loss, only the T4 group had a lower weight loss with statistical significance (p<0.05) than the groups T1 and T2.

**Discussion**

Sows that received 15 and 20 mL of Catosal® at farrowing had lower weight loss during the suckling period with a difference from T1 such as 3.21 kg and 5.14 kg respectively. This fact is clearly associated with an increased feed intake (appetite) in these treatment groups. Catosal® application at farrowing stimulates the appetite of sows during lactation and prevents from weight loss at the critical time point where sows should feed newborn piglets.

**Introduction**

In intensive pig production systems, pigs are exposed to multiple stressors such as handling, mixing with unfamiliar conspecifics, and movement to other buildings, all of which may adversely affect performance of the animals. Stress causes the release of catabolic hormones like cortisol which can negatively affect metabolism, leading to reduced weight gain in these growing animals (Ekkel et al., 1995). Coforta®/Catosal® is a metabolic stimulant and tonic supplement containing 100 mg butaphosphan and 0.05 mg of cyanocobalamin per ml as active ingredients. It has been reported to reduce stress by reducing cortisol levels (van der Staay et al., 2006; de Groot et al., 2003). This field study aimed to investigate the effects of Catosal® on the weight gain of pigs when given strategically during stressful periods such as handling, movement and transfer to other buildings.

**Materials and Methods**

This field study was conducted in a 300 sow level farm. Twenty clinically healthy, purebred sows and their piglets were divided into two groups, the treatment group (N= 108 piglets), and control group (N=111 piglets). In the treatment group, the sows received two injections of Catosal® at 20 ml per dose once at the start of farrowing and the second dose 28 days post-farrowing (weaning day). The corresponding piglets were given Catosal® at the following dosages and schedules: 1 ml at day 3 of age, coinciding with the administration of iron dextran and toltrazuril 0.4 ml/ kg; 1 ml at day 28 (weaning day); 2 ml when the piglets were transferred from the farrowing building to the flat deck, and 5 ml upon transfer from the flat deck to the grower buildings.

The sows and piglets from the control group remained untreated with any preparation similar to Catosal®, nor with a placebo, apart from a single dose of Catosal® given to the piglets at 10 days of age, which was the usual farm program.

All piglets were weighed at birth, at weaning, during transfers and upon market.

**Results and Discussion**

The pigs in the Catosal® group had significantly higher average daily gain (ADG) in the different stages of production compared to the control group. Even by adjusting weight gain at 40 days and 80 days of rearing period in the flat deck and grower-finisher buildings, respectively, and at 150 days birth-to-market rearing period in order to have an equal basis of comparison, weight gain was significantly higher in the group from post-weaning until market. By the end of the trial, the ADG of the Catosal® group was higher by 58 grams per day, which translated to an average of 8.5 kilogram-difference in the weight gain of the Catosal® group.

**Conclusions**

In this field trial, Catosal® given to pigs during stressful periods in production resulted to a significantly increased daily weight gain and market weight of pigs. This resulted, based on the return on investment calculation, to high profitability for the farmers (17.02 USD per head under Philippine conditions). There were no treatment-related side effects neither in piglets nor in pigs.

Clinical efficacy of acetylsalicylic acid as an adjunct to the antibacterial treatment of porcine respiratory disease

Lorenzo Fraile¹ Carles Vilalta¹ Rosa López-Jimenez¹ María Teresal Varela² Sergio Lopez-Soria¹ Miquel Nofrarias¹ Tomás Alcala³ Sonia Espín⁴
¹. CReSA, Bellaterra, Spain; ². Laboratorios SYVA, León, Spain; ³. Departamento de Métodos Estadísticos, Zaragoza, Spain; ⁴. Explotacions Agrícoles i Ramaderes S.L, Bellcaire d’urghell, Spain

Introduction

Infection and environmental conditions make inflammation a manifestation of respiratory disease in pigs that decrease the ability of the lungs to exchange gases. In fact, the inflammatory response may become so overwhelming as to be life threatening in itself (1, 2).

The benefits of therapeutic intervention with non-steroidal anti-inflammatory drugs (NSAIDs) are because of their properties as inhibitors of the actions, synthesis or release of inflammatory mediators. In addition, one of the effects of NSAIDs, such as acetylsalicylic acid (AAS), is to act as antipyretics, improve the general clinical status of animals and increase food and water intake. The aim of this study was to investigate the clinical efficacy of AAS as an adjunct to the antibacterial treatment of porcine respiratory disease.

Material and Methods

142 piglets of 4 months of age were divided in two groups (experimental and control group). These animals were suffering a respiratory disease. The inclusion criteria was the presence of pyrexia (>39.7 °C) in the animals. Experimental group (A) received Doxycycline hyclate and AAS by drinking water at a dose of 10 mg/Kg (doxiporc®, Laboratorios Policherm, Spain) and 100 mg/kg of body weight (fiebrina porcino®, Laboratorios SYVA, Spain) for five consecutive days, respectively whereas control group (B) received only the antibiotic treatment. The animals were clinically examined before treatment (day 1) and at 2, 3, 4, 5 and 6 days after treatment for rectal temperature (°C) and abdominal breathing, cough and depression. Each parameter was scored using a scale of 0 = normal, 1 = slight or moderate and 2 = severe according to Moore et al. (1986). A statistical analysis was performed by paired t-test using the statistical software SPSS System v15. The alpha level used for determination of significance for all analyses was P < 0.05.

Results

The experimental group showed always a mean temperature lower than the negative control group (group B) throughout the trial (see figure) and this fever decrease for animals receiving AAS (group A) is statistically significant at days 2, 5 and 6 of the trial (p<0.05) in comparison with animals not receiving AAS (group B). However, it was not observed significant differences for respiratory symptoms throughout the trial between both groups.

Discussion

NSAIDs are used to block the production and/or the effects of inflammatory mediators and modulators which may have a deleterious effect on alveolar exchange of gases (3). Results support the idea that AAS is an effective adjunct in the treatment of porcine respiratory disease complex to decrease fever. However, we did not observe a synergic effect to decrease respiratory symptoms in animals receiving antibiotic and AAS. Nevertheless, it was not possible to check the lung inflammation to observe the anti-inflammatory effect at lung level as observed in bovine for other NSAIDs (4).

PK and PK/PD of Pharmasin® 250 mg/g Premix (tylosin phosphate) following multiple oral administration in pigs

Mariana Karanikolova 1 Stela Vesselova 1 Valeri Nazarov 1 Stanislava Ivanova 1 Dimitar Pashov 2 Spas Petkov 3 Alain Kanora 3
1. Department of R&D, Biovet JSC, Peshtera, Bulgaria; 2. Department of Pharmacology, Faculty of Veterinary Medicine, Stara Zagora, Bulgaria; 3. Huvepharma NV, Antwerp, Belgium

Introduction
In this study we determined some pharmacokinetic (PK) parameters of tylosin as Pharmasin® 250 mg/g Premix (Huvepharma NV) and related these to its pharmacodynamic (PD) with a view to a substantiated clinical use.

Materials and Methods
Eleven mixed breed pigs, weighing 20–25kg without a history of macrolide administration were enrolled in the study. Ten animals, equally male and female, received tylosin (as phosphate) at 10 mg/kg BW / 24h (Pharmasin® 250 mg/g Premix) via feed offered ad libitum prepared daily at 6.00 am for 5 consecutive days. During the treatment 40 heparinized blood samples were obtained from each pig at predetermined intervals. One pig received no drugs and served as negative control. On the 5th day the treated pigs were euthanized: 2 animals at each of the 5 different time points. Blood, organ and tissue samples from respiratory and GI tract were collected. Plasma and organ (tissue) tylosin concentrations were measured by validated HPLC method.

Results
The plasma concentration-time profile of tylosin showed nearly identical daily courses within the treatment period (Fig. 1).

![Figure 1. Plasma tylosin concentrations during multiple oral administration of tylosin phosphate (Pharmasin 250 mg/g Premix) at 10 mg/kg b.w. / 24 h](image)

There were no significant differences between the 4 daily peak concentrations (Cmax) and between Cmin or AUC values (Repeated measures ANOVA Scheffe post hoc test). However, the individual plasma concentration data were quite variable and showed that in 70% of the animals, steady state was reached at 54.4±7.7 h after administration initiation. After 4 days of treatment Cmax was 0.55±0.04 μg/mL, Cmin was 0.30±0.03 μg/mL, Cavg was 0.42±0.03 μg/mL and AUC0-24h was 10.14±0.84 μg.h/mL. Steady state tylosin concentrations in lung tissue and bronchial mucosa and secretions peaked 4h after the 5th administration, being 0.95±0.05 μg/g and 1.09±0.06 μg/g, respectively, and persisted to the last sampling point (12th h) being 0.85±0.06 μg/g and 0.97±0.04 μg/g, respectively. The corresponding tissue/plasma ratios of AUC were 1.81 and 2.04.

*Bronchial mucosa and secretions; Tissue/Plasma; NC, Not Calculated (each datum represents mean of 2 animals).

Discussion and Conclusion
The mean plasma steady state values of Cmin and of Cmax were higher than the MIC90 described for clinically important porcine bacterial pathogens of respiratory tract: M. hyopneumoniae – 0.25 μg/mL1, E. rhusiopathiae – <0.13 μg/mL3, Leptospira spp. – 0.06 μg/mL3. This was valid also for organ (tissue) steady state concentrations in respiratory tract which were higher than those in plasma. The concentration in ileal and colonic content provided active levels against L. intracellularis – MIC90=4 μg/mL2 and some sensitive strains of B. hyodysenteriae – MIC90>16>256 μg/mL2. The efficacy PK–PD breakpoint of macrolide antibiotics is a time above the MIC (T>MIC) of 50–80% of dosage interval4. In this study active tylosin antimicrobial levels persisted throughout the period of administration. Therefore, tylosin phosphate as Pharmasin® 250 mg/g Premix at the dosage schedule tested complies with the requirements of PK–PD approach. This supports its clinical use in the control of respiratory and gastrointestinal infections.

Pharmacokinetics of Pharmasin® 250 mg/g Premix (tylosin phosphate) following single oral administration in pigs

Mariana Karanikolova¹ Stela Vesselova¹ Valeri Nazarov¹ Stanislava Ivanova¹ Dimitar Pashov² Spas Petkov¹ Alain Kanora³
¹. Department of R&D, Biovet JSC, Peshtera, Bulgaria; ². Department of Pharmacology, Faculty of Veterinary Medicine, Stara Zagora, Bulgaria; ³. Huvepharma NV, Antwerp, Belgium

Introduction
Tylosin is a macrolide antibiotic that acts mostly against Gram-positive bacteria and mycoplasma. Although it has been used in veterinary medicine for a long time the data on its pharmacokinetic (PK) properties in pigs are incomplete. This study aimed at providing PK data of tylosin as Pharmasin® 250 mg/g Premix (Huvepharma NV) that could aid PK-pharmacodynamic (PD) integration as a rational base for its clinical use.

Materials and Methods
Six healthy pigs, equally male and female, weighing 20–25 kg without a history of macrolide administration were enrolled in the study. The animals received by intubation a single p.o. dose of tylosin (as phosphate) 10 mg/kg BW (Pharmasin® 250 mg/g Premix), as water suspension. Heparinized blood samples (n=13 per animal) were taken at predetermined intervals. Plasma tylosin concentrations were measured by a validated HPLC method. The results obtained for tylosin disposition were tested by compartmental method (using Akaike’s information criterion) and by non-compartmental approach as well.

Results
Plasma concentration vs. time data best fitted applying the non-compartmental model. The highest plasma concentration (C_max = 1.08±0.08 μg/mL) was achieved 2h post administration. Thereafter, plasma levels declined remaining higher than 0.38±0.017 μg/mL at 12h post administration (Fig. 1). The half-life (t_1/2) was 6.66h. AUC0-β and AUC0-∞ were 8.2±0.49μg.h/mL and 11.84±0.58μg.h/mL, respectively (Table 1).

*Harmonic mean, each datum represents the mean ± SEM

Discussion and Conclusion
The elimination half-life of tylosin, calculated after single oral dose (6.66h), was higher than that reported after i.v. injection (4.5h) and the peak plasma concentration was comparable to the one found after i.m. injection (1.0 μg/mL). Throughout the period of determination plasma tylosin levels were higher than the MIC90 described for clinically important porcine bacterial pathogens: Mycoplasma hyopneumoniae - 0.25 μg/mL, Erysipelothrix rhusiopathiae - <0.13 μg/mL, Leptospira spp. – 0.06 μg/mL.

A primary precondition in PK–PD approach for the effectiveness of macrolide antibiotics is a time above the MIC (T>MIC) of 50–80% of dosage interval. The results of this study show that tylosin PK at the dosage schedule tested complies with this requirement and can ensure therapeutically effective concentrations throughout the 12h period of determination. This supports clinical use of tylosin phosphate as Pharmasin® 250 mg/g Premix in the control of respiratory and gastro-intestinal infections.

PK and PK/PD of Pharmasin® 100% w/w WSG (tylosin tartrate) following multiple oral administration in pigs

Stela Vesselova1 Mariana Karanikolova1 Valeri Nazarov1 Stanislava Ivanova1 Dimitar Pashov2 Spas Petkov3 Alain Kanora3
1. Department of R&D, Biovet JSC, Peshtera, Bulgaria; 2. Department of Pharmacology, Faculty of Veterinary Medicine, Stara Zagora, Bulgaria; 3. Huvepharma NV, Antwerp, Belgium

Introduction
In this study we investigated the pharmacokinetic (PK) behavior of tylosin as Pharmasin® 100% w/w WSG (Huvepharma NV) in pigs in order to explore PK–pharmacodynamic (PD) integration as rational basis for its clinical use.

Materials and Methods
Eleven mixed breed pigs, weighing 20–25 kg without a history of macrolide administration were enrolled in the study. Ten animals, equally male and female, received tylosin (as tartrate) at 10 mg/kg BW / 24h (Pharmasin® 100% w/w WSG) as medicated drinking water offered ad libitum daily freshly prepared at 6.00 am for 5 consecutive days. During the treatment 40 heparinized blood samples were obtained from each pig at predetermined intervals. One pig did not participate and served as negative control. On the 5th day the treated pigs were euthanized: 2 animals at each of the 5 different time points. Blood, organ and tissue samples from respiratory and GI tract were collected. Plasma and organ (tissue) tylosin concentrations were measured by validated HPLC method.

Results
The plasma concentration-time profile of tylosin showed nearly identical daily courses within the treatment period (Fig. 1).

There were no significant differences between the 4 daily peak concentrations (C_{max}) and between C_{min} or AUC values (Repeated measures ANOVA Scheffe post hoc test). However, the individual plasma concentration data were quite variable and showed that in 70% of the animals steady state was reached at 46.9±6.33 h after treatment initiation. After 4 days treatment C_{max} was 0.58±0.04 μg/mL, C_{min} = 0.28±0.03 μg/mL, C_{av-ss} = 0.45±0.04 μg/mL, and AUC_{24h} = 10.73±0.92 μg.h/mL. Steady state tylosin concentrations in lung tissue and bronchial mucosa and secretions peaked 2h after the 5th administration, being 0.93±0.06 μg/g and 1.06±0.06 μg/g, respectively, and persisted to the last sampling point (12thh), being 0.67±0.12 μg/g and 0.78±0.13 μg/g, respectively. The corresponding tissue/plasma ratios of AUC were 1.88 and 2.17.

Discussion and Conclusion
The mean plasma steady state values of C_{min-ss} and of C_{av-ss} were higher than the MIC_{90} described for clinically important porcine bacterial pathogens of respiratory tract: M. hyopneumoniae – 0.25 μg/mL, E. rhusiopathiae – <0.13 μg/mL, Leptospira spp – 0.06 μg/mL. This was valid also for organ (tissue) steady state concentrations in respiratory tract which were higher than those in plasma. The concentration in ileal and colonic content provided active levels against L. intracellularis – MIC_{90} = 4 μg/mL and some sensitive strains of B. hyodysenteria – MIC_{90} >16>256 μg/mL².

Generally, PK–PD breakpoint for clinical and bacteriological efficacy of macrolide antibiotics is a time above the MIC (T>MIC) of 50–80% of dosage interval. In this study active tylosin antimicrobial levels persisted throughout the period of administration. Therefore, tylosin tartrate as Pharmasin® 100% w/w WSG at the dosage schedule tested complies with the requirements of PK–PD approach. This supports its clinical use in the control of respiratory and gastro-intestinal infections.

Introduction
Tylosin is a macrolide antibiotic that acts mostly against Gram-positive bacteria and mycoplasma. Although it has been used in veterinary medicine for a long time the data on its pharmacokinetic (PK) properties in pigs are incomplete. The aim of this study was to obtain PK data intended to facilitate PK–pharmacodynamic (PD) integration in clinical use of tylosin as Pharmasin® 100% w/w Water Soluble Granules (Huvepharma NV).

Materials and Methods
Six healthy pigs, equally male and female, weighing 20–25 kg without a history of macrolide administration were enrolled in the study. The animals received by intubation a single p.o. dose of tylosin (as tartrate) 10 mg/kg BW (Pharmasin® 100% w/w Water Soluble Granules), dissolved in water. Heparinized blood samples (n=13 per animal) were taken at predetermined intervals. Plasma tylosin concentrations were measured by a validated HPLC method. The results obtained for tylosin disposition were tested by compartmental method (using Akaike's information criterion) and by non-compartmental approach as well.

Results
Plasma concentration vs. time data fit best by applying the non-compartmental model. The highest plasma concentration (Cmax = 1.10±0.08 μg/mL) was achieved 2h post administration. Thereafter, plasma levels declined remaining higher than 0.31±0.2 μg/mL at 12h post administration (Fig. 1). The half-life (t1/2 β) was 5.6h. AUCtlast and AUC0-∞ were 7.79±0.58 μg.h/mL and 10.31±0.75 μg.h/mL, respectively (Table 1).

Discussion and Conclusion
The elimination half-life of tylosin, calculated after single oral dose (5.6h), was higher than that reported after i.v. injection (4.5h) and the peak plasma concentration was comparable to this found after i.m. injection (1.0 μg/mL). Throughout the period of determination plasma tylosin levels were higher than the MIC90 described for clinically important porcine bacterial pathogens: Mycoplasma hyopneumoniae – 0.25 μg/mL, Erysipelothrix rhusiopathiae – <0.13 μg/mL, and Leptospira spp. – 0.06 μg/mL.

According to PK–PD approach the breakpoint for clinical effectiveness of macrolide antibiotics is a time above the MIC (T>MIC) of 50–80% of dosage interval. The results of this study show that tylosin PK at the dosage schedule tested complies with this requirement and can ensure therapeutically effective concentrations throughout the 12h period of determination. This supports clinical use of tylosin tartrate as Pharmasin® 100% w/w Water Soluble Granules in the control of respiratory and gastro-intestinal infections.

Efficacy of flavomycin to susceptibility of haemolytic Escherichia coli in weaner to finishing pigs

Nuvee Prapasarakul1, Waree Niyomtuma1, Prapipat Khemsapb2, Suthatip Prapatsornpinyo 3
1. Department of Veterinary Microbiology, Faculty of Veterinary Science, Chulalongkorn University, Bangkok, Thailand; 2. Huvepharma (Thailand) Ltd., Bangkok, Thailand; 3. Panuspokphand Pig Farm Co., Ltd., Chonburi, Thailand

Introduction
Escherichia coli is regarded as a commensal and opportunistic pathogen of gastrointestinal tract. α-haemolytic E. coli (HEC) is clearly more potential to induce pathogenic lesion due to possessing of exotoxins (4). This causes colibacillosis and oedema disease and directly impacts to severe economic loss (5). In Thai pig industrial, intensive use of antimicrobials is a common alternative for control of infectious diseases. There has been a dramatically increasing of resistant bacteria against antimicrobials such as beta-lactams, macrolides, fluoroquinolones, tetracyclines and lincosamides because of use of different several antimicrobials during production periods other than 2 weeks prior to slaughter. However, not only pathogenic bacteria are affected from the administration, but also enteric commensal may rise up the risk of resistance in farm-level (6). Flavomycin is phosphoglycolipid antibiotic in flavophospholipal group that has been approved as a feed additive. It is active against Gram’s positive bacteria and also inhibits in vitro conjugation of Gram’s negative bacteria such as E. coli. The current study was to evaluate minimal inhibitory concentration (MIC) to 6 antimicrobials of E. coli derived from weaner to finishing pigs that received flavomycin as a feed additive. We also determined an efficacy of flavomycin to 30 enterotoxogenic E. coli (ETEC) isolated from piglets.

Materials and Methods
Sample collection. 10 ppm of flavomycin was the addition of routine feed additive during 10 to 21 weeks of pig ages. Pig feces were collected and contained in transport media.

Bacteria. 30 ETEC isolated from piglets with colibacillosis since 2008, were derived from stock isolates of Dept Vet Micro. 63 E. coli comprising with 30, 16 and 17 isolates that were collected at 5, 15 and 25 week age, respectively. Haemolytic traits on 5% sheep blood agar were used for colony selective criteria. When HEC was not observed on the primary plate, non-HEC would be selected for MIC determination.

MIC determination. 6 antimicrobials comprising with flavomycin, colistin, chlorotetracycline, enrofloxacin, amoxicillin and oxacillin were used. Broth micro-dilution was carried out according to the recommendation of CLSI (2, 3).

Results and Discussion
Range of MIC distribution is shown in Fig 1. The MIC values of 30 ETEC against amoxicillin, oxacillin, and chlorotetracycline, were over 256 ug/ml. They were inhibited by flavomycin at 4-32 ug/ml. Enrofloxacin and colistin were the effective agents to the tested E. coli.

HEC was mostly isolated from the period before adding of flavomycin and were disappeared in pig aged 15 week. The MIC50 of each batch of isolation is compared in Table 1.

The MIC of 63 isolates was consistent to that of ETEC in 2008. Beta lactam resistant bacteria may be a native clone in the area of study. Flavomycin clearly reduced HEC in fattening pigs and its susceptibility was lower in the final week. These confirmed a direct efficacy to pathogenic agents (1) and may be able to maintain susceptible level from weaner to finishing.

Pharmacokinetic/pharmacodynamic relationships of HydroDoxx® 500 mg/g Powder (doxycycline) in porcine respiratory disease complex (PRDC)

Mariana Karanikolova1 Stela Vesselova1 Valeri Nazarov1 Spas Petkov2 Koen De Gussem2 Alain Kanora2

Introduction

The porcine respiratory disease complex (PRDC) is a leading cause of animal and economic losses in swine production6. Because bacteria are involved in this condition, antibiotics are a short-term measure in a multifaceted strategy of disease control. In the swine industry, tetracyclines have been applied particularly for respiratory tract infections7. Doxycycline (DOX) is a semi-synthetic tetracycline and a broad-spectrum bacteriostatic antibiotic against Gram-negative and Gram-positive aerobic and anaerobic bacteria, Rickettsiae, Chlamydiae, mycoplasmas and some protozoa10. DOX is characterized by a better lipid solubility, greater tissue penetration, improved antimicrobial activity and a different pharmacokinetic profile1,2. The objective of this paper was to review existing literature data on pharmacokinetic (PK) and pharmacodynamic (PD) properties of DOX with a view to evaluate their relationships as a base for its clinical effect in PRDC as HydroDoxx® 500 mg/g Powder for use in drinking water.

Pharmacokinetics

The multiple oral administration of DOX at 6.6, 11.5 and 12.9 mg/kg BW daily produces steady-state concentrations of respectively 0.37-0.89, 0.56-0.87 and 0.71-1.14 μg/mL9. In another experiment steady-state plasma levels ranging between 0.9 and 1.5 μg/mL have been observed during 8-day oral medication at a dosage regimen of 11.8-13.3 mg/kg/day5. Administration via drinking water at 10 mg/kg daily for 5 days results in mean plasma concentration at steady-state of 1.37±1.21 μg/mL10.

Pharmacodynamics

It was reported that MIC values of DOX for important porcine bacterial respiratory tract pathogens are 0.25 to 0.5 μg/mL8. In other studies, further values were determined3,10 (Table 1).

PK-PD integration

Steady-state DOX plasma levels determined after oral medication with DOX at a dose of 11.5 mg/kg BW daily exceed MIC values 0.25 to 0.5 μg/mL9. In conformity with the type of its antimicrobial action, DOX belongs to concentration-time dependent (co-dependent) drugs with integrated PK-PD variables AUC/MIC and T>MIC with proposed values of 125 h and 50-80%. Based on this principle and analyzing the results obtained after 5-day administration of DOX via drinking water at a dose of 10 mg/kg daily other authors assume that the calculated mean values of (AUCss/MIC90) 24h and %T>MIC for Bb and Mh achieve the breakpoints for these indices10. For Pm the %T>MIC exceeded 70%. Considering these results the authors conclude that DOX at 10 mg/kg daily should ensure the plasma concentrations required for successful therapy against Bb and Mh and possibly against Pm but probably not against Ap8.

Clinical effectiveness and conclusion

The results from clinical investigations of DOX under field conditions in pigs showed that DOX after oral administration at a dose of 10 mg/kg BW was effective in controlling PRDC. The effect was demonstrated in the reduction of respiratory disease incidents, decrease in lethality and increase in economically significant zootechnical parameters with significant differences between the treated and untreated groups4,11. It can be concluded that HydroDoxx® 500 mg/g Powder for use in drinking water administered to pigs at the recommended rate (10 mg/kg BW) is effective to prevent and treat PRDC.

Introduction
The study objective was to determine the clinical efficacy of orally administered tylosin tartrate in growing pigs that have been artificially infected with Mycoplasma hyopneumoniae (Mh), compared to tylosin phosphate.

Materials and Methods
Four groups of 6 SPF pigs (Danube white), equal number of sexes (10.0-12.0 kg), 10 weeks of age, were used. All groups (I, II and III) were infected with Mh. Twenty-four hours after the challenge, the infected group (I) was treated via feed with tylosin (as phosphate) (Pharmasin® 250 mg/g Premix) and group II was treated through drinking water with tylosin (as tartrate) (Pharmasin® 100% w/w WSG). Both groups received a dose of 10 mg tylosin per kg BW for 8 consecutive days, followed by 5 mg tylosin per kg BW until the end of the period of risk (14 days). The efficacy of the medication was assessed by observing the rectal temperature, clinical symptoms and gross lung lesions, histology, serology for detection of antibodies against Mh using an ELISA test (Dako Cytomation, Denmark A/S), nasal swabs and lung biopsy for bacteriological examinations (after euthanasia and necropsy of all pigs), bodyweight gain and feed conversion efficiency. The results of the examination were determined according to t-test of Student–Fisher.

Results
Specific clinical symptoms of respiratory disease and gross lung and histological lesions were observed in the infected unmediated group (III). Tylosin (as phosphate) administration via feed in pigs of group I and tylosin (as tartrate) administration via water in pigs of group II both lead to a statistically significant decrease in clinical signs and gross lung lesions (Table 1). Bacteriological examinations of nasal swabs and lung showed a statistically significant reduction in re-isolation rate of Mh (Table 1). In both tylosin treatment groups, zootechnical parameters (bodyweight gain and feed conversion ratio) were statistically significantly higher than those recorded in the infected unmediated group of pigs (Table 2).

Discussion and Conclusion
Tylosin is one of the oldest antibiotics for veterinary medicine that is still frequently being used to treat enzootic pneumonia. The results show that tylosin (as phosphate) administration via feed and tylosin (as tartrate) administration via water both have a significant metaphylactic and therapeutic effect in experimentally challenged Mh infection in pigs. This is further confirmed by the differences in clinical, bacteriological and zootechnical parameters, which were also significantly different compared to group III. The data obtained in this experiment are consistent with the results recorded in previous studies. The significant clinical efficacy of tylosin after oral treatment is due to the wide distribution of the drug in pigs and its reaching and accumulation in target tissues. These results indicate that the use of tylosin administered as tartrate or phosphate can be successfully used in strategic programs to control enzootic pneumonia caused by Mh in pigs.

Efficacy of Denagard(tiamulin) and amoxycillin combination on porcine mycoplasmosis control in a Thai pig farm

Mongkol Lumyai¹ Sittikorn Traiyarach¹ Metta Makhanon² Sasiwimon Talummuk² Komkrich Teankum¹ Roongroje Thanawongnuwech¹  
1. Chulalongkorn University, Bangkok, Thailand; 2. Novartis (Thailand) Ltd, Bangkok, Thailand

Introduction

Mycoplasmosis is one of the major bacterial pneumonia in pigs, usually co-infected with other organisms leading to a complex of respiratory diseases or porcine respiratory disease complex (PRDC)¹. Vaccination is a common tool for controlling the disease; however, the elimination of mycoplasma is still incomplete due to the nature of the organism. By administration of tiamulin (Denagard®), an effective pleuromutilin against mycoplasma², the infection could be significantly resolved. Additionally, a combination of tiamulin with other antibiotics such as amoxycillin could facilitate the elimination of Mycoplasma hyopneumoniae and other concurrent pathogens. The objective of this study was to evaluate the efficacy of a combination of Denagard® and amoxycillin to control concurrent porcine mycoplasmosis in comparison with lincomycin combined with amoxycillin in a Thai pig farm.

Materials and Methods

A mycoplasmosis-affected pig farm in Thailand was selected based on clinical signs, bacterial culture results, slaughter check and serological profile. Serologically, pigs were 100% sero-positive on Mycoplasma indirect ELISA test as early as 16 week-old. Evidently, PRRSV and PCV2 were also detected in this herd. A total of 180 pigs (10 week old) were allocated into 2 groups: Group A (n = 90) fed with Denagard® (100 ppm) and amoxicillin (300ppm) and Group B (n = 90) fed with lincomycin (110ppm) and amoxicillin (300ppm). Those pigs were randomly put into each pen in the same housing without the environmental effect. Treatment was conducted in the growing pig feed from 10 to 14 week-old continuously (one week before the presence of the clinical signs). The clinical history and the production parameters were recorded during the study as well as the number of culled pigs until two weeks after the treatment. To measure average daily weight gain (ADG) pigs were individually weighted each week from 10 and 14 weeks of age.

Results and Discussion

A higher number of clinically sick and culled pigs were observed in Group B (sick = 19, culled pigs = 3) than in Group A (sick = 11, culled pigs = 1) (n=90) during the studied period (10-14 week-old). Similarly, ADG of Group A pigs receiving a combination of Denagard® and amoxicillin was significantly better than in Group B using Mann Whitney test (P<0.01) (Fig. 1). Concurrent infection among PRRSV, PCV2, Mycoplasma and possibly other bacteria did exist in the studied farm. Interestingly, vaccination of those mentioned 3 major respiratory pathogens was not practised and the combination of Denagard® and amoxicillin did demonstrate helping those treated pigs growing better than the other medicated group. Minimizing the negative effects of secondary bacterial infection using the drugs of choice in this farm is considered as an important management tool to effectively control PRDC. Unfortunately, the lung scores and other lab results were not available at the time of submission.

Fig. 1 Clinical signs (A) and average daily weigh grain (ADG) (B) in the treatment groups (10-14 wk).

Pharmacology and therapeutics
Homogeneity of an oxytetracycline solution administered with a dosing pump

Anne Hemonic; Isabelle Corrégé; Nicolas Berthelot
IFIP-Institut du porc, LeRheu, France

Introduction

On pig farms, collective treatments can be achieved by oral administration of medicines through drinking water with dosing pumps. Homogeneity of the medicated solution at the drinkers is a key factor for therapeutic success, respect of the maximum residue limits (MRL) in meat and prevention of antimicrobial resistance. The aim of this study was to assess homogeneity of an oxytetracycline (OTC) solution, according to type of stock solution tanks and to solubility of OTC.

Materials and Methods

Homogeneity in the stock solution tank

Three types of tanks commonly used on farms (1) were tested:
• One flat-bottomed tank without stirrer,
• One flat-bottomed tank with a motorized propeller,
• One conic-bottomed tank with a pump mixing the solution.

Each tank was filled up with a well-dissolved OTC solution. Sixty samples were taken 3, 5, 7 and 24 hours after the solution had been prepared at 3 heights of the tank (top, middle and bottom).

Homogeneity at the drinker

Tests were conducted on an experimental pipe, simulating on-farm conditions. An OTC solution prepared in a mixing tank with (solution A) or without solvent (solution B) was administered by a hydraulic pump to the drinkers. Fifty or 60 samples of 50 ml were taken at the drinker continuously or after a break, with 4 combinations of water flows and pressures. Concentrations of OTC were assessed by colorimetric analysis.

Results and Discussion

Homogeneity in the stock solution tank

For the 3 tanks and at a given time, all the coefficients of variation (CV) in the 3 heights and in the entire tank were below 5%. We concluded there was no concentration gradient in tanks at any given time, with or without a stirrer. These results completed those obtained during a test comparing the homogeneity of low or highly soluble preparations of amoxicillin (2).

Homogeneity at the drinker

With solution B, samples taken after each break showed increases and drops of concentrations (figure 1), certainly matching settling and releasing of OTC in the pipe. This didn’t occur with continuous sampling but in both cases, CV were up to 5% for the 4 combinations of flows and pressures (Figure 1). So, without any solvent, the solution wasn’t homogeneous at the drinker.

With continuous sampling of solution A, CV were below 5% and average concentrations were between 104 and 109% of the expected concentration (1g/l) (Table 1). This met the quality requirements of an industrial medicated feed.

After a 12 hour break of solution A, the first samples showed concentration levels between 1.2 and 2.5 times higher than the average levels of the next samples. The involved volume (400 ml), corresponding to the pipe coming down towards the drinker, might globally match the first morning-time drinking of one pig weighting 70 kg (less than 6% of its daily water intake). So, this doesn’t question the respect of the MRL.

Conclusion

Our results demonstrate that a well-dissolved medicated solution guarantees a correct homogeneity in the stock solution tank even without a stirrer. At the drinker, the homogeneity of such a solution meets the quality requirements of an industrial medicated feed.

Stability of different amoxicillin medicated premixes in flour feed

Eric Bousquet1 Mehdi Laraichi1 Guillermo Cano2 Aurélien Guicherd3 Jacques Goutalier3
1. Virbac, Carros, France; 2. Tests and Trials, Lleida, Spain; 3. Phatophy, Lyon, France

Introduction

Interest of a specific coating process of amoxicillin (Suramox®) has been previously demonstrated in order to protect active ingredient degradation in medicated feeds and to insure that adequate amount of active ingredient is available for pigs (1-2). Different comparative studies at laboratory, pilot or industrial scale in Europe showed a better protection of amoxicillin with this coating process against degradation during pelleting and storage of feeds (3).

As medicated feeds are also used in some countries as flour feeds (without pelletization), objective of the present study was to compare stability of amoxicillin in flour feed at industrial scale for different medicated premixes registered in Europe.

Materials and Methods

Five products containing respectively 5% (Suramox®, A, B, C) and 10% (D) of amoxicillin (expressed as base) were tested in the same Spanish feed plant. One batch of a pig grower feed was supplemented by each premix at the concentration of 400 ppm (mg of amoxicillin per kg feed). One blank feed batch was manufactured between 2 medicated batches to avoid cross contamination. Size of medicated feed batches was equal to 3 tons each. Mixing of raw materials lasted for 2.5 minutes in the mixer where each premix was added manually. Amount of each premix was accurately weighed in order to calculate exact concentration of amoxicillin in feed. Three samples of each medicated feed batch were taken at regular intervals covering the total emptying time of the mixer and stored during 14 days in standardized conditions (respectively 30°C/65% of relative humidity (RH) and 40°C/75% RH before assay). Amoxicillin concentrations in feed were determined by High Performance Liquid Chromatography with UV detection. Each sample was analyzed twice and mean concentration was calculated.

Results

Lower degradation rates were measured with Suramox® (6.1% and 13.9% after storage at 30°C and 40°C respectively) than with the other products (degradation ranging from 30.5% to 44.4% and from 45.2% to 60.3% after storage at 30°C and 40°C respectively).

Table: Amoxicillin mean concentrations in feed after storage during 14 days (expressed as percentage of theoretical concentration)

</tbody>
</table>

Discussion

Degradation during storage has been previously shown at laboratory scale when flour feed was stored during 15 days at 40°C/95% RH : degradation was limited to 10% for Suramox® and around 50% for other products, consistent with present data (3). This study confirms that amoxicillin may be damaged in feed even without pelletization during transport and storage according to temperature and humidity conditions found in Europe (particularly when feed is stored in silos during summer). A specific coating process of the active ingredient may reduce degradation in such conditions.

Stability of tylosin in liquid feed used in commercial pig farms

Alain Kanora; Spas Petkov; Koen De Gussem
Huvepharma NV, Antwerp, Belgium

Introduction
In some countries, pig farms are using recyclable foodstuff originating from human consumption and are commonly being added as nutritional basis for liquid feeds. Farmers can also mix commercial feed with water to obtain liquid feed. These two feed systems have the benefit that feed becomes tastier and more acid due to fermentation; both properties will increase consumption. The stability and activity of veterinary medicinal products (VMP) used in liquid feed are often not studied; particularly data on antibiotics are unavailable.

VMD (UK) currently allows the use of in-feed antimicrobials in liquid feed in accordance with the cascade regulations, but veterinarians need to base their decision on the stability of the veterinary specialty first before prescribing the use in liquid feed. In this way issues like overdosing, underdosing, resistance build-up, etc. can be avoided. Therefore, the use of tylosin phosphate (Pharmasin® medicated feed premix) in liquid feed was studied by evaluating the impact on the active substance with regards to stability.

Materials and Methods
Locally collected dry feed from a GMP certified production site was sourced and diluted at ration 2:1 with tap water to obtain a liquid feed matrix.

Pharmasin® 250 mg/g and Pharmasin® 100 mg/g were added to the liquid feed in dosages providing 100 ppm in the feed based on dry matter.

The mixtures were stored under normal environmental conditions (20-25°C, ambient humidity) and sampled at 0, 1, 6, 24 and 72 hours.

The samples were analyzed by a microbiologic assay for tylosin content. The method is a four-dose diffusion assay using Micrococcus luteus ATCC 9341 as a test micro-organism.

Results
The ppm levels of all tested Pharmasin® formulations remained perfectly stable for more than 5 hours. The VMD recommendation of 1h stability was perfectly matched and also the maximum meal contact time for pigs was prior to onset of a slight activity loss.

Table 1: Tylosin concentration (ppm) in liquid feed samples on dry basis

Discussion and Conclusion
It can be concluded from this study that Pharmasin® Medicated Premix used in a responsible way in liquid feed remains perfectly stable and that there is no loss of activity of the used tylosin phosphate. Even after 24 and 72 hours, tylosin activity was in excess of 80% of the initial value.

**Pharmacokinetics and tolerance of Catosal® in pigs**

Bernard H. Schmidt¹ Ralph Krebber² Martina Rehagen¹

¹. Bayer Animal Health GmbH, Leverkusen, Germany; ². Bayer CropScience AG, Monheim, Germany

**Introduction**

Catosal® is a metabolic stimulant for use in numerous target animal species including the pig in many countries worldwide. It contains 100 mg of butafosfan and 0.05 mg of cyanocobalamin (vitamin B12) per ml. Experimental studies indicated that Catosal® attenuates stress responses of piglets (1), and reduces the prevalence of certain production diseases in sows and piglets (2,3). The present report documents the tolerance and the pharmacokinetics of butafosfan after a single intramuscular (i.m.) injection of Catosal® to piglets.

**Materials and Methods**

Two independent studies were performed in an accredited experimental animal centre in Germany. The first one assessed the local and systemic tolerance of Catosal® in healthy German Landrace hybrid piglets (22.5 – 28.5 kg body weight (b.w.)). Catosal® was injected i.m. at the dosages of 0.1, 0.3, and 0.5 ml/kg (N=6 per dose group). A control group of 6 piglets received saline at the dose volume of 0.5 ml/kg b.w. Between injection and the third day thereafter, the animals were closely monitored for clinical signs of intolerance and local reactions at the injection site.

The second study assessed the pharmacokinetics of butafosfan in four Hamshire/Pietrain piglets weighing 36.5 – 47.0 kg. The animals received Catosal® at a dose volume of 0.1 ml/kg i.m., corresponding to 10 mg butafosfan/kg b.w. Frequent blood sampling was performed over a period of 24 hours after treatment. Serum was analyzed for butafosfan concentrations using HPLC with tandem mass spectrometric detection. Relevant pharmacokinetic parameters were calculated using non-compartmental analysis and the linear/log trapezoidal rule. All results are given as arithmetic means ± standard deviation.

**Results**

Tolerance: No local reactions at the injection site, immediate systemic reactions or other adverse events were observed in either study after i.m. injection.

Pharmacokinetics: Based on the individual serum concentrations of butafosfan, the concentration-time profiles depicted in Figure 1 were obtained.

**Conclusion**

Intramuscular injection with Catosal® at a dose volume of 0.1 ml/kg b.w. and 5 times thereof is well tolerated and safe in pigs. The pharmacokinetics of butafosfan show a fast and efficient absorption into blood, a high distribution volume and fairly rapid elimination from the porcine body.

Introduction

Interest of a specific coating process of amoxicillin (Suramox®) has been previously demonstrated in order to protect active ingredient degradation in medicated feeds and to insure that adequate amount of active ingredient is available for pigs (1-2). Different comparative studies at laboratory, pilot or industrial scale in Europe showed a better protection of amoxicillin with this coating process against degradation during pelletization and storage of feeds (3-4).

Objective of the present study was to complete stability data of amoxicillin in pelleted feed at industrial scale for different medicated premixes registered in Europe.

Materials and Methods

Five products containing respectively 5% (Suramox®, A, B, C) and 10% (D) of amoxicillin (expressed as base) were tested in the same Spanish feed plant. One batch of a pig grower feed was supplemented by each premix at the concentration of 400 ppm (mg of amoxicillin per kg feed). One blank feed batch was manufactured between 2 medicated batches to avoid cross contamination. Size of medicated feed batches was equal to 3 tons each. Amount of each premix was accurately weighed in order to calculate exact concentration of amoxicillin in feed. Steam pressure was equal to 4 atm and temperature ranged from 53.7 to 65.5°C before pelletization. Temperature ranged from 71.3 to 75.2°C after pelletization. Six samples of each medicated feed batch were taken after cooling of the pellets at regular intervals covering the total batch delivery. Samples were analyzed at the time T0 of reception by the laboratory (Phatophy). In the meantime, aliquots of 3 out of 6 samples per batch were stored during 14 days in standardized conditions (25°C/65% of relative humidity (RH) before assay at T14). Amoxicillin concentrations in feed were determined by High Performance Liquid Chromatography with UV detection. Each sample was analyzed twice and mean concentration was calculated.

Results

Mean degradation ranged from 10.2% to 39.3% at T0. A further degradation was measured during storage for all products except Suramox®, leading to a total degradation between 18.3% and 53.1% at T14 for products A, B, C and D.

</tr>
</tbody>
</table>

Discussion

Degradation was limited around 10% for Suramox®, without significant evolution during storage (variation within analytical variability). Degradation recorded for the other products was consistent with previous studies following pelletization and eventual storage of pig medicated feeds (3-4).

This study confirms that a specific coating process of the active ingredient may reduce degradation after pelletization and storage of feeds.

Demixing by elutriation of different amoxicillin medicated premixes in feed

Eric Bousquet¹ Mehdi Laraichi¹ Carine Rousseau¹ Christine Segot¹ Aurélien Guicherd² Jacques Goutalier²

1. Virbac, Carros, France; 2. Phatophy, Lyon, France

Introduction
Demixing of medicated feeds is a concern for feed millers and veterinary practitioners, leading to heterogeneous feeds and increase of antimicrobials dosage variability. Elutriation is a demixing phenomenon due to different speeds of powder particles while falling through the air. A standardized test has been developed to assess elutriation of powders from previously described experiments (1). This test has been correlated with demixing of supplemented feeds in plants (2) and previously performed for a range of antimicrobials premixes (3-4). Objective of this study was to complete elutriation tests on 4 amoxicillin premixes registered in Europe.

Materials and Methods
Four products containing respectively 5% (Suramox®, A) and 10% (B, C) of amoxicillin (expressed as base) were tested in a pre-starter feed (median particle size : 390 μm). Median particle size of the 4 products was determined by laser granulometry. Each product was then tested twice in order to allow statistical analysis. Around 1 kg of flour feed was supplemented by each product according to incorporation rate recommended (400 ppm of amoxicillin in feed). A tracer was added in each feed sample at the concentration of 500 ppm in order to validate the tests. For each test a 300 ml feed sample was dropped in an 8 m high tube. After drop, top and buttom 50 ml feed samples were taken for tracer assay by colorimetry and amoxicillin assay by high performance liquid chromatography. In each test, an elutriation index (EI) was calculated from previously defined index (5) for the tracer and for amoxicillin (where Ct and Cb are respectively concentrations in top and bottom samples):

\[ EI = \frac{Ct - Cb}{Ct + Cb} \times 100 \]

This index ranges from −200 to +200, extreme values corresponding to maximal demixing whereas zero value corresponds to lack of demixing. A non parametrical analysis of variance on ranks was performed to compare EI between products.

Results
Amoxicillin EI was lower for Suramox® than for the other products.

*, **: significantly different from Suramox® (resp p<0.05 and p<0.005)

Discussion
For products with high negative EI, amoxicillin is more concentrated in bottom of the sample after test (amoxicillin particles too large or too dense falling more quickly within large feed particles). For products with high positive EI, amoxicillin is more concentrated in top of the sample after test (thin amoxicillin particles falling more slowly within thin feed particles). This is reflected by median particle size higher than feed one for products with high negative EI (products A and B) and median particle size lower than feed one for product with high positive EI (product C). Lower demixing with Suramox® may be due to amoxicillin particle size with specific coating process (median particle size : 380 μm), consistent with feed median particle size (390 μm).

**Introduction**

A synergistic effect has been demonstrated when Denagard® (tiamulin) and chlortetracycline (DEN-CTC) are used concurrently in-feed to address the effects of bacterial pneumonia.1 The economic benefit of administering DEN-CTC in-feed has been documented by others.2, 3 The purpose of this study was to evaluate the performance differences in disease control between pigs fed no in-feed antibiotic, OTC (oxytetracycline 440 ppm) or DEN-CTC (38.5 ppm tiamulin; 440 ppm chlortetracycline).

**Materials and Methods**

A total of 1344 weaned pigs (avg. age 21 days) were placed in one of two all-in all-out commercial wean to finish barns. Pigs were fed common diets throughout the nursery phase (D1(weaning)-D39). On day 39, pigs were mixed by gender and allocated to one of three treatment groups (3 x 2 factorial design): no medication, OTC or DEN-CTC. The in-feed antibiotic was fed for 17 days followed by a subsequent 17 days of no medication (total trial D39-D73). Data analysis for average daily gain (ADG) and feed efficiency (F:G) were done using all weight in, all weight out and total feed consumed. Pen averages were used as the experimental unit with 16 pens/treatment.

**Results**

The DEN-CTC group had an ADG advantage over the non-medicated (0.07 kg/day) and the OTC (0.05 kg/day) groups for the entire 34 day trial (p < 0.001;Table 1). This resulted in the DEN-CTC pigs being significantly heavier than the non-medicated (2.59 kg) or OTC pigs (1.77 kg) at the end of the 34 day trial (p < 0.001) period. The DEN-CTC group showed an improved F:G compared to the non-medicated or the OTC group (p < 0.09). This resulted in the DEN-CTC pigs requiring 2.54 kg and 2.81 kg less feed to reach the same end weight as the non-medicated or OTC pigs, respectively. The in-feed antibiotic increases costs by $0.12 USD per head for the OTC pigs and $0.61 USD per head for the DEN-CTC pigs. If one assumes a $140 USD per ton feed cost and a market price of $40 USD per hundred pounds, the DEN-CTC treatment returned $2.67 USD more per head than the OTC treatment. Each Dollar spent on Denagard plus chlortetracycline returned $ 4 USD in improved performance over no medication or oxytetracycline in-feed medication.

**Discussion**

In the investigated production system the impact of Denagard plus chlortetracycline early in the grow finish phase had a significant impact in improving performance during and after the in feed antibiotic application. The improvements in performance translate into improved return on investment for the production system of $4 USD per head over either the non medicated or OTC treatments.

Monitoring of antimicrobial usage for pigs in Denmark

Helle Stege¹ Claes Enoe² Erik Jacobsen² Lis Alban³ Jens P. Nielsen¹
1. KU-Life, Copenhagen, Denmark; 2. Vetinst, Copenhagen, Denmark; 3. VSP, Kjellerup, Denmark

Introduction
The Danish system for monitoring of veterinary drug use, Vetstat, was implemented during 1999 - 2001 (1). Close to 100% of the drugs used in pig herds are provided on prescription, hence, reported to Vetstat from pharmacies. The aim of this presentation was to present the antimicrobial (AM) usage for pigs during 2004-2009.

Materials and Methods
The overall use of AM in Denmark (measured as kilo active compound) was downloaded from the Vetstat homepage. In general pigs account for 80% of the total usage of AM. The number of slaughter pigs produced per year (including export of live growers of 30 kg) was obtained from Danish Statistics. When Vetstat data from 2009 were extracted they only included entries until September so the total use of this year was estimated by extrapolation (table 1). When comparing the AM use between farms and/or veterinarians, the total amount of active compound must be converted to “number of Animal Defined Daily Doses, ADD” (2), according to the products’ potency and concentration and the animal’s weight. The measure used to compare AM usage between farms/ veterinarians is “percentage animals treated per day” which is calculated as: Average number of ADDs used per day divided by the average number of animals present. ADD data on AM usage for pigs were extracted from Vetstat (User page).

Results
Overall AM usage (kg) in Denmark, 2004-2009 is presented in fig. 1 and table 1. Apart from the increase from 2008 to 2009 (t-test; p = 0.02) there has been no significant changes in the average AM usage (g/pig/year) during the years. The most-used-AMs for pigs were tetracyclines, penicillins, sulpha-tmps, macrolides and tiamulines. The main part of the AM was prescribed for per oral administration to growers for gastro-intestinal disorders. Based on ADD calculations, the present national average is 10-12% growers treated per day as opposed to 1.5-2% for breeding stock and 2% for finishers (data from Vetstat, User page, not presented).

Discussion
The overall AM usage is reported from the pharmacies (>95%) by automated transfer to Vetstat, based on their stock managing system. The conversion from actual prescription to amount of active compound is formalized and simple. Hence, these data are very reliable. The AM usage has been stable during 2004-2009 with an average use of 3.5 - 4.0 g AM per produced slaughter pig per year (table 1). Similarly, the usage measured as ADDs or percentage animals treated per day have been reasonably stable during the years. However, ADD data are more prone to errors because of the assumptions and calculations involved.

Fig. 1 Total AM usage (kg) – prescribed by veterinarians

Table 1. Overall use of AM (kg) per year - mean and stddev. Pigs account for 80% of total use. AM use per pig (g/pig/year) is presented. The apparent increase in AM/pig/year was tested (t-test) comparing 2007 with 2009 and 2008 with 2009, respectively.

Assessment of exposure of Draxxin® compared to Draxxin plus iron administered to 3 day old piglets

Steven P. Lesman1 Ian A. Nanjiani2 James R. Allison3 Ann E. Fielder1 Clark D. Smothers1 Scott A. Brown1 Joseph A. Robinson1

Introduction
Although undesirable from a pharmaceutical perspective, and usually off-label in terms of product directions, it is common farm practice in some countries for injectable products to be mixed immediately prior to administration. The advantage of this procedure is that it minimizes the number of injections that have to be given to animals. The downside is that it creates the possibility of interactions that could affect drug safety and/or efficacy, both in the form of pharmacological interactions between the active ingredients and chemical reactions between the formulations. The latter are most likely to affect absorption kinetics from the site of injection and influence drug bioavailability.

Iron injections are commonly given to piglets in the first week of life to counteract the low iron content of the sows’ milk. Draxxin® (Pfizer Animal Health) is an injectable formulation of the antibiotic tulathromycin that is sometimes given to piglets of the same age. There have been reports of producers mixing the products prior to injection. Although Draxxin is considered a long-acting product, the duration of activity derives from the intrinsically long half-life of tulathromycin, which accumulates in lung tissue and establishes therapeutic concentrations that persist for many days. The formulation is an aqueous solution that allows rapid absorption of drug from the site of injection. The greatest pharmaceutical risk, therefore, is of an incompatibility that delays or prevents drug uptake and reduces bioavailability. This study was performed to investigate this possibility. Based on previous pharmacokinetic work, lung concentrations of tulathromycin at 24 hours were used to assess the overall outcome of the drug absorption phase.

Materials and Methods
This two-treatment randomized parallel group study was designed to compare Draxxin (tulathromycin) mixed with iron to Draxxin alone when dosed intramuscularly to 3-day old Landrace/Duroc cross piglets. The doses were Draxxin 2.5 mg/kg bodyweight and 200 mg iron (Ursolfein®)/animal. Sixteen piglets were randomized to each treatment group according to a generalized block design. Blocking was based on litter and pen location. At 24 hr, blood was collected for PK and necropsies performed to harvest lung tissue. The plasma and lung homogenate samples were analyzed for tulathromycin concentrations by an LC-MS/MS procedure.

Results
The concentration data are summarized in the following table:

<table>
<thead>
<tr>
<th>Matrix</th>
<th>Treatment</th>
<th>Least Squares Mean</th>
<th>Lower</th>
<th>Upper</th>
</tr>
</thead>
<tbody>
<tr>
<td>Plasma (ng/mL)</td>

</tr>
<tr>
<td>Lung (ng/g)</td>
<td>T02</td>
<td>3290</td>
<td>3010</td>
<td>3600</td>
</tr>
</tbody>
</table>

Non-inferiority was demonstrated comparing Draxxin with iron (T02) to Draxxin alone (T01). The 95% confidence intervals for the ratios of Draxxin with iron to Draxxin alone were 83 - 106% and 92 - 110% for tulathromycin concentrations in plasma and lung homogenate, respectively.

Discussion
Both plasma and lung tissue concentration data show that T02 (Draxxin administered with iron) was not inferior to T01 (Draxxin alone). This study demonstrated that the mixing of Draxxin with a commonly used commercial injectable iron solution did not adversely affect the lung and plasma tulathromycin concentrations at 24 hours post injection in 3 day old, commercially reared pigs. The study did not specifically address safety, but no adverse events were noted. Unapproved mixing of products is to be discouraged, but this study did not reveal any specific adverse impact.

Reference
Introduction

Florfenicol is a broad spectrum antimicrobial approved for use in swine in most pig producing countries. It is approved for use variably as a premix, drinking water concentrate, and/or injectable formulation. Florfenicol is primarily used in swine for the treatment and prevention of respiratory disease. There is no guidance currently available to swine veterinarians concerning the use of florfenicol sequentially with other antimicrobials. A checkerboard dilution technique was utilized to assess the activity of florfenicol with antimicrobial combinations against 4 bacterial pathogens of swine. The results of this checkerboard evaluation provide the first available guidance to swine veterinarians utilizing florfenicol sequentially with other antimicrobials.

Materials and Methods

Bacterial Isolates:

Four bacterial isolates were used in this pilot project: Streptococcus suis (Ss), Salmonella choleraesuis (Sc), and Bordetella bronchiseptica (Bb). Escherichia coli (Ec) was also included although it is not one of the respiratory pathogens for which florfenicol has been approved. All bacterial isolates were obtained from swine field cases submitted to a diagnostic laboratory.

Antimicrobials Evaluated:

Antimicrobial concentrations were tested with florfenicol as serial dilutions in the ranges indicated in Table 1.

<td>0.5-32 μg/ml</td>
</tr>
<tr>
<td>Tu</td>
<td>tulathromycin</td>
<td>1.0-64 μg/ml</td>
</tr>
</tbody>
</table>

Bacterial Susceptibility:

The minimum inhibitory concentration (MIC) of each antimicrobial tested was determined for each of the four bacterial isolates selected. The checkerboard dilution technique was then utilized to allow calculation of the fractional inhibitory concentration index (FICI) for florfenicol in combination with other antimicrobial agents. The combinations were then categorized based on FICI results as synergistic (S), antagonistic (A), or indifferent (I).

Discussion

1. Most antimicrobials tested in vitro in combination with florfenicol were indifferent in effect.
2. No antagonistic interactions were found between florfenicol and any tested antimicrobial in vitro.
3. Synergistic relationships between florfenicol and OTC and between florfenicol and tulathromycin were detected in vitro.
4. These in vitro results suggest that antimicrobials commonly used in swine medicine would have no anticipated antagonistic effects when used sequentially with florfenicol.

Monitoring of enrofloxacin (Baytril®) sensitivity of clinical field bacterial strains from pigs in the Benelux using E testing

Dominique Gevaert
Bayer SA-NV, Diegem (Machelen), Belgium

Introduction
In veterinary routine diagnostic laboratories antimicrobial sensitivity testing is performed by agar disc diffusion. The E test (AB Biodisk, Solna, Sweden) is a newer technique offering technical and veterinary advantages, because the result is expressed as the minimal inhibitory concentration (MIC, μg/ml) rather than sensitive, intermediate or resistant. For concentration dependent antibiotics such as fluoroquinolones, AUC/MIC and Cmax/MIC ratios have been described as predictive for the clinical outcome and thus valuable indicators in routine veterinary practice (1). Bayer has established with the leading veterinary routine diagnostic laboratories in the Benelux a protocol to use the E test for enrofloxacin (Baytril®, Bayer) on all bacteria isolated from routine samples against which Baytril is registered in swine.

Material and Methods
Between June 2005 and January 2010, the E test for enrofloxacin was carried out routinely on all swine pathogens, isolated by 4 laboratories in the Benelux and falling under the scope of the various marketing authorisations for Baytril in swine. Samples were submitted by practitioners. A bacterial suspension was spread onto Mueller-Hinton plates and the E test for enrofloxacin was put on its surface. Enrofloxacin concentration ranged from 0.002 up to 32 μg/ml. After overnight incubation at 37°C, the MIC was read where the zone of growth inhibition intersected the MIC scale on the strip. The concentration inhibiting growth of at least 90% (MIC90) of the isolates was calculated.

Results
In total 2339 swine pathogens examined. The MIC90 value and respective number of strains is as follows: Actinobacillus pleuropneumoniae: 0.094 (n=413), Bordetella bronchiseptica: 1 (n=103), Escherichia coli: 1 (n=1116), Pasteurella/Mannheimia spp.: 0.032 (n=475), Salmonella spp.: 0.25 (n=232). A total of 87 isolates with MIC exceeding 2 μg/ml were found (3.7%). No relevant differences in sensitivity of strains between the participating laboratories were found.

Discussion
The E test is not often used for routine bacteriology because of the costs of the test. However, routine monitoring of has proven to be feasible under field conditions. It supports swine veterinarians in their treatment schedule: the lower registered dose of 2.5 mg enrofloxacin per kg bodyweight can still be recommended for infections caused by Actinobacillus pleuropneumoniae and Pasteurella/Mannheimia spp.. The registered higher dose of 5 mg enrofloxacin per kg bodyweight is recommended in infections caused by Bordetella bronchiseptica, Escherichia coli and Salmonella. Even after more than 20 years of use of Baytril in the Benelux, the registered bacteria remain highly sensitive to enrofloxacin. However, this may change upon the introduction of several cheap generics, because generics have shown to lead to increase in use and, subsequently, the rise of resistance (2).

**Comparison of the efficacy of a florfenicol (Nuflor®) feed premix with an analogous product in the treatment of Swine Respiratory Disease (SRD)**

Alberto E. Cevidalli1 Ernesto Bongiovanni2 Marco Bosetti3

1. Intervet Schering-Plough Animal Health, Peschiera Borromeo, Italy; 2. Practitioner, Casalbello, Italy; 3. Practitioner, Soncino, Italy

**Introduction**

Florfenicol is a broad spectrum antibiotic of the phenicol group. Previous studies have shown it to be highly efficacious in the treatment of SRD, when administered intramuscularly (1,2,3). The object of this comparative field trial was to evaluate the efficacy of florfenicol administered in feed at a dose rate of 10 mg/kg body weight for five consecutive days in the treatment of SRD under Italian field conditions.

**Materials and Methods**

The trial was carried out on the grower units of two farrow-to-finish herds. If at least 10% of the pigs in a pen exhibited acute respiratory signs, the pen was included in the trial and randomly allocated to one of the following treatments: florfenicol medicated feed 200 ppm (Nuflor premix Intervet Schering-Plough) or a feed containing a combination of two antibiotics (1400 ppm of sulfadimethoxine and 560 ppm of chlortetracycline). Pens were included independently of each other once the inclusion criteria had been met, and the treatment period was 5 days (days 0-4). The experimental unit was the pen and both populations (clinically ill and exposed) were commingled in each pen.

The parameters on which efficacy was assessed included: rectal temperature, dyspnea, depression and Clinical Illness Index Score (CIIS). The animals were observed for 12 days (Day 0 to Day 11). Success rates, i.e. therapeutic success for the ‘ill’ population, and the prevention of illness for the ‘exposed’ population, were recorded on Day 6 and on Day 11.

**Results**

Seven hundred and thirty-three pigs were included in the trial on Day 0: 117 were showing acute respiratory signs and 616 belonged to the exposed population. Altogether, 422 pigs were treated with florfenicol-medicated feed and 311 with the control product.

With the exception of prevention in the exposed animals on Day 6 (when the success rates were equal for both groups), the florfenicol-mediated animals always performed better. With respect to the individual parameters (rectal temperature, dyspnea, depression, CIIS), in general, florfenicol always showed better results, in some particulars with statistical significance.

**Table 1. Cumulative success rates of the two trial sites**

<table>

<td>87</td>
<td>73</td>
</tr>
<tr>
<td>CTC</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**Discussion**

Statistical analysis of the primary end-points (success rates) demonstrated that florfenicol-medicated feed was not inferior to a medicated feed containing high levels of the control product. The analysis of the secondary end-points (clinical parameters) confirms altogether greater efficacy for the florfenicol medication, some of the differences for individual parameters being statistically significant.

In respect of the treatment of ill pigs, the average rectal temperature of the florfenicol-treated group was statistically significantly lower than that of the control group (p<0.05) over the period measured (days 1-5).

Effects on overall production of the treatment of piglets with NUFLOR®PREMIX on a farm with respiratory disease

Manolo Toledo¹ Rut Menjon² Jesus M. Bollo² Marta Jimenez²
1. Piensos Jimenez S.L., Lorca, Murcia, Spain; 2. Intervet Schering Plough, Madrid, Spain

Introduction
The aim of the study was to assess the efficacy of the in-feed treatment of piglets with florfenicol to prevent losses caused by swine respiratory disease, during both treatment and subsequent production phases.

Florfenicol (Nuflor® 40 mg/g Premix for Swine), a new broad-spectrum antimicrobial, is a 3rd generation phenicol, a fluorinated analogue of thiamphenicol obtained by substituting one hydroxyl group with fluorine. A methyl sulfonyl group (CH₃-SO₂) replaces the p-nitro group (NO₂) found in chloramphenicol, thus ruling out the risk of aplastic anemia. This also provides a broader spectrum of activity and prevents the chloramphenicol acetyltransferase (CAT) resistance problems of thiamphenicol and chloramphenicol (2).

Materials and Methods
The trial farm, in a high stock density area of southeast Spain, houses 2,000 sows in three cycles. The farm is positive and unstable for PRRS. Sows are blanket vaccinated four times per year against PRRSv (modified-live vaccine without adjuvant). Replacements are sourced from other units, and all animals entering the farm are vaccinated against PRRSv.

The earliest clinical signs became apparent around the time of weaning. These included an unacceptable percentage of stillborn piglets, a high percentage of runts, non-specific diarrhea, loss of condition, nervous signs, arthritis and an increased mortality rate, all of which failed to respond to treatment with antibiotic (amoxicillin in the drinking water and by injection). PRRS was confirmed by PCR in 1, 2, 3, 4 and 5 week-old animals. Samples from affected piglets revealed florfenicol-sensitive isolates of Streptococcus suis and Haemophilus parasuis.

The existing in-feed antibiotic treatment (100 ppm tiamulin + 80 ppm colistin in feed for 6 weeks after weaning), a previously tested schedule (1), was changed to 80 ppm florfenicol (2 kg/Tm Nuflor® 40 mg/g Premix for Swine) fed over the same period. The results of the two systems were compared, the previous treatment acting as a control for the florfenicol regime.

Results
Nursery phase: Mortality rates fell from 3.7% to 1.8%. The percentage of runts decreased from 7% to 2%, and the uniformity of the batches sent to slaughter improved. No differences were found for Average Daily Gain ADG (294 g/day). The economically important results are shown in Table 1. The number and cost of treatments needed to be given via the drinking water or by injection was reduced (-1.17€).

Fattening phase: The mortality rate from historical farm records was 7%. In the florfenicol-treated group (3600 animals) the mortality rate was reduced by 4.5%. The feed conversion efficiency improved from 2.79 to 2.73, and the ADG increased from 638 to 700 g/day. The economically important results are shown in Table 2.

The total saving for the group treated with Nuflor®40 mg/g Premix for Swine, over the course of the whole production cycle, was 9.37 € per pig.

Discussion
Piglets are susceptible to respiratory and digestive conditions in those production pyramids in which PRRSv has led to immune destabilization. This and severe secondary bacterial complications badly affect production.

This trial demonstrated that the use of a broad-spectrum antibiotic such as Nuflor®40 mg/g Premix for Swine, to which the most important respiratory bacteria are highly sensitive, is an effective solution. Both health and productivity improved throughout the production cycle, resulting in considerable economic benefits.

Usage of homeopathy as treatment for several disorders in pigs in an organic production system

Roberto G. Martinez; Marisol Esquivel; Enedina Silva; Jorge R. Lopez; Mario E. Haro; Roberto Martinez-Rodriguez

Facultad de Medicina Veterinaria y Zootecnia. Universidad nacional Autonoma de Mexico, Mexico, DF, Mexico

Introduction
The necessity of healthy food creates different systems of production; such as the case of organic production. Homeopathy medicine is ideal for this type of production owing to it is a medicine treatment that respects the natural reactions of the organism, and it is considered as a safe therapy par excellence. This is based on "The principle of Similarity", and in order to this principle works it is necessary to have the infinitesimal doses which are: The substances which in considerable doses are able to provoke in healthy individuals clinical manifestations, they are able to eliminate such manifestations in an unhealthy individual if they are prescribed in small doses.

Material and Methods
This research was carried out in a farm localized 100 km northwest Mexico City, in an area which was adapted for the hosting sows in an organic production system. In this area were 15 breeding sows with different farrowing number and once farrow the piglets. All the animal were examined twice a day in order to identified any health problem and be able to implement a specific treatment. The following diagnostics and treatments were carried out:

- Sows underwent a change of management and grouping, with treatment based on Aconitum napellus and Carbo vegetalis 30 centasimal (c), administered twice a day, by 18 days.
- Abscesses in teats, in shoulder and in ham of an adult sow. Treatment Silicea terra 30c (three times per day) and Silicea terra 200c (every three days) from 5 to 20 days.
- Banged sows. Arnica Montana 30c (twice a day) per 18 days.
- Sow with severe burn in one foot. Belladona atropa 30c (twice a day) Cantharis 6x (topic) once a day.
- Obstetrical problems, retention of piglets, yellow vaginal secretion with bad smell and almost non appetite. Caulophyllum 30c, Belladona atropa 30c and Arnica Montana 6c (every 2 hours and decreasing the frequency until twice a day).
- Respiratory disorders in piglets froms 3 to 15 day of age and in one adult sow. Aconitum napellus and Belladona atropa 30c (three times a day per 4 days).
- Suckled piglets from 3 to 20 days, having yellow diarrhea. Arsenicum album 30c (three times a day, form 2 to 3 days).
- Castration injuries, Dye madre de caléndula once a day per 2 days.
- Prevention of anemia ferropriva. Ferrum metalicum 6c (twice a day).

Results
In connection with the banged and under stress sows after the weaning there were a reaction in all of them (15 animals). Talking about the abscess it was a reaction in 2 out of 3 sows (66.6%). The burnt sow treated with Belladona and Cantharis responded favorably. All of the sows with postpartum disorders responded favorably (100%). The combination of Acotinum and Belladona had a response of respiratory disorders in 34 out of 40 piglets (84%). Arsenicum alba had favorable response in suckled piglets with diarrhea, 14 out of 15 piglets (93%). None of the piglets had anemia.

Discussion
The results of this research carried out with the objective, they proved that it is possible to use homeopathy as a treatment of individual disorders in animals in an organic raising system. At the same time it is an alternative to the application of prophylactic treatments in biggest populations of pigs. The implementation of the treatment did not show any problem with management or containment of the animal.

Efficacy of Denagard 20% Injection for Treatment of Polyarthritis in Nursery

Sasiwimon Talummuk; Penchan Chaiyanate; Metta Makhanon
Novartis (Thailand) Limited, Bangkok, Thailand

Introduction
Polyarthritis in suckling pig to nursery pig are very common clinical signs caused by pathogens including Mycoplasma hyorhinis (MHR), Haemophilus parasuis, and Streptococcus suis. These respiratory pathogens are transmitted from sows to piglets by direct contact. Infected piglets can be carriers after weaning (4). Early treatment by injection is the state-of-the-art method for effective control of polyarthritis caused by the listed pathogens. Tiamulin provides pronounced effect for treatment of Mycoplasma and Gram positive bacteria like Streptococcus suis due to MIC studies (2, 3). However, there are many sources of Tiamulin injection in Thailand. The objective of this study is to compare the efficacy of Denagard 20% injection, original Novartis-Sandoz, and the local generic tiamulin injection for treatment of polyarthritis in nursery (1).

Materials and Methods
Farm history: A farrow to fattening farm was affected by serious polyarthritis problems, 20-30% mobility rate and 5-10% mortality rate from suckling piglets to nursery (Fig.1). Preventive program was water treatment with amoxicillin after weaning for 5-7 days. Pigs show minor response.

20 pigs with severe swollen joints and respiratory signs were selected and divided into two groups. Group 1 was treated by Denagard 20% injection and Group 2 was treated by generic tiamulin injection for three days. Nasal swabs were collected from all pigs before onset of treatment to confirm mycoplasma infection. Joint diameter of four legs was measured by vernier clipper before the first tiamulin injection (day 1), the third injection (day 3) and two days after withdrawal of treatment (day 5). pH-value of the two different tiamulin injection products was measured. Nursery signs of pain after injection was observed. Statistical analysis of the joint diameter was done by ANOVA at p<0.05.

Results
MHR was isolated from all nasal swab samples. pH of Denagard 20% injection is 8.5 while the generic tiamulin is 2.2. Some of the pigs receiving tiamulin generic injection showed sign of pain. Comparison of the mean joint diameter is summarized in Table 1.

Discussion
The mean joint diameter of Denagard 20% injection treatment group show a gradual decrease from the first to the last day of evaluation. Significant differences of joint diameter were found from three legs on day 3 and day 5. Interestingly, MHR carriers status can be detected in all pigs from nasal swabs. The acidic pH in generic formulation and kind of active ingredient used in the generic products can influence the performance and efficacy and cause pain in sick nursery pigs at the site of injection. From this study it can be concluded that based on the higher product performance Denagard 20% Injectable application causes significant reduction of swollen joints in nursery pigs suffered from polyarthritis. Its significant efficacy is showed during three to five days after treatment.

Effect of Polyfil™ (8% Phosphorylcholamine and Vitamin B12, A and E) Injection on Blood Composition and Chemistry of Gilts

Chanathip Thammakarn1 Jamlong Mitchaothai2
1. School of Animal Production Technology and Fisheries, Faculty of Agricultural Technology, King Mongkut’s Institute of Technology Ladkrabang, Ladkrabang, Bangkok, Thailand; 2. Department of Clinic for Swine, Faculty of Veterinary Medicine, Mahanakorn University of Technology, Nong Chok, Bangkok, Thailand

Introduction
Supportive treatments to weak or sick pigs with efficient and feasible methods would lead to minimize the low pig production. In principle, phosphorylcholamine (PC) is a phospho-monooester playing important role in membrane biosynthesis (1). Vitamin A, E and B12 are crucial vitamins for the metabolisms of pigs. Hence, this study was performed in order to evaluate the effect of administration of PC, vitamin A, E and B12 (Polyfil™) on blood composition and chemistry of gilts.

Materials and Methods
Eighteen gilts were randomly selected for the present study. All experimental pigs were equally allotted into two groups; the control and the treatment. The pigs in the treatment group have got injection of Polyfil™ (Laboratorios Ovejero, S.A., Spain) 5 ml once a week for 3 times weekly, while the pigs in the control group did not get any administration. Blood samples were collected from all pigs in both experimental groups at before the start of this study and at 3 days after each Polyfil™ injection. All blood samples were analyzed for blood composition (erythrocyte concentration & indices and leukocyte concentration & proportion), thrombocyte concentration and blood chemistry (SGOT, SGPT, BUN, creatinine, calcium, phosphorus and total protein). The statistical analysis is Repeated Measurements.

Results
The results of the present study have been showed in the Table 1. There was no effect of the administration of Polyfil™ on erythrocyte concentration and indices (HB, MCV, MCH and MCHC) and leukocyte concentration and proportion of leukocytes. The injection of Polyfil™ significantly increase (p<0.05) the concentration of blood phosphorus and significantly lower (p<0.05) the level of BUN. However, there was no effect of the Polyfil™ administration on other studied blood chemistry (SGOT, SGPT, Creatinine, Calcium, Total protein).

Discussion
Most of measured valued fell in the normal rages (2). The composition of blood and erythrocyte indices were not affected by administration of Polyfil™, this might be explained that the ingredients in Polyfil™ improve only composition of cell membrane. The increase of phosphorus in blood would be the results of PC containing in Polyfil™, which directly increase in blood stream or more incorporation into blood cells. The lower BUN of gilts in the treatment group indicated lower urea production, which might be the results of more utilization of amino acids. Therefore, the administration of Polyfil™ in gilts increased blood phosphorus and lowers BUN.

Susceptibility of Streptococcus suis strains isolated from diseased pigs in Thai PRRSV positive swine farms to Ceftiofur

Angkana Tantituvanont1 Walaisiri Muangsiri2 Waree Niyomthum1 Thitima Triippat1 Indhira Kramongthong1 Dachrit Nilubol1
1. Faculty of Veterinary Science, Chulalongkorn University, Bangkok, Thailand; 2. Faculty of Pharmaceutical Sciences, Chulalongkorn University, Bangkok, Thailand

Introduction

Ceftiofur, a broad-spectrum cephalosporin is approved for the treatment of swine respiratory disease including Streptococcus suis (S. suis). Although Ceftiofur effectively reduced mortality associated with PRRSV and S. suis1, several field investigations in Thailand have reported varying degree of success when ceftiofur is used to control S. suis infection in PRRSV infected pigs. Unsuccessful control in PRRSV infected herds could be due to increased antimicrobial resistance, decreased pharmacokinetic in PRRSV infected pigs2 and etc. Although the in vitro antimicrobial susceptibility of S. suis has been widely investigated, ceftiofur susceptibility of S. suis isolated from PRRSV positive swine herds has not been reported. The objective of this study was to investigate the Minimum Inhibitory Concentrations (MICs) of ceftiofur against S. suis isolated from Thai PRRSV positive swine farms.

Materials and Methods

10 PRRSV positive swine herds located in the Eastern, Western, Northern and Southern regions of Thailand were recruited into the study. The PRRSV status of All 10 herds was considered PRRSV stable/ inactive, which PRRSV viremic phase and clinical diseases displayed during nursery period. Seroconversion against PRRSV as measured by ELISA (Idexx, USA) was 6 – 8 weeks of age. Necropsy examination was performed monthly for 3 consecutive months on pigs displaying clinical diseases associated with PRRSV and S. suis including respiratory distress, swollen joints and convulsion. Lung, tonsil and joint fluid samples were subjected for S. suis isolation.

Bacterial (S. suis) isolation was performed on sheep blood agar. Suspected colonies were separated by colonial morphology and confirmed by biochemical characteristics including API20 and Polymerase Chain Reaction (PCR). Ceftiofur susceptibility testing was performed using an agar dilution technique according to the standardized method described by Clinical and Laboratory Standard Institute (CLSI)3.

Results

A total of 119 Streptococcus spp. isolates were recovered from 86 diseased pigs. The biochemical characteristics and PCR assay demonstrated that out of 119 Streptococcus spp. isolates, only 17 isolates were S. suis and 2 of 17 were S. suis type 2. MICs values ranged from 0.125 - 256 μg/mL (Table 1). Considered MICs values of Ceftiofur be ≤0.03 μg/mL, most of the S. suis isolates demonstrated a high degree of ceftiofur resistance. A low degree of resistance was found in only 2 herds.

**No. of S. suis isolates**

* S. suis NCTC 10234: Standard Streptococcus suis capsular type 2

Discussion

The results of this study indicated an increased level of ceftiofur resistance of S. suis isolated from Thai PRRSV positive herds especially herds located in high proximity area and high level of antimicrobial usage. Factors associated with increased ceftiofur resistance in PRRSV positive herds should be investigated. In addition, the ceftiofur pharmacokinetics-pharmacodynamics data and its clinical outcomes should be used to justify the optimum therapeutic regimen.

Pharmacokinetics study of medicated feed containing chlortetracycline (Aurofac®) with or without BMD® in concurrent PRRSV and Mycoplasma hyopneumoniae – infected pigs

Dachrit Nilubol1 Indhira Kramongthong1 Thitima Tripipat1 Mark Eastaugh4 Ratchai Leethochawalit1 Angkana Tantituvanont2

Alpharma Pharmaceuticals (Thailand) Ltd., Bangkok, Thailand; 4. Alpharma Animal Health (Beijing) Trading Co, Ltd, Singapore, Singapore

Introduction

Several investigators have reported a synergistic effect for BMD and CTC resulting in decreased resistance of several pathogens (1,2). Our previous studies suggest that the use of CTC in combination with BMD at the day of infection results in the significant reduction of lung lesion associated with Mycoplasma hyopneumoniae induced pneumonia (3). The objective of the study was to investigate the pharmacokinetics of Chlortetracycline when fed in combination with BMD in pigs co-infected with PRRSV and Mycoplasma hyopneumoniae.

Materials and Methods

Ten 3 to 4 week-old PRRSV and Mycoplasma hyopneumoniae negative pigs were randomly assigned with stratification by weight to 2 groups (A and B) of 5 pigs each. Pigs in both groups were challenged with both PRRSV and M. hyopneumoniae at 0 days post infection (DPI). While PRRSV was administered to pigs intranasally, M. hyopneumoniae was given to pigs intratracheally. While group A received medicated feed containing chlortetracycline (Aurofac®, Alpharma Animal Health, Thailand) at dosage 20 mg/kg BW and (BMD®, Alpharma Animal Health, Thailand) at dosage 33 ppm, group B received medicated feed containing only chlortetracycline. All medicated groups received medicated feed from 0 through 14 DPI (14-day total).

The pigs were gruel-fed twice a day at 600 and 1200 hrs. The dosages of CTC and BMD given to the pigs were 20 mg/kg BW per day and 33 ppm per kilogram of feed intake per day, respectively. The total amount of the drugs administered per day was calculated and separated into half to provide the pigs twice a day with gruel feed.

On 3 and 7 DPI, blood was serially collected from the same pigs at 0, 1, 2, 4, 6, 8, 12, 16, and 24 hours post medication (starting at 600 hrs and finishing at 600 hrs next day) into heparinized tubes. Plasma was separated and stored in 80 °C until analysis. All plasma samples were determine the concentration of CTC. The plasma concentrations of CTC were analyzed using a validated high-performance liquid chromatography assay. Plasma concentration data of CTC were subjected to non-compartmental analysis based on statistical moment theory. All pharmacokinetic calculations were performed using linear modeling software (WinNonlin Version 3.2, Pharsight, California, USA).

Results

Pigs administered with the combination of CTC and BMD showed similar plasma drug concentration to pigs administered with CTC alone on 3 and 7 DPI. Although the average plasma CTC concentration of pigs administered with the combination of CTC and BMD was higher than that of pigs administered with CTC alone, the difference was not statistically significant. The average plasma chlortetracycline concentration of infected pigs was similar to that of non-infected pigs. There was no significant difference in Cmax, AUC, t1/2 and 1z between the two treatment groups (p >0.05). No significant differences in pharmacokinetic parameters were observed in pigs administered with either chlortetracycline alone or in combination with BMD (p >0.05) on 3 and 7 DPI. However, longer half-life was observed in the non-infected pigs administered with a mixture of CTC and BMD (26.1 h) compared to CTC alone (17.6 h).

Conclusion

The results showed that administering BMD in combination with chlortetracycline had slightly influence on chlortetracycline absorption. BMD showed to affect the elimination of chlortetracycline in the non-infected pigs, although the half-life values were not significantly different between pigs given CTC alone or in combination with BMD.

Evaluation of the Pulmotil® premix effect on production parameters of sows and their litters in a commercial farm on the sisal zone in Yucatan, Mexico

M Carvajal1 J López1 J Rodriguez2 P Gómez2 C Quijano2 M Quijano2 M Noh3 J Hernández3
1. Elanco® Animal Health, León, GTO, Mexico; 1. Facultad de Medicina Veterinaria y Zootecnia Universidad Autonoma de Yucatan, Mérida, YUC, Mexico; 3. Private practice, Mérida, YUC, Mexico

Introduction
Previous studies have shown that the use of antibiotics in sows during the lactation diets reduces problems associated with infections peripartum and improves reproductive behavior. It reduces the transmission of pathogens of the sows to the piglets improving the health of these (1). This practice increases the survival of piglets and the produced kg per week at weaning and the finishing (2).

The objective of this study was to assess the effect of the use of Pulmotil® (Tilmicosin) in females during the stage of lactation on their litters productive parameters.

Materials and Methods
A study was conducted in a pig farm with 900 sows in the state of Yucatan, México. Animals were positive to diseases related to respiratory and gastro enteric signs. The total of born piglets from six groups of sows was studied. Each group was formed with 40 sows. The groups were divided according to treatment: 3 groups received 300 g of Tilmicosin (Pulmotil®) + 200 g sulfamethoxazole and 50 g of Trimethoprin/ton of food. Other 3 groups received a premix based on 400 g of Oxytetracycline + 200 g of sulfamethoxazole and 50 g of Trimethoprin/ton (Other). Both treatments were managed in the diet a week before birth and during lactation. The piglets were individually identified and compared the weight to the birth, weaning, daily gain, and mortality. Data were analyzed in computing programs: SPSS 15.0 and WinEpiscope 2.0.

Results and Discussion
The average birth weights of piglets from sows of both treatments were compared. There was no significant difference (p=0.144). The mortality rate of piglets of Pulmotil® group and the other group was 2.9 % y 3.4% respectively. Although there is epidemiologic association between the treatment and mortality rate (OR=0.78), there was not significant differences because the confidence interval include the number one (IC=0.49 <OR<1.26).

Effects of dietary supplementation with a blend of essential oils on growth performance of weaned pigs

Tobias Steiner1 Edouard Charlemagne2 Gaëlle Pichard3 Christian Tenier3 Diego Padoan1

Introduction

Essential oils (EO) have been gaining growing attention in livestock feeding in the last few years. They are incorporated in animal feed to improve productivity of livestock through amelioration of feed properties and promotion of the animal’s production performance. The in vitro antimicrobial, antiviral, antifungal and antioxidant activities of EO are well described and backed up by numerous scientific reports (1, 2). In the meanwhile, an increasing number of studies addressing the gastro-intestinal effects of EO under in vivo conditions are available. The intestinal microflora, gut morphology, gastric emptying, activity of endogenous digestive secretions and performance parameters are considered to be influenced by dietary EO (3). In studies with weaned piglets inclusion of the blend of EO investigated herein improved weight gain and feed conversion in comparison with pigs fed negative control diets or diets supplemented with antibiotic growth promoters such as avilamycin, neomycin sulphate and oxytetracycline (4, 5). The present study was carried out to determine the effects of a blend of oregano, anis and citrus EO and fructo-oligosaccharides (Biomin® P.E.P. 125) on performance of weaned piglets.

Materials and Methods

The trial was carried out in two consecutive periods with 168 piglets (Adenia * Pietrain) in total at the experimental station of Primex S.A.S., Languidic, France. Piglets were 42 days old at the beginning of the experiment. In each period piglets were equally assigned to 14 floor pens. There were six piglets in each pen, resulting in 42 piglets per treatment. The treatments were: 1: Control and 2: Supplementation with EO. Piglets in the Control Treatment 1 were fed a starter diet based on wheat, barley and soybean meal. Piglets in Treatment 2 were fed the basal diet supplemented with the phytogenic feed additive Biomin® P.E.P. 125 at a dosage of 125 g/t. Feed and drinking water were provided ad libitum. Individual body weights and pen feed intake were recorded at 42 and 62 days of age. The dataset was subjected to analysis of variance using the software Statgraphics Centurion and an LSD test (α = 5 %). Data was analysed using either pen or pig as experimental unit. The model included effects of period and EO supplementation.

Results

Performance was not affected by period (P>0.05). Initial BW was 12.4 kg and did not differ between treatments (P>0.05). Using pen as experimental unit, average daily gain was 551 and 530 g in Treatment 1 and 2, respectively, and did not differ (P>0.05) between treatments. However, using pig as experimental unit revealed a significant increase in average daily gain (555 vs. 527 g, P<0.05) in pigs fed EO. Feed intake did not differ between treatments (783 vs. 793 g, P>0.05). Furthermore, supplementation with EO improved feed conversion ratio (feed/gain) by 5.2% (1.42 vs. 1.50, P<0.05).

Discussion

Addition of the blend of EO in starter diets for piglets at the age of 42 to 62 days significantly improved growth performance. This data confirms the findings of a study with piglets weaned at 22 days of age, in which the inclusion of the blend of EO investigated herein improved weight gain and feed conversion by 6.2 and 3.5%, respectively, in comparison with a negative control (5). Further studies indicated reduced numbers of intestinal microorganisms, enhanced nutrient digestibility and lower levels of ammonia and biogenic amines in pigs fed the same blend of EO (4, 6). Thus, the mode of action of EO is supposed to be related to a relief from the activity of intestinal microorganisms and related intestinal immune stress (3). In conclusion, EO are regarded as potential performance enhancers in feeding programs for weaned pigs.

Estimating the metabolizable energy (ME) of Albac® in growing and finishing swine diets.

Daniel A. Nelson
Alpharma Animal Health, East Bethel, MN, USA

Introduction
Albac® (bacitracin-zinc, Alpharma, Inc., Bridgewater, NJ) is approved for increased rate of weight gain and improved feed efficiency when fed at 11 to 55 ppm (10 to 50 g/ton). Theoretically, these improvements can be equated to a metabolizable energy (ME) value contributed by the bacitracin.

Materials and Methods
A total of 840 pigs (5 treatments, 8 repetitions/treatment, 21 pigs/pen) were used during the period from approximately 28.0 to 123.0 kg body weight. A 6-phase dietary grow-finish program was utilized. All diets were corn-SBM based and maintained a constant available lysine/calorie ratio. Dietary treatments contained 1.0, 2.0, 3.0, and 4.0 % added fat (Animal/Vegetable Blend). An additional treatment contained 1.0% added fat and 27.5 ppm (25 g/ton) Albac. A standard curve was generated from these increasing levels of dietary fat and a regression line was created using average daily gain (ADG) and gain to feed as the response variables.

Results
Overall ADG, gain to feed and final body weight (BW) increased linearly, and average daily feed intake (ADFI) declined linearly as the level of dietary fat increased in the diets, validating the model used in this experiment to estimate the ME contribution of Albac (Table 1). The cost/kg gain, mortality and removals, carcass backfat and lean yield were not different (P>0.10) as the level of fat increased in the diet. Over the entire experiment, pigs fed the 1.0% added fat + 27.5 ppm Albac diet had a higher ADG, a heavier final BW, and better feed efficiency than pigs fed the 1.0% added fat diet (Table 1). Using overall ADG as the response variable, 27.5 ppm Albac was equivalent to 2.47% added fat or 123.2 kcal ME/kg of complete feed. Using overall gain to feed as the response variable, 27.5 ppm Albac was equivalent to 1.29% added fat or 64.4 kcal ME/kg of complete feed (Figure 1). Nutritionists can assign an ME value for Albac of 257,500 kcal/kg within feed formulation software.

Effect of an *Escherichia coli* phytase supplementation on the digestibility and retention of phosphorus and calcium in growing finishing pigs

Alain Kanora¹ Monita Vereecken¹ Koen De Gussem¹ Cezary Purwin² Krzysztof Lipiński²
1. Huvepharma NV, Antwerp, Belgium; 2. University of Warmia and Mazury, Olsztyn, Poland

**Introduction**

Most commercial diets for fattening pigs are formulated using cereals and oilseed meals, in which the bioavailability of the P is poor, thus requiring additional P supplementation. Phytase enzyme inclusion in pig diets is used to reduce the need for added inorganic phosphorus (P) from feed phosphates and animal byproducts.

In this trial the effect of various doses of an *Escherichia coli* derived phytase (Optiphos®) on the digestibility and retention of phosphorus and calcium was studied in growing-finishing pigs.

**Materials and Methods**

This balance study was carried out with 24 growing pigs with an initial weight of 53 kg, individually housed in metabolic cages to allow quantitative collection of faeces and urine. The four dietary treatments included a positive control (total P 5.1 g/kg; available P 2.5 g/kg and Ca 6.2 g/kg), a negative control (total P 3.6 g/kg, available P 1.0 and Ca 4.2 g/kg) and the negative control diet supplemented with 125 or 250 FTU/kg Optiphos® (confirmed by analysis). The experimental diets were fed for 16 days. The study consisted of a 10 days adaptation period followed by a 6 days period of total collection of faeces and urine. Concentrations of P and Ca were examined in samples of feed, faeces and urine. Experimental results were processed statistically with the use of one-way analysis of variance and Duncan's test.

**Results**

Supplementation of Optiphos® to the NC diet resulted in a significant positive effect on phosphorus digestibility for both supplemented enzyme doses. The P retention reflected the P digestibility in a consistent way. The effects of Optiphos® on Ca digestibility and retention showed similar trends as demonstrated for phosphorus showing significant improvements at 125 FTU/kg or higher.

a,b,c,d: values in a row not sharing a common superscript differ significantly (P ≤ 0.05)

**Discussion**

Dietary supplementation with Optiphos® at concentrations of 125 and 250 FTU/kg improved phosphorus and calcium utilization in growing pigs fed corn-soybean meal diets. Phytase addition increased the total-tract digestibility and the retention of P and Ca.

Efficacy of a thermo-tolerant probiotic, containing Bacillus subtilis spores, in weaned pigs

Spyridon K. Kritas1, Evanthia Petridou2, Georgios Valergakis1, Paschalis Fortomaris1, Elinor McCartney3, Toshihiro Marubashi4
1. Aristotle University of Thessaloniki, Veterinary Faculty, Dept Animal Husbandry, Thessaloniki, Greece;
2. Aristotle University of Thessaloniki, Veterinary Faculty, Dept Microbiology and Infectious Diseases, Thessaloniki, Greece;
3. Pen & Tec Consulting SCP, Barcelona, Spain; 4. Calpis Co., Ltd., Kanagawa, Japan

Introduction and Objectives

Subtherapeutic antimicrobials are customarily used in pigs to improve daily gain and feed utilization (Barton 2000). Despite their beneficial effects, the recent concern on drug residues in food and the potential transfer of antibiotic resistance to human pathogens has directed scientists towards alternative solutions such as probiotics. Probiotics are live cultures of harmless bacteria that equilibrate intestinal microflora to the benefit of the animal (Fuller 1989). Calsporin® is a thermo-tolerant probiotic product based on viable spores of the specifically-selected probiotic strain Bacillus subtilis C-3102. To support EU approval in piglets, the efficacy of Calsporin® was evaluated under typical European conditions in Greece.

Materials and Methods

This trial was conducted in a commercial farrow-to-finish pig farm with a capacity of 400 sows and its own feed-mill. After weaning at the age of 32±2 days, the piglets were transferred in flat decks in pens of 7-11 animals, where they remained until the age of 74 days. To test the efficacy of Calsporin®, 2 trial groups of weaned pigs (32 to 74 days of age) were formed: a control group (T1) fed basal mash feed with no antimicrobials or probiotics, and a T2 Calsporin® group of piglets that received the same feed but supplemented with 3 x 10⁸ cfu Bacillus subtilis C-3102 per kg of feed during flat deck period.

Two sets of experiments were performed, having the pen as the experimental unit: a first summer set (May 2 to August 15, 2008), and a second winter set (December 4, 2008 to March 19, 2009). In order to achieve homogeneity of treatment groups and to avoid cross-contamination, a cross-over, blocked design was used. In the summer set of trials, pigs of weaning batch 1 were equally split in 2 rooms (in 6 out of 12 pens per room), while the same was repeated during next week (weaning batch 2). At the end of weeks 1 and 2, two treatment rooms each of 12 pens were formed with almost the same population composition with regard to initial bodyweight, age, gender, dam parity and litter of origin. The pigs of room 1 were served as T1 (control) group and those of room 2 as T2 (Calsporin) group. This format was repeated with weaning batches 3 and 4 at a later time block, with the exception that room 1 was then designated as T2 Calsporin® and room 2 as T1 Control. The winter set of experiments employing another pair of experimental groups, had exactly the same design as the first set. Thus, at the end of the trial, a total of 908 weaned piglets were used derived from 2 sets of experiments (summer & winter) x 2 experimental groups (rooms) x 24 replicates (pens) of weaned piglets.

</tbody>
</table>

Results and Discussion

Feed and faecal sampling confirmed the presence of Bacillus subtilis C-3102 in T2 feed and faeces at expected concentrations, and the absence of cross-contamination to T1 Controls. There was no significant difference in mortality or feed intake between groups. However, as presented in the Table 1, significant improvement on production parameters (final bodyweight, average daily gain and feed conversion ratio) were recorded after Calsporin® consumption. Thus, compared to T1 Controls, the T2 Calsporin® piglets were 5.9% heavier (P<0.0001), exhibited 9.5% better growth (P<0.0001) and 9.9% improved feed efficiency (P<0.0001) after 42 days on trial.

Although these studies were carried out under commercial farm conditions, cross-contamination of Bacillus subtilis C-3102 between Control and Calsporin® piglets was avoided by careful separation of treatments. A cross-over, blocked study design ensured the validity of the data and the best homogeneity of the groups. Calsporin® produced consistent improvements in zootechnical performance over 8 weanings involving around 1,000 piglets, under both summer and winter production conditions. The results of these studies illustrate the contribution of a stable, in-feed probiotic to efficient pig production without antibiotic growth promoters.

A survey of free and conjugated deoxynivalenol in feed and feedstuffs from Asian and Pacific countries.

Si-Trung Tran; Trevor K. Smith
University of Guelph, Guelph, ON, Canada

Introduction
Deoxynivalenol (DON, vomitoxin), one of the most important mycotoxins produced by many Fusarium species, is found as a common contaminant of crops worldwide. DON can reduce production efficiency and cause serious economic losses to livestock and poultry producers. Recent studies have described the presence of conjugated forms of DON (glycosides and fatty acid). The optimal conditions for conjugated DON hydrolysis with trifluoromethanesulfonic acid (TFMSA) have also been determined. The aim of the current study was, therefore, to investigate the natural occurrence of free and conjugated DON in feed and feedstuffs from Asian and Pacific countries.

Materials and Methods
One hundred forty-nine feed and feedstuffs samples were collected from China, Indonesia, Malaysia, New Zealand, the Philippines, Taiwan, Thailand, and Vietnam in 2009.

The conditions for conjugated DON hydrolysis with TFMSA used for corn were 0.5 N TFMSA, 20 min and 22 °C while the conditions used for wheat were 0.5 N TFMSA, 40 min and 40 °C. Free and conjugated DON in the current study were determined using ELISA kits (AgraQuant® DON test kits, Romer Labs Inc., Union, MO, USA).

Results
Free DON was found in all samples (116 corn, 21 wheat and 12 feed samples). Conjugated DON, however, was not detected in 39 of 149 samples. Levels of DON ranged from 0.05 to 6.70 μg/g in corn, from 0.02 to 0.71 μg/g in wheat and from 0.06 to 0.47 μg/g in feed.

The highest levels of free DON were found in corn samples from China and Indonesia while samples from Malaysia, Thailand and Vietnam were less contaminated. Conjugated DON was found mainly in corn from Indonesia with 12 of 20 samples showing high levels of conjugated DON (27-84 %). Lower levels of conjugated DON (12–33 %) were detected in 14 of 20 corn samples from Malaysia. Conjugated DON was not detected in corn from the Philippines and in the majority of corn samples from New Zealand and Vietnam. Similarly, no conjugated DON was seen in 15 of 21 wheat samples while high levels of conjugated DON (up to 67 %) were found in 9 of 12 feed samples.

Discussion
In the current study, increases in total DON compared to free DON in corn are of the same magnitude as those reported by Liu et al. (2005) for Fusarium head blight-infected wheat or Zhou et al. (2007) for barley. Samples highly contaminated with DON, however, did not necessarily show a high concentration of conjugated DON, in contrast to the findings of Zhou et al. (2008) in barley and malt. Although significant differences between free DON and total DON concentrations were observed, there was considerable variation between regions. The reasons for the differences between regions could be due to climatic conditions or plant genetics.

The current survey of free and conjugated DON in feed and feedstuffs from Asian and Pacific countries emphasizes the potential challenges in understanding the hazard posed by feed and feedstuffs contaminated with DON. Although much research has been carried out since the original discovery of free and conjugated DON, the significance of these mycotoxins for animal health remains to be determined.

Effect of phytase supplementation on the digestibility of phosphorus and calcium in lactating sows

Alain Kanora1 János Tossenberger2 László Babinszky2 Koen De Gussem1 Monita Vereecken1
1. Huvepharma NV, Antwerp, Belgium; 2. Kaposvár University, Department of Animal Nutrition, Kaposvár, Hungary

Introduction

The application of phytase in pig diets has become common practice to improve the bio-availability of phytate P and to reduce phosphorus excretion. The response of phosphorus digestibility to phytase depends on a number of factors, such as dose-rate, animal category and type of diet. In this trial the effect of various doses of an \textit{Escherichia coli} derived phytase (Optiphos®) on the digestibility of phosphorus and calcium was studied in lactating sows.

Materials and Methods

The trial was conducted with 48 crossbred lactating sows (six treatments, 8 sows/treatment). The six dietary treatments included a positive control (total P 6.8 g/kg), a negative control (total P 4.2 g/kg) and the NC diet supplemented with 125, 250, 500 and 1000 FTU/kg Optiphos® (confirmed by analysis). The experimental diets, formulated on a corn-soybean basis, were fed from about 5 days before farrowing until 27 days post-farrowing. Animals were housed individually in pens to allow grab sampling of faeces between days 18 and 22 of lactation. Faecal collection by marker method was performed and chromic oxide was used as a marker to estimate total tract digestibility of P and Ca. The trial data were analyzed with ANOVA (SAS, 2004). In case of any significant treatment effects the differences among the treatments were checked by LSD-test (SAS, 2004).

Results and Discussion

Supplementation of Optiphos® to the diet resulted in significant positive effect on phosphorus digestibility for all supplemented Optiphos® doses. The digestibility of phosphorus improved up to a phytase dose of 250 FTU/ kg. A curvilinear dose response was observed, reaching a plateau at 250 FTU/kg. A similar trend was demonstrated for the effect of Optiphos® on Ca digestibility. (Graph 1 and Table 2)

Graph 1: Faecal digestibility of P and Ca at 18-22 days of lactation after supplementation of different dosages of Optiphos®

The digestibility of P and Ca improved up to a dosage of 250 FTU/kg. Phytase doses in excess of that level were not associated with further improvement of P or Ca digestibility. The poor dose-response relation is very surprising, because in earlier experiments with other phytase enzymes (Jongbloed et al., 2004) in sows clear dose-response effects were seen.

Conclusion

Obviously, the enzyme Optiphos® is very efficient in generating digestible P at a low supplementation level in lactating sows.

Reference

Introduction

At the end of lactation, sows are in a state of negative energy balance (NEB). The metabolic state is the key factor limiting the fertility and embryonic survival. The NEB reduces fertility and reproduction parameters. The inclusion of Lianol® Solapro in the lactation diet improves these parameters.

Material and Methods

Forty Belgian Landrace sows at CRA-W from three groups were distributed between two feeding treatments upon entering the farrowing unit seven days before expected farrowing: control and supplement. The supplement was Lianol® Solapro, a complementary feeding stuff based on fermented potato protein. It was distributed manually as top feeding on the first diet (14.1 MJ of ME/kg, EVAPIG®) at a rate of 10 g/day until three days after farrowing and thereafter it was added to the second diet (14.7 MJ of ME/kg, EVAPIG®) at a rate of 0.1%. The piglets are weaned at 4 weeks of age. Total energy requirement (TER, MJ of ME/d) of sows during lactation was calculated1. Energy balance (EB) was calculated by subtracting the calculated TER from the intakes. The plasma concentrations of IGF-I were determined in the plasma of sows at weaning. Elisa Kit (Mediagnost®) was used after cryo-precipitation of proteins: acid-ethanol method2.

After weaning, sows were managed in the same modalities of breeding until their next farrowing. The sows were scanned pregnant at 4 weeks. At next farrowing, the number of piglets born alive, stillborn and living at day 4 was recorded. Each piglet was weighed at 4 days of age. Data were analyzed by analysis of variance with litter and group as factors. A F-test allows comparing intra-litter variance (Excel®, 2003); intra-litter variance of control and Lianol® corresponds to the residual variance estimated from an analysis of variance with litter and group as factors.

Results

While the EB was more negative (P<0.10), Lianol® sows had higher plasma IGF-I at weaning. It resulted in higher rates of sows keeping pregnancy until birth. Similarly, Lianol® gave better quality embryos that develop in stronger piglets. Indeed, the rate of survival born alive (P<0.10) or at the fourth day (P<0.05) were higher for Lianol® sows. The piglets present at day 4 had grown equally well in both groups, but while there were more survivors, the intra-litter variance of weight was lower (P<0.05); the litters were more homogenous.

Conclusion

Lianol® Solapro is a fermented potato protein which is added to the feed of sows. This study confirms its beneficial effect on several sow fertility parameters and on the quality and survival of the piglets that are born in the subsequent litter.

References

Introduction
Milk is a pivotal factor in piglet survival, growth, development and pre-weaning piglet body composition. The demonstration that heavier weaning piglets attain market weight faster than lighter weaning piglets1 has sparked increasing interest in exploiting the lactation period to enhance overall piglet growth and pork production. The incorporation of Lianol® Solapro in the sow’s diet increases milk production and feed efficiency.

Material and Methods
Forty Belgian Landrace sows at CRA-W from 3 groups were divided into a feeding control group and a Lianol® Solapro group upon entering the farrowing unit (7 days prior to expected farrowing). Distribution was done manually as top feeding on the first diet (14.1 MJ of ME/kg, EVAPIG®, rate of 10 g/day) until 3 days post-farrowing. Thereafter, it was added to the 2nd diet at 0.1% (14.7 MJ of ME/kg, EVAPIG®). Piglets are weaned at 4 weeks of age. Sows were weighed and backfat thickness was ultrasonographically measured on P2-site1 at the beginning and end of trial. Sow weight loss was determined by subtracting uterine weight content2. Piglets were weighed at birth and after 4 and 24 days age. Total energy requirements (TER, MJ of ME/d) of sows during lactation were calculated3. The Energy Balance (EB) was found by subtracting calculated TER from the intakes. Milk production over the 1st 3 weeks was estimated from litter weight gain and litter size4. IGF-I concentrations were determined in the sow plasma when entering the farrowing unit and at 4 and 24 days of lactation. Elisa Kit (Mediagnost®) was used after protein cryo-precipitation: acid-ethanol method5. Data are processed by variance analysis (GLM procedure, Minitab® 15.1.30.0). Included: effects of feeding treatment, of group and corresponding interaction.

Results
Litter size (total born, born alive, at 24 hrs) and the average weight of piglets per litter were similar. While the EB was more negative for Lianol® sows (P=0.07), they did not lose more weight and backfat thickness, weight of litter at weaning, litter ADG and milk production were not lower. Lianol® sows showed optimal feed efficiency. Sow plasma IGF-I was significantly higher (P<0.001) at day 4 of lactation and at weaning.

Conclusion
Lianol® Solapro added to the feed of sows supports milk production and increases litters of lactating sows.

Introduction

Sufficient sow colostrum production and colostrum intake by piglets are vital for the piglet immune status. Due to the increased prolificacy, the average weight of the piglets and their capacity to suckle and stimulate the sow colostrum production has decreased. This results in a diminished colostrum intake and poorer piglet immune status. Lianol® Solapro, a fermented potato protein added to the feed of sows, increases vigor and colostrum intake of piglets and sow colostrum production.

Material and Methods

Forty Belgian Landrace sows at CRA-W from three groups were divided into a feeding control group and a Lianol® Solapro group upon entering the farrowing unit (7 days prior to expected farrowing). Distribution was done manually as top feeding on the first diet (rate of 10 g/day) until 3 days post-farrowing and thereafter it was added to the 2nd diet at a rate of 0.1%. Farrowings, number of piglets born alive and stillborn and feed intakes were monitored. To determine colostrum intake the interval between birth and first sucking was measured, piglets were weighed at birth and 24 hrs later. The total sow colostrum production is found by adding piglet colostrum intakes1. The concentrations of IGF-I were determined in the sow plasma when entering the farrowing unit and at lactation day 4, in plasma of four 4-day old piglets of each litter but also in the colostrum whey (collected at parturition). Centrifugation to 13,000 g gave the whey. Elisa Kit (Mediagnost®) was used after cryo-precipitation of proteins: acid-ethanol method2. Data were processed by analysis of variance (GLM procedure, Minitab® 15.1.30.0). Included: effects of feeding treatment, of group and corresponding interaction.

Results

Litter size (total born, born alive, at 24 hrs) and the average weight of piglets per litter were similar. During the 1st 24 hrs, Lianol® piglets showed a higher weight gain (P<0.05) and had a higher colostrum intake (23%, P<0.05) than control piglets. Colostrum production was significantly higher in Lianol® sows (+20%, P<0.01). They showed a plasma IGF-I concentration which was significantly higher on day 4 of lactation (P<0.001). From entering farrowing to day 4 of lactation, Lianol® sow plasma IGF-I concentrations were significantly higher (P<0.001). IGF-I is known to stimulate lactogenesis3. IGF-I in colostrum was not influenced by treatment. However, Lianol® piglets had significantly higher plasma IGF-I until 4 days of age (P<0.001). Their daily weight gain was 22% higher during the first 4 days of life (P<0.05).

Conclusions

Lianol® Solapro added to the feed of sows increased piglet vigor as well as colostrum intake and colostrum production.

Application of Lianol® Ferti in sows to increase the number of piglets per litter

Jos Schillebeekx1 Rudi Forier2 Alain Kanora3 Koen De Gussem3
1. DAP Schillebeekx, Koersel, Belgium; 2. Ardol BV, Susteren, Netherlands; 3. Huvepharma NV, Antwerp, Belgium

Introduction
Lianol® Ferti is a highly digestible fermented potato protein of which the use results in prometabolic peptides. The fertility effect of the Negative Energy Balance (NEB) can be countered by feeding Lianol® Ferti to sows, increasing peptide levels and enhancing milk production. These effects are mediated by an elevated IGF-1 level in serum, known to increase these parameters. Lianol® Ferti has the proven ability to enhance the heat to shorten the weaning to insemination period and to reduce the number of empty sows. This trial aimed at confirming the influence of Lianol® Ferti administration to sows around weaning on the number of piglets born in the next litter.

Materials and methods
A group of 30 F1 sows (Belgian landrace and French Landrace) on a Belgian breeding farm were equally split in an untreated control group (parity: 3.5) and a Lianol® Ferti group (parity: 3.7) receiving 10 g Lianol® Ferti per sow per day, during 5 consecutive days, starting on Monday before weaning until Friday after weaning (weaning on Thursday). IGF-1 serum levels were measured at the start on Monday and again the next Monday, at insemination. Secondly, the number of piglets born and weaned in the next litter, were registered.

Results
The IGF-1 levels of the untreated control group showed an increase of 4.4 ng/ml, being 8.25%. However, the IGF-1 levels of the group having received 10 g of Lianol® Ferti for 5 days showed a noticeable increase of 14.0 ng/ml, which is an increase of 30.2%.

Secondly, the litter size numbers of the consequent parturition were compared in terms of live born piglets, number of piglets weaned and mortality rate. The untreated group showed 11.36 live born piglets whereas the treated group had 12.02 live born piglets, i.e. an increase of 5.8% or 0.66 piglet more at birth.

When evaluating the number of weaned piglets, the control group had a total of 9.95 piglets, whereas the Lianol® Ferti group produced 10.80 weaned piglets, i.e. an improvement of 8.54% or 0.85 piglet more at weaning.

Moreover, the mortality rate in the Lianol® Ferti group (10.1%) was considerably lower than that of the untreated control group (12.5%).

Discussion and conclusion
IGF-1 influences the ovarian activity by increasing the sensitivity and response of the follicles to FSH and LH. It is also crucial for the survival and nidation of the embryo, but also for its quality. Therefore, the IGF-1 increase at insemination is clearly reflected in the litter size of the parturition following Lianol® Ferti treatment.

The use of 10 g Lianol® Ferti per day per sow during five days in the period around weaning was confirmed to increase the IGF-1 levels and the litter size.

**Effect of phytase supplementation on the digestibility and retention of phosphorus and calcium in weaned piglets**

Alain Kanora¹ János Tossenberger² László Babinszky² Koen De Gussem¹ Monita Vereecken¹

1. Huvepharma NV, Antwerp, Belgium; 2. Kaposvár University, Department of Animal Nutrition, Kaposvár, Hungary

**Introduction**

Phytase enzyme inclusion in pig diets is used to reduce the need for added inorganic phosphorus (P) from feed phosphates and animal byproducts. In this trial the effect of various doses of an *Escherichia coli* derived phytase (Optiphos®) on the digestibility and retention of phosphorus and calcium was studied in weaned piglets.

**Materials and Methods**

A balance study was carried out with 48 piglets (barrows) with an initial weight of 13.5 kg. Animals were housed individually in metabolic crates to allow collection of faeces and urine. The six dietary treatments included a positive control (total P 6.5 g kg⁻¹; Digestible P 3.2 g kg⁻¹, Ca 7.1 g kg⁻¹), a negative control (total P 4.2 g kg⁻¹, Digestible P 1.6 g kg⁻¹, Ca 4.9 g kg⁻¹) and the NC diet supplemented with 125, 250, 500 or 1000 FTU kg⁻¹ Optiphos®.

Experimental diets were formulated on a corn– soybean basis. The study consisted of a 9 days adaptation period followed by a 5 days period of total collection of faeces and urine. At the end of the collection period the faeces and urine samples were melted, homogenized and prepared for laboratory analysis. The calcium and P content of the diets, the dry matter, P and calcium content of the faeces, and the P and calcium content of the urine samples were determined in accordance with the provisions of AOAC (1989). The trial data were analyzed with ANOVA (SAS, 2004).

**Results**

Supplementation of Optiphos® to the NC diet resulted in a significant positive effect on phosphorus digestibility for all the supplemented enzyme doses. The P retention reflected the P digestibility in a consistent way. The effects of Optiphos® on Ca digestibility and retention showed similar trends as demonstrated for phosphorus although significant improvements were noticed at 250 FTU kg⁻¹ and higher. (Table 1 and Graph 1)

**Discussion**

Due to the restricted dietary phosphorus supply, the piglets had a very limited urinary phosphorus excretion (data not shown). As a consequence, the P retention of the piglets showed similar trends to those of phosphorus digestibility. The urinary calcium excretion was higher than the characteristic (physiological) value of weaned pigs (data not shown).

This high urinary Ca excretion (hypercalciuria) indicates, that the digestible phosphorus content of the diets did not cover the requirements of the animals, and consecutively the absorbed Ca could not be retained in the bones due to a lack of phosphorus in the blood.

As a conclusion supplementation of Optiphos® resulted in the improvement of the phosphor and calcium digestibility.

**Graph 1:** Faecal digestibility and Retention of P and Ca
Age dependent changes in relative and absolute size of leukocyte subsets in the porcine peripheral blood

Iwona Markowska-Daniel; Malgorzata Pomorska-Mol
National Veterinary Research Institute, Pulawy, Poland

Introduction
The development of the porcine immune system is not complete at birth. Because of its maturation, the amount of leukocyte (LEU) populations vary during life. According to our best knowledge, up today, there are no data about changes in pigs blood LEU during whole fattening period. Therefore, the aim of the study was to analyze data on the changes of LEU subsets from birth up to about 5 months of age.

Materials and Methods
Study was conducted on healthy pigs (n=118), aged from birth to slaughter. Blood were collected 12 times. Samples were analyzed using hemocytometer and immunophenotyped in order to determine CD3+ (T LYM), CD21+ (B LYM), T LYM subset: CD4+, CD8+ and double positive (DP) - CD4+CD8+. Statistical analyses were performed with Statistica 8.0 (Statsoft, Poland).

Results
The number of LEU and LYM increased with age from 12.38x10⁹/L-1 on the first day to 25.70x10⁹/L-1 at the 5 month of life and from 5.11x10⁹/L-1 to 9.64x10⁹/L-1 respectively (p≤0.05). The percentage (%) of LYM was the highest around 14 days of life. The lowest % of LYM was observed at 84 days of life.

The absolute size of granulocytes (GRA) decreased 1.5-fold just after birth, remained stable until 21 days, and subsequently increased from weaning to 5 months of age. Strong positive correlation (COR) was found between number and % of GRA and the pigs' age. Starting from 70 day of life the % of GRA outnumbered about 1.5-fold the % of LYM. Just after birth the % of CD3+ cells increased over 20% and remained stable until 5 months of age. Positive COR between numbers of CD3+ cells and the age was determined. Apart from a significant increase between 14 and 21 day old piglets (p≤0.05) no age-related changes were observed in the % of CD21+ LYM, but positive COR was found between their numbers and age. The numbers of CD3+ and CD21+ cells increased 2-fold from birth to 140 day of life. Just after birth, significant increase of the % of CD8+ was noted (p≤0.05). The % of CD4+ cells were the highest between 14 and 21 days of ages, but these values did not differ significantly from the neighboring age groups. The numbers of DP cells increased with the age (p≤0.05) and positive COR was observed between their numbers and age. The absolute number of CD3+ cells increased 2-fold from birth to 2 weeks after weaning. After this time only CD4+ subset remained stable up to 5 month of life. The amount of remaining populations gradually increased 1.5- and 2.5-fold from 6 week to 5 month of life, respectively for CD8+ and DP cells. Negative COR was evidenced between age and CD4/CD8 ratio.

Discussion
In pigs, as in different species of animals, the LYM/GRA ratio revealed changes during life. On day first GRA numbers were almost the same as LYM numbers. Over the first 3 weeks of life a predominance of LYM were observed. Starting from 70 day of life GRA outnumbered LYM. Results demonstrated that % of LYM populations does not reflect their actual size and is therefore of limited value. The increase of CD3+ cells numbers were caused by rising amounts of CD8+ and DP cells. The results of our investigation showed that just after birth the numbers of DP cells, containing activated and memory T cells, increased increased almost two-fold. Directly after weaning the numbers of these cells increase again at about 40%. These data are in agreement with previous results, dealing about age-related changes in LEU counts in pigs up to 41 day of life (3). Till weaning the numbers of LYM were lower than in weaners (p≤0.05). From our results it follows that CD4+/CD8+ ratio decreases with age, which is in accordance with other studies (1, 3). The amounts of DP LYM in blood of pigs increase with age (1, 3). The % of DP LYM ranges from 4 to 60% (1). In our study the % of DP cells increased from 6.63% at birth to 17.48% in 20 weeks old pigs, while the absolute number increased almost 5-fold. Age-dependent increase of DP LYM seem to be a result of antigen-dependent maturation of naïve CD4+ Th cells to antigen-specific memory Th cells (1). On the basis of this study we suggested that immunophenotyping of LYM, especially for diagnostic purposes, should base on the absolute size rather than on the % of LYM subsets, according to appropriate age-matched reference values. Additionally, because there are age-related differences in LYM subsets distribution, there is a need to use appropriate age matched control group (as closely as possible) in the experiment with pigs, especially those which include immunophenotyping.

Effect of three different antibiotics on commensal intestinal microflora and on some productive traits of weaning piglets

Paolo Bosi1 Giuseppe Merialdi1 Lia Bardasi1 Salvatore Scandurra1 Mario Vecchi2 Stefano Messori2 Paolo Ferro3 Irma Nisi2 Luisa Casini2 Paolo Trevisi2
1. Istituto Zooprofilattico Sperimentale della Lombardia e dell’Emilia Romagna, Bologna, Italy; 2. Diproval, University of Bologna, Bologna, Italy; 3. Elanco Animal Health, Div. Eli Lilly Italia, Sesto Fiorentino (FI), Italy

Introduction
Weaning constitutes a critical situation in the life of pigs and it is associated with a number of stress factors, such as separation from the sow and abrupt change from milk to solid feed. These factors may affect the gut physiology, the gut microflora and the immune system of weaning piglets, leading to enteric disorders (1). Weaning piglets are frequently treated with antibiotics for diseases control. Antibiotics can have an additional detrimental effect on gut microflora, leading to decrease in lactic flora and increase in potential pathogenic Enterobacteriaceae concentrations. An in vivo experiment was performed to study the effect of three different antibiotics on gut microflora and on some productive parameters and in weaning piglets.

Materials and Methods
Seventy-two newly weaned conventional piglets were received by an experimental unit at 24 days of life. They were randomly assigned to 4 different diets: conventional weaning diet without antibiotics (C), diet T with tilmicosin (Pultotil TM®) supplementation (400 mg/Kg), diet A with amoxicillin (Gammamix®) supplementation (400 mg/Kg) and diet D with doxiciclin (Pulmodox®) supplementation (300 mg/kg). The experiment had an overall duration of 4 weeks. Antibiotics were added to diets for 3 weeks. During the last week all groups were fed with diet C. The body weight and the feed intake of every single pig was recorded weekly. At day 0, 7, 14, 21 a fecal sample was collected from each pig for enumeration of Enterobacteriaceae and lactobacilli. At day 2 a blood sample was collected from each animal for IgM and IgA titration. A fecal score was recorded daily. 12 subjects/diet and 6 subjects/diet were sacrified after 3 and 4 weeks respectively and samples were taken to measure full and empty weight of the small intestine; jejunum content for the bacteria counts villus height and crypt depth on villi.

Results
In the groups with antibiotic diets, average daily gain increased by 34.7 % and by 9.0 %, in the 1st week and in the 3 weeks of treatment respectively. Feed intake was increased by the antibiotics in the 1st week and in the 3 weeks of treatment (+ 19%; + 8.3%). (Table 1). Faecal Enterobacteriaceae counts were changed by the antibiotic treatments, and this effect was linked with diet T (Table 2). Lactobacilli were lower in A.

Total IgM content in blood of all pigs after 21 days was averagely reduced in groups with antibiotic diet (P=0.012) while IgA total contents were not affected (data not shown). No differences were recorded for other parameters (data not shown).

Discussion
The presented results suggest that antibiotics can have a different impact on gut microflora in agreement with previous observations (2). This should be taken in consideration in the choice of the antibiotic in such a critical moment as weaning.

Study of the productive benefits of breeding sows due to the dose increase of a commercial organoaluminosilicate

Juan C. Medina¹ Ernesto Ponce Manzano² David Herrera M.¹
1. NUTEK S.A de C.V., Tehuacan, PUE, Mexico; 2. Asesor Independiente, Tehuacan, PUE, Mexico

Introduction
Mycotoxins are substances produced by the metabolism of growing fungi. They can be present in grains under favorable conditions in the field, storages and transportacion. Animals exposed to mycotoxins, even in low levels develop a wide range of clinical signs such as weight gain reductions, smaller offspring numbers, teratogenic effects and decrease of productivity in all animal species. The aforementioned represents economic losses for the producers. Council for Agricultural Science and Technology (CAST,2003) refers that potential economic cost of crop losses from mycotoxins in the US only, are large with a mean of $ 932 million per year. Mean mitigation costs were estimated to be about $ 466 million and the mean simulated livestock cost were $ 6 millions per year. This study focused on improving productive parameters by using a combination of mycotoxins binders (aluminosilicates (aflatoxins adsorbent) and organoaluminosilicates (zearalenone and mycotoxin adsorbent)). The farm subject of this study did not perform mycotoxins analyses in the past, and the addition of binders was used as a preventative measure. The farm currently adds 2.5 kg/ton of Zeolex Extra more 1 kg/ton of ZEOTEK and use US # 2 quality grains (sorghum or maize).

Objective
To demonstrate that the addition of 0.5 kg/ton of ZEOTEK in the feed of breeding sows improves their productive parameters and afford a positive cost-benefit ratio for the production facilities.

Material and Methods
The company subject of this study has around 4,000 breeding sows. The experiment was made using two groups of 1,800 swine each for four months. The first group was given a diet including 1 kg of ZEOTEK per ton of feed (control group) while the other was given a diet including 1.5 kg of ZEOTEK per ton of feed (experimental group).

Results
Statistically significant results were observed in the average feed consumption between the groups involved in the experiment. The rest of the parameters evaluated only had numerical differences (fertility percentage, piglets per birth, mortality of piglets, average age at weaning, piglet average age at weaning, weaned piglets per sow/year, breeding mortality, etc).

Discussion
The continuous use of binders on preventive doses decreased the effects of mycotoxins presents in the grains used to make feed. Important facts were the sows consumed less feed during nursing (3.4 kg/weaned piglet). The experimental group consumed an average of 9.3 USD less of feed per sow. Thus the addition of higher doses of mycotoxin binders decreased the amount of feed needed to maintain the productive parameters of the farm. These results have been report by many other studies in several species.

**Kafirins effect on ileal digestibility of sorghum protein in growing pigs**

Luis Hernandez2 Gerardo Mariscal1 Tercia C. Reis de Souza3 Juan Becerra1 Hector Jimenez1
1. INIFAP - CENID Fisiologia, Ajuchitlan, QRO, Mexico; 2. FES Cuautitlan - UNAM, Cuautitlan, MEX, Mexico; 3. Universidad Autonoma de Queretaro, Queretaro, QRO, Mexico

**Introduction**

Sorghum is characterized for its low protein digestibility, which is attributed to tannins. However, tannins effect is observed only at high levels (1). Sorghum proteins are classified in: albumins, globulins, prolaminis and glutelins. Among them, kafirins (prolamins) are the most abundant. In low tannin sorghums (<1.0%) the low digestibility of their protein has been associated to the kafirin content (1). In vitro studies report that digestibility of sorghum protein decreases when kafirin proportion increase (2). The objective of this work was to evaluate in vivo the kafirins effect on ileal apparent (IAD) and ileal standardized (ISD) digestibility of sorghum protein in growing pigs.

**Materials and Methods**

A low tannin (<0.5%) sorghum hybrid was produced; half of the plot was over fertilized with nitrogen to increase the kafirins level, in order to get the same hybrid with high and low kafirin content. Four Duroc x Landrace pigs weighing 60 kg were fitted with a “T” cannula at the ileal level. Pigs were placed in metabolic cages and fed twice a day (09:00h and 16:00h), at 2.5 times their Digestible Energy requirement. Experimental diets were fortified sorghum. The experimental period lasted seven days (five days for adaptation and two days for collection). Ileal digesta were collected in plastic bags during 24h and Frozen at -20 C. At the end of the experimental period ileal digesta were freeze-dried and ground. The next analyses were performed in diets and ileal digesta: Dry matter (DM), crude protein (CP), chromium and tannins. Western Blot analyzes, using an anti kafirinas antibody previously produced, were performed on ileal digesta. IAD of CP and DM and ISD were also analyzed (1) using a “cross over” design with the “Mixed” procedure of SAS (3).

**Results**

The CP content was similar, 10.4 and 10.0%, for the high and low kaffirin sorghum respectively. Tannin content was very low in both sorghums (<0.02%). However, the relationship between the fractions 2 (alcohol soluble) and 3 (alcohol plus reducing agent) of Landry-Moureaux was different. The low kafirin sorghum 0.73:1 vs high kafirin sorghum 0.5:1. The DM and CP ileal apparent digestibility, as well as CP standardized ileal digestibility were lower in high- as compared with low kafirin sorghum, 0.811 vs 0.839 (P<0.10), 0.693 vs 0.745 (P<0.05) and , 0.813 vs 0.868 (P<0.05), respectively. These results were supported by western blot analysis.

**Discussion**

The lower digestibility in high kaffirin sorghum is due to the higher content of disulfide links, which negatively affect protein digestibility (4).

Yeast autolysate: microbiological and immunological properties in vitro and effect on piglet performance in vivo

Anja Ganner² Sabine Masching¹ Gerd Schatzmayr²
1. Biomin Holding GmbH, Herzogenburg, Austria; 2. Biomin Research Center, Tulln, Austria

Introduction
Dietary yeast derivatives such as yeast cell walls, beta-glucan fractions, yeast autolysate and yeast nucleotides have been proposed to improve piglet health by preventing infectious diseases, by modulating the immune system and by controlling pathogenic bacteria.

Although various yeast derivatives have been used as feed additives for a long time, their in vitro and in vivo mode of action to improve swine performance is still not well understood.

Target of the present study was to investigate a yeast autolysate in vitro for its chemical composition, for its microbiological binding capacity and immunological properties and in vivo for its effect on piglet health and performance.

Materials and Methods

In vitro
Cell culture studies: As an in vitro model a chicken bone marrow-derived macrophage cell line (HD_11) was used. The nitric oxygen (NO) production was determined as an indicator for immune stimulation. It was determined after 48 h of incubation with yeast products in the supernatant of the cultures using a Griess reagent which provides a colorimetric reaction. Results were compared with the positive control (LPS E. coli 0127; 20 ng/mL +/-10 μMol NO) and calculated as a % of the positive control.

Additionally the yeast autolysate was examined for its capacity to bind E. coli F4 with a quantitative microbiological microplate-based assay by measuring the optical density as growth parameter of adhering bacteria. The growth rate of adhering bacteria correlates with the amount of adhering bacteria bound to the yeast product. Total mannan and glucan were determined by HPLC using an isocratic method and a Refractive Index (RI) Detector. Polysaccharides were hydrolyzed with 72% sulfuric acid; with a subsequent Carrez-precipitation interfering materials were removed. Total protein was determined by Total Kjeldahl Nitrogen (TKN).

In vivo
A feeding trial was conducted to evaluate the efficacy of yeast autolysate on performance and health status of weaning piglets in a 56 days study. 40 mixed sexed piglets weaned after 28 days were divided into 2 experimental groups with 2 replicates: control group A, group B (1kg yeast autolysate product/t feed).

Statistical analyses were performed with t-test, SPSS 18.

Results

In vitro
Nitric oxygen production was enhanced up to 80 % compared to the positive control. Microbiological assay: E. coli F4 adhered with an amount of 1000000 CFU/mg to the yeast autolysate. Mannan content was 17%, glucan content 25% and total protein in dry matter 43%.

In vivo
In the course of the trial a clear positive influence could be observed by the addition of yeast autolysate. Live weight on day 56 (43.13 kg) and daily weight gain (604) were improved in comparison to the control (40.92 kg live weight day 56, P = 0.048; 505 g dwg, P = 0.025). Feed consumption was increased (P ≥ 0.05), FCR (kg/kg) of the trial group was 1.74, from the control 1.71 (P ≥ 0.05).

Discussion
The present study revealed that yeast autolysate is an inducer of nitric oxygen production by macrophages. This stimulation might improve animal health by alerting the immune system and preparing it to respond quickly to infections and to counteract the effects of weakened immunity. Additionally yeast autolysate containing mannan-oligosaccharides have been proposed to lessen the effect of enteropathogenic bacteria such as E. coli F4 by displaying alternative adhesion sites and thus binding such pathogens and moving them throughout the gut without colonization. Therefore enteric diseases can be prevented and piglet health maintained. Pathogen binding and modulation of the immune system, as shown in vitro, might have been reasons for the increase in performance of piglets in the feeding trial.

In vitro and in vivo results indicate that this particular yeast autolysate product is a health and performance improving agent.
**Introduction**

Gram-negative bacteria associated diseases are a present issue in pig health causing economical losses in swine production. Finding a way to protect pigs against overwhelming bacterial growth in the gut and trying to minimize the symptoms is of great importance.

Colistin (Polypeptidantibiotic) is said to be an effective antibiotic against gut infections caused by gram-negative bacteria (E.coli, Salmonella sp.) and in this relation neutralizing endotoxins. Endotoxins are of special interest, as cell wall parts of gram negative bacteria are known to be associated with different disease patterns as MMA and sudden piglet death. Endotoxin associated diseases are very complex in their etiopathology due to different modes of action in inflammation cascades. Therefore it is very important to ensure an overall protection for the animal. On the one hand endotoxin counteracting feed additives should be able to bind toxins and bacteria and on the other hand keep inflammation processes under control and modulate the immune-system.

Aim of this study was to prove the positive effect of a feed formulation containing a yeast-derivate, a clay mineral and a plant extract with anti-inflammatory properties on health status and performance of weaning piglets.

**Materials and Methods**

90 piglets chosen from 15 litters were used for this experiment. A 3 x 3 – trial design was employed, meaning 3 groups with 3 replications each.

The piglets were approx. 4 weeks of age with a mean initial weight of 8.39 kg.

- Group A (control): standard piglet diet without any addition.
- Group B (positive control): standard piglet diet without any addition, but receiving 100 mg Colistin/litre drinking water for 21 days.
- Group C (treated) supplied with 0.2% of the feed additive formulation over the whole trial period.

A 2-phase feeding system was used, where starter diet was fed between days 1 – 14 and grower diet from day 15 until the end of the trial. Feed and water were supplied ad libitum intake.

Clinical observation was done twice a day and all incidences recorded. Weight of each single animal was recorded at the beginning, at days 14, 42 and 56. The amount of feed distributed, feeding frequency and mixing ratio were recorded automatically per pen and day. All animals were supervised by the responsible veterinarian on a regular basis. All data generated out of the trial was subjected to statistical analysis by means of PASW 18.0.

**Results**

On day 56 weight of piglets of group C was improved with a statistical difference of p=0.019 compared to the control group. Daily weight gain (dwg) (days 1 – 56) showed significant differences (p=0.007) between groups A and B and A and C. For feed conversion rate (FCR) and feed intake no statistical differences could be observed, but for group C FCR (1.77) was lower as for group A (1.83) and B (1.88).

In group A one animal died without showing any symptoms. On day 7 single incidences of diarrhea occurred in some pens and lasted for 13 days in changing intensities: group A showed diarrhea for 8 days, group B for 7 days and group C only for 4 days.

**Discussion**

The present study shows that a natural feed additive composed of 3 synergistically acting ingredients can replace a feed antibiotic and results in better total end weight, dwg and FCR as well as reduced diarrhea incidences. Although most of the animals showed signs of diarrhea, the growth performance was within the standards. Results indicate that the additive supported the animals in a critical phase of weaning.

Clays binding toxins, yeast derivates binding bacteria as well as acting anti-inflammatory and plant extracts acting anti and pro-inflammatory might have a synergistic effect in vivo and might have been the mode of action for a better performance in our study.

Effect of dietary crude protein level on villous morphology and diarrhea incidence in weaning pigs

Tercia C. Reis de Souza, María de Jesús Guerrero Carrillo, Araceli Aguilera Barreyro, María Guadalupe Bernal Santos, Konisgmar Escobar García, Gerardo Mariscal Landín

1. Universidad Autónoma de Querétaro, Querétaro, QRO, Mexico; 2. INIFAP, Ajuchitlán - Querétaro, Mexico

Introduction
Post-weaning diarrhea is a problem in nursery pig nutrition and management, mainly after the elimination of in-feed antibiotics (1). The most important nutritional factor for reducing scouring in pigs is to reduce the dietary crude protein (CP) level; because it can reduce the severity and extent of post-weaning diarrhea (2,3). However, if the dietary CP level is too low, it may affect the growth of villi (4,5). The objective of this study was to measure the effect of dietary CP level on villous morphology, and severity of diarrhea during the first 14 days after weaning.

Materials and Methods
Fifty pigs weaned at 20.2±2.0 d of age (initial BW: 6.34±1.09 kg) were allotted to 2 treatment groups based on litter of origin, and BW. There were 5 pigs per pen and 5 pens per treatment. Two antibiotic-free diets were formulated. The HCP diet contained 19.4% CP, and the LCP diet contained 15.8% CP. The severity of diarrhea was based on a daily visual faecal consistency score (FS) on a scale from 0 to 3 (6). At the end of the experiment 5 piglets by treatment were slaughtered by exsanguinations from the jugular vein, and the entire intestinal tract was excised for sample collection. One segment of intestine (5 cm) was removed from the duodenum, middle jejunum, and distal ileum. The intestinal samples were fixed in neutral buffered formaldehyde and embedded in paraffin, sectioned at 5 micron thickness and stained with hematoxylin and eosin (HE). Villous height and width, and crypt depth were measured on the stained sections under microscope. A minimum of 10 straight, intact villi in each intestinal position was measured for each piglet within each treatment. Villous height was measured from the crypt base to villous tip, and villous width at mid-section. All measurements were made in 10 micron increments.

Results and Discussion
There were significant declines of villous height in the jejunum (P<0.001) and ileum (P<0.05) with the reduction of dietary CP (Fig. 1), however villous width and crypt deep were not affected. The intestinal villi increase the exchange area, thus enhancing both digestion and absorption, and they are very important for piglets to absorb nutrients (5). Decreasing dietary CP from 19.4 to 15.8%, villous height of the jejunum and ileum decrease almost 50% in the current study, implying that severe protein deficiency may have reduced villous growth (4,5) and functional development of intestinal epithelium (4). Protein content of the diet had a greater effect on villous morphology in the jejunum than in the duodenum in agreement with other observations (4).

Severity of diarrhea was not affected by the dietary CP level. There was a quadratic effect of the post-weaning day (P<0.0001, R2=0.94) on FS of piglets fed both diets described by the following equation: FS=-0.012+0.399d-0.022d2, where d= post-weaning day (Fig. 2). FS increased during the first nine days and decreased until day 15 post-weaning.

Previous studies have reported that reduced CP diets benefit to the health of piglets by reducing the diarrhea incidence (1,5,6). Nevertheless, our results can’t confirm the above findings. Probably, the reduction of intestinal functional area in piglets fed the LCP, increased the quantity of nutrient not digested and absorbed, which could be substrate for the fermentation by the microbiota, and consequently diarrhea. In conclusion, LCP diet decreased the villous height in jejunum and ileum and doesn’t have a positive effect in diarrhea control.

Effect on the number of stillborn when adding synthetic vitamin E or natural vitamin E to the sow diet

Jesper S. Olesen1 Claes Enoee2
1. Porcus Swinespecialists, Ringe, Denmark; 2. Veterinærinstitutet, Copenhagen, Denmark

Introduction
An ever rising number of total born piglets in modern swine production make both the number of live born rise but unfortunately also the number of stillborn. When a sow herd experiences a period with many stillborn it is often considered to be an infectious agent that causes the problem. This trial suggests that the cause of many stillborn also could be a physiological one. The thesis was that the muscle of the uterus with big litters was fatigued before the farrowing was finished and that the antioxidant effects of vitamin E could positively influence that process. It was shown earlier that different amounts of selenium and vitamin E given during gestation can have effects on the number of stillborn (1). It is also shown that sows given a diet with natural vitamin E (d-alfa-tokoferol-acetate) have a higher concentration of the vitamin E in plasma and milk compared with sows given a diet with synthetic vitamin E (dl-alfa-tokoferol-acetat) (2). Those two studies were background for this trial.

Materials and Methods
The study was a double blinded clinical trial with 2 treatment groups and 1 control group. The treatment groups received 1000 mg vitamin E in minimum 7 days just before farrowing. One treatment group had natural vitamin E and the other treatment group had synthetic vitamin E. The control group received a placebo. In the 3 groups there were a different number of farrowings: in the placebo group 148, in the synthetic group 147, in the natural group 140.

The statistics were done by Claes Enoee in SAS version 9.1.3 in PROC UNIVARIATE and PROC GLIMMIX.

Results
After analyzing the complete dataset the percent of stillborn was 10% in the group that received natural vitamin E and 11.7% in the groups that received synthetic vitamin E and placebo. After the initial descriptive analysis it was clear that the big difference in stillborn within the treatment groups was to be found among the older sows (third parity sows and older).

In the younger sows (first and second parity sows) the difference between placebo and natural vitamin E was not significant (p=0.37). In the older sows the difference between placebo and natural vitamin E was significant (p=0.03). Analyzing the dataset with the older sows alone, the percent of stillborn was 12.4% in the group that received natural vitamin E and 14.8% in the group that received synthetic vitamin E. Among the older parity sows that received placebo the percent of stillborn was 16.7%

See diagram 1.

Discussion
This study showed that in one Danish sow herd adding of 1000 mg natural vitamin E for a minimum of 7 days significantly reduced the number of stillborn in older sows (3 litter sows and older sows). This proves the thesis of the trial that there might also be physiological reasons for high numbers of stillborn not only infectious ones. The number of stillborns was reduced from 16.7% to 12.4% in the older sows.

A UK farm study to evaluate productivity parameters following routine iron injection of outdoor piglets

Richard B. Pearson
George Veterinary Group, Malmesbury, UK

Introduction
The vast majority of indoor units administer supplementary iron to piglets in the first few days of life. This is done to prevent iron deficiency anaemia from occurring, which is characterised by hypochromic/microcytic anaemia. Supplementary iron is usually provided in the form of 200mg of iron as iron dextran delivered by intramuscular injection. In contrast, it is quite rare for outdoor born piglets to receive routine iron, it being widely believed that access to the outdoor environment allows piglets sufficient soil intake to prevent iron deficiency. The aim of this study was to evaluate possible differences in productivity parameters arising from an intervention using routine iron injection of neonatal piglets on a large commercial outdoor unit in Southern England. If differences in productivity parameters were seen then the study was to be extended to include a comparison of haematological parameters between treated and untreated piglets.

Materials and Methods
The unit comprised an 1800 sow outdoor herd which was split into two 900 sow units (Units 1 and 2). Both units had the same management, feed, genetics, average weaning age (26 days) and soil type. Farrowed sows were group managed in paddocks containing 12 uninsulated arcs, with fenders attached. During the summer wallows were established in all farrowing paddocks. Prior to the start of this study iron injection of piglets was not practised. The treatment consisted of 200mg of iron as iron dextran (1ml of Uniferon- Pharmocosmos). In the first instance Unit 1 was allocated to treatment and Unit 2 to control. For a period of 4 weeks (Batch 1) all piglets were treated on Site 1 at ~48 hours old. Thereafter, treatment was switched to Site 2 for a period of 4 weeks with Site 1 acting as control (Batch 2). This format was continued for six batches. A total of 9897 piglets were born alive in litters to be iron treated and, 9365 piglets were untreated. Recorded parameters included number born alive, piglet mortality, number weaned, number ‘rolled over’ (deemed too small and back-fostered) and average weaning weight.

Results
Mean weaning weight was 7.37kg for the iron group and 7.11kg for the control group over the 6 month study. This difference was highly statistically significant. There were no significant differences between the two groups for number weaned per sow, number ‘rolled over’ or piglet mortality. A strong seasonal effect was noted with batches born in the summer showing significantly poorer results for weaning weight and number weaned per sow. The effect of iron treatment on weaning weight was more pronounced in the first three batches of the trial (piglets born February, March and April). In February the difference between the two groups was just under 0.6kg.

Blood parameters for the two groups showed significant differences for haemoglobin, MCH, MCV, PCV and RBC count.

Discussion
The overall results suggest a significant benefit from routine iron injection for weaning weight but no benefit for the other parameters measured. Changes in the behaviour of both sows and piglets are suspected to be responsible for the apparent seasonal effects noted. During colder weather sows and piglets spend longer inside their arcs rather than outside. In warmer weather sows, given the option, spend long periods of time wallowing and hence their skin surface is often covered in adherent soil. When these sows return to suckle their litters, the piglets obviously consume relatively large amounts of soil and their iron intake is therefore higher. The improvement in weaning weight would appear to be mediated through improved blood parameters in iron treated piglets. Improved weaning weight is strongly correlated with post weaning performance and on this unit iron treatment was estimated to provide an ROI in excess of 10:1.

The effect of a dietary supplementation of paylean on nitrogen retention and nitrogen excretion in growing pigs

Ryozo Takada
Niigata University, Faculty of Agriculture, Niigata City, Japan

Introduction
A diet supplemented with Paylean (Ractopamine HCl) for growing-finishing pigs is known to increase growth and the protein contents and to decrease the fat contents of dressed carcasses. We conducted a nitrogen balance test in growing pigs to assess the effect of Paylean supplemented in the diet on nitrogen retention and urinary excretion.

Material and Methods
Ten LWD barrows with a mean weight of about 53 kg were used in the experiment. The pigs were housed individually in cages. During the first week of the experiment, all pigs were given the control diet ad libitum. In the second week, the pigs were allocated to the control group (5 animals), which was continuously fed with the control diet ad libitum, or the Paylean group (5 animals), which was given a diet supplemented 5 ppm of Paylean (Ractopamine HCl) into the control diet. During this period, feed intake was measured daily, while body weight was measured weekly. For the last 3 days of the second week, feces and urine were collected separately. Fecal samples were collected from the rectum every morning, while the entire volume of urine was collected every day. Chromium oxide (0.1%) was added to the test diets to determine nitrogen digestibility with the indicator method.

The control diet, a feed for growing pigs, was composed mainly of corn and soybean meal, with a crude protein (CP) level of 15.5% and a lysine level of 0.92%.

- Urinary nitrogen was calculated by multiplying the urinary nitrogen content determined with an NC coder by the weight of the total urine collected over the 3-day period. Fecal nitrogen was calculated by multiplying the nitrogen intake for the 3-day period by the nitrogen digestibility. Nitrogen retention was calculated using the following equation:

  \[ \text{Nitrogen retention (g)} = \text{Nitrogen intake - (Urinary nitrogen + Fecal nitrogen)} \]

Results and Discussion
In the first week, there were no differences between the control group and the Paylean group. In the second week, however, daily weight gain was significantly higher (p<0.01) in the Paylean group (1103 g/d) compared to the control group (880 g/d). There were no differences in daily feed intake between the 2 groups. Feed efficiency was significantly higher (p<0.05) in the Paylean group compared to the control group.

- No significant differences were noted in nitrogen intake between the 2 groups, but somewhat higher mean value was observed in the Paylean group. Nitrogen retention (g/3 d) was significantly higher (p<0.05) in the Paylean group compared to the control group, and nitrogen retention efficiency (nitrogen retained/nitrogen intake) was more markedly higher in the Paylean group (p<0.01). Although no significant differences were observed in urinary nitrogen excretion (g/3 d), urinary nitrogen excretion (% (Urinary nitrogen/nitrogen intake)) was definitely lower in the Paylean group compared to the control group (p=0.01). There were no significant differences in nitrogen digestibility between the 2 groups.

- The above results revealed that dietary supplementation of Paylean increased the nitrogen retention and decreased urinary excretion in growing pigs.

Introduction

The phytic acid is a component present in defatted corn germ meal (DCGM) (1), a strong chelation agent with activity on polyvalent cations like calcium, iron, zinc, copper and manganese. So the use of phytic acid can be interesting to improve the pig meat, which has high level of iron, a potent cation involved with meat oxidation, where through the chelation of iron, the phytic acid reduces the damages of meat oxidation (2). Therefore this response also affects the availability of some minerals reducing their absorption, increasing the environmental pollution and affecting the animal performance. The low digestibility of phosphorus phytic increases the cost of ration because it is necessary to use inorganic sources of this mineral or to add phytase enzyme. The objective of this study was to evaluate the influence of phytic acid present mainly in DCGM, associated or no with phytase on the performance, mineral excretion, carcass, meat quality and serum parameters of finishing pigs.

Materials and Methods

Thirty six commercial pigs, 16 barrows and 16 gilts, with 60.31 ± 5.32 Kg BW, located on individual pens were distributed to randomized block design, factorial 2 X 2 X 2 (with and without DCGM, with and without phytase, barrows and gilts) establishing four treatments: T1 - diet without DCGM and without the addition of phytase; T2 - diet without DCGM and with phytase (1000 PU); T3 - diet with 40% of DCGM and without phytase; T4 - diet with 40% of DCGM and with phytase (1000 PU). The commercial phytase used is NATUPHOS® 500, at 1000 phytase unit (PU). The rations and water were offered ad libitum, been the rations isoenergetic and isonutrients. Were analyzed the performance parameters (daily weight gain, daily feed intake and food conversion), carcass and meat characteristics and the meat oxidation (Longissimus dorsi muscle) through T-BARS method. Also were evaluated the serum values of calcium, phosphorus and iron. To determine the levels of phosphorus and calcium in the feces, was adopted the technique of partial collection of feces, using as marker the chromic oxide 0.3%. At 87.19 ± 7.08 kg BW, the pigs were slaughtered and submitted to evaluation of carcass traits and meat quality.

Results and Discussion

There was no difference in performance parameters and none negative influence between the factors on carcass characteristics (P>0.05). The results of the fecal levels of phosphorus and calcium are showed on the Table 1.

Different letters within the columns means difference by Duncan Test (P<0.5)

Animals that received the DCGM and that were fed with rations with phytase had a greater fecal excretion of phosphorus and calcium (P <0.05). The last result is according to Simons et al. (4). The serum levels of phosphorus, calcium and iron were similar between the factors, but Gebert et al (5) observed that the pigs that received diets with phytase (1000PU) presented an increased of serum concentration of iron and phosphorus. There were no effects of the treatments on the meat quality, but to the meat oxidation the ration with DCGM (with greater level of phytic acid) shows a lower lipid oxidation than the diet without DCGM (0.16 versus 0.21 mg/kg T-BARS). There results were similar to Harbach et al. (2) findings. The phytase didn’t affect the oxidation of the L dorsi muscle.

**Using enzymatic complex in feed containing defatted corn germ meal for pigs during growth and finishing**

Sylvia L. Vinokurovas; Caio A. Silva; Ana M. Bridi; Arturo P. Lozano; Marina A. Tarsitano; Roberta A. Silva; Danyel B. Dalto

*Universidade Estadual de Londrina, Londrina, PR, Brazil*

**Introduction**

In the Brazilian swine culture, the largest part of production costs is from food, basically constituted by corn and soybean meal. In this scenario, the search for alternative ingredients, associated to enzymatic complexes, is a very common procedure nowadays. Defatted corn germ meal (DCGM) is a co-product from the corn oil extraction, presenting several nutritional attractions and significant availability. Nutritionally, it has been indicated in the feed of pigs as an alternative product (1). However, there are restrictions on the high inclusions of DCGM due to the high levels of fiber and low energy in its composition. The correction of these aspects might increase the cost of the feed. A solution is to reduce the negative effects caused by the excess fiber with the addition of enzymatic complex. Then, the objective of this paper is to study the effects of including 20% DCGM and an enzymatic complex for pigs’ performance, carcass characteristics and meat quality.

**Materials and Methods**

A total of 50 pigs (PIC) were used, 25 castrated male and 25 female, with initial average weight of 41.14 kg, kept in two animals per pen. The test was conducted during 83 days, been evaluated the performance, carcass characteristics, meat quality and the cost of the treatments. The experimental design was in random blocks, with 5 treatments and 5 repetitions/treatment, being each pen considered an experimental unit. Feed named control was formulated based on corn and soybean meal and the remaining ones were made of corn, soybean meal and 20% DCGM. Two diets containing DCGM received a commercial enzymatic complex (Allzyme® SSF) on the dose of 0.02%, being that in one of the diets the matrix of the enzymatic complex was considered in the formulation. In the other, the complex was added on top, that is, out of the formulation. Then it was defined 5 treatments: T1- control feed (corn + soybean meal); T2- feed with 20% DCGM; T3- feed with 20% DCGM + EC; T4- feed with 20% DCGM without EC reformulated (discounting the nutritional matrix of the enzymatic complex); T5- feed with 20% DCGM + EC (in its additive form – on top).

**Results and Discussion**

Results for zootechnical performance are presented in Table 1.

**Table 1 - Means of daily weight gain (DWG), daily feed consumption (DFC) and feed conversion (FC) for pigs submitted to feed with and without the inclusion of enzymatic complex**

Duncan test (P<0.05)

Significant difference was verified for DWG with advantages for T5 and worst results for T4. For FC, the worst result was verified in T4 (P<0.05) For the parameters related to carcass characteristics, no significant differences (P>0.05) were observed among the treatments. The highest final pH values for meat were observed for T1, but influences from this parameter could not be verified (in any of the treatments) on the quality of the meat. According to the conditions of this experiment and the prices for the ingredients, that the best economic and average cost indexes were those obtained for the treatment with DCGM with the inclusion of the enzymatic complex in diets based on soybean and corn in pigs in finishing phase. (2) have observed that the addition of the complex has possibly affected positively the DFC and FC, indicating greater efficiency through the usage of complex in feed, resulting in lower feed cost. The addition of enzymatic complex in diets with 20% DCGM for pigs in growth and termination phases has improved the mean weight gain, without affecting the characteristics of meat quality, as well as presenting better economic efficiency.

Interactive effect of Ractopamine and dietary energy density on performance and characteristics traits of pigs selected for fast weight gain

Vinícius S. Cantarelli2 Nikolas O. Amaral2 Fernando M. Toledano1 Thiago H. Kuribayashi2 Tarciso C. Villela2 Elias T. Fialho2

1. Ouro Fino Saúde Animal, Cravinhos, SP, Brazil; 2. Universidade Federal de Lavras, Lavras, Brazil

Introduction

Progeny of Large White sire line evaluated in this work differentiate themselves in the market through high intake capacity, result of long of time of selection for feed intake capacity and speed of growth. In the initial period of growing, the high capacity of consumption provides speed up weight profit, however, in the final phase of finishing this can result in excess of fat in the carcass. Thus, supplementation of ractopamine (RAC) in the diet has been an alternative to reduce the feed in this phase and increase the yield of carcass meat (2). However, more studies should be conducted to determine the best nutritional program supplementation with RAC for these animals, especially with regard to energy consumption. Due to changes in genetics and management practices within the swine industry, this study was conducted to evaluate the performance and carcass traits of finishing barrows and gilts, from crossbred sows x Large White terminal sires, receiving diets with different metabolizable energy levels and supplemented with RAC.

Material and Methods

Animal care and experimental protocols were approved by the University of Lavras Interdepartmental Animal Care and Use Committee before initiation of this experiment. The experiment was conducted at the pig farm of the Department of Animal Science, Federal University of Lavras (UFLA), Lavras, MG, Brazil. A total of 88 crossbred pigs (from crossbred sows x Large White boars), 48 barrows and 40 gilts (initially 75 ± 6.5 Kg) were used. The experimental design was randomized blocks with time the treatments (8) were arranged as a 2x4 factorial (two sexes - barrows and gilts - and four levels of metabolizable energy (ME) - 3000, 3150, 3300 and 3450 Kcal / kg) with 6 replicates for barrows and 5 for gilts. There were 2 pigs per pen. All diets (corn-soybean meal) met or exceeded NRC (1998) requirements, were supplemented with 10 ppm of RAC during the 28-d feeding trial. The data were subjected to ANOVA was generated using the GLM procedure (SAS Inst. Inc., Cary, NC). Least squares means were generated and separated using the LSD procedures when there was a significant (P 0.05) F-test for a main effect or interaction.

Results

The feed conversion (FC) decreased linearly with increased energy density of diet for barrows and gilts. There was no significant interaction between energy level and sex. The other performance variables such as ADG and ADFI as well as carcass traits were not affected (P> 0.05) by levels of energy in the diets used in this study. In relation to sex, gilts shown lower final weight (1.83%), lower average daily gain (6.55%), lower average daily feed intake (13.73%), better feed conversion (6.29%), lower backfat thickness (26.62%), larger longissimus muscle (9.40%) and higher meat yield (4.25%) all those significant by (P<0.05).

Discussion

The increase in energy density in the finishing phase makes the voluntary intake of animals reduced, thus resulting in improved feed conversion. However, as observed in other studies (1, 3), increasing the energy level of diets supplemented with RAC improved feed conversion of barrows and gilts without affecting feed intake. In relation to sex, the result shown that the efficiency of gilts to deposit lean tissue in the carcass should be due to the influence of hormonal activity, that increase basal metabolism and lowered the feed intake capacity. Results of this study indicate that including ractopamine (10 ppm) with higher ME levels in the diets could lower FC in both barrows and gilts in the finishing phase. However the inclusion of RAC with higher energy concentration in the late-finishing diet did not affect the others variables of growth performance as well as the carcass.

Performance and carcass traits of pigs selected for feed efficiency fed diets containing Ractopamine with different energy density

Nikolas O. Amaral1 Vinicius S. Cantarelli2 Fernando M. Toledano1 Tarciso C. Villela2 Thiago H. Kuribayashi2 Elias T. Fialho2
1. Ouro Fino Saúde Animal, Cravinhos, SP, Brazil; 2. Universidade Federal de Lavras, Lavras, Brazil

Introduction
Soft pork fat has become an economical concern of the Brazilian pork industry. Accordingly, progeny of Pietrain sire line evaluated in this work is characterized by the excellent resulting in conformation and lean meat content in the carcass, result of the intense selection auto-restriction of feed. Moreover, including Ractopamine (RAC) in swine finishing diets produces more muscular carcasses as well improve feed conversion including those with restrictive feeding regimes (1). It is well known, however, that the differences in feed intake and efficiency of protein deposition between barrows and gilts resultant of crosses between different strains, especially with regard to energy consumption can result in different responses of these finishing pigs to RAC supplementation in the diet. The objective of this work was to evaluate the performance and carcass traits of finishing barrows and gilts, from crossbred sows x Pietrain sires, receiving diets with different metabolizable energy levels and supplemented with RAC.

Materials and Methods
Animal care and experimental protocols were approved by the University of Lavras Interdepartmental Animal Care and Use Committee before initiation of this experiment. The experiment was conducted at the pig farm of the Department of Animal Science, Federal University of Lavras (UFLA), Lavras, MG, Brazil. A total of 88 crossbred pigs (crossbred sows x Pietrain terminal sires), 48 barrows and 40 gilts (initially 75 ± 5.5 kg) were used. The experimental design was randomized blocks with time the treatments (8) were arranged as a 2x4 factorial (two sex – barrows and gilts) and four levels of metabolizable energy –ME (3000, 3150, 3300 and 3450 Kcal ME / kg) with 6 replicates for barrows and 5 for gilts. There were 2 pigs per pen. All diets (corn-soybean meal) met or exceeded NRC (1998) requirements, were supplemented with 10 ppm of RAC during the 28-d feeding trial. The data were analyzed by ANOVA by using the GLM procedure (SAS Inst. Inc., Cary, NC), with the main affects of level ME and sex as well the Energy x sex interaction, included in the statistical model. Least squares means were generated and separated using the LSD procedures when there was a significant (P <0.05) F-test for a main effect or interaction.

Results
The data shown a significant interaction (P<0.05) between sex and ME on feed conversion (FC). For barrows, the FC decreased linearly with increased ME of diet. However, we found non-significant difference (P>0.05) of energy levels on the others performance and carcass traits variables. In relation to sex, gilts shown lower final weight (1.63%), lower average daily gain (5.26%), lower average daily feed intake (15.82%), better feed conversion (10.2%), less backfat thickness (17.79%) and higher meat yield (3.27%) all those signfi cant by (P<0.05).

Discussion
According to (3), regardless of supplementation with RAC, Increasing the energy density of swine diets has been shown to have no affect on feed intake, resulting in improvements in feed efficiency F:G. However, in the present experiment this effect was only observed for barrows. A possible explanation for this result would be a physical limitation of intake capacity of gilts as a observed by the smaller numerical variation in feed consumption as a function of energy density. The greater efficiency in lean deposition and lower voluntary feed consumption of gilts should be explaining the other results (2). It is therefore suggested that supplementation of diets with RAC (10 ppm) with higher ME levels could lower FC in the finishing barrows. However the inclusion of RAC (10 ppm or 10 mg/Kg) with higher energy concentration in the late-finishing diet did not affect the others variables of growth performance as well as carcass traits of barrows therefore gilts shown better carcass traits in finishing phase.

Assessment of body condition and body composition during the transition period between confinement and organic production system in pregnant sows in Mexico

Ernesto Hurtado-Guerrero; Marco A. Herradora-Lozano; Roberto A. Martínez-Gamba
Departamento de Producción Animal: Cerdos de la Facultad de Medicina Veterinaria y Zootecnia de la Universidad Nacional Autónoma de México, México, DF, Mexico

Introduction
To date only few farms are using organic pig production in Mexico. One of the main challenges facing producers during the process of conversion to organic is the transition period, in which a decreased productivity is perceived in relation to the production parameters obtained before the process. The major obstacle comes from the difficulty to fulfill all the regulations needed to obtain the organic certification, like feeding and management. The sows body condition and composition, can explain why the productive performance of the sows are affected during the transition period between a confinement system to a free range with alternative feeding system. The objective of this study was to evaluate the body condition and composition of gestating breeding sows during the transition period of tie used to implement a organic production system in a pig farm from the centre of Mexico. The production conditions including the feeding and management systems were also monitored, to find out how this change in procedures affects the sows.

Material and Methods
Fifteen York-Landrace sows with different parity were allocated into 3 groups with different treatments; organic management – alternative feeding (O-A), organic management- conventional feeding (O-C), and conventional management – conventional feeding (C-C). Two types of isoenergetic and isoproteic diets were used, one was “conventional” with sorghum and soy cake, and the other “alternative” based on lentil sprouts and banana-potato silage. The organic management was carried out in accordance with the established by KRAV. All sows were weighed, the back fat (BF) measured, and the body condition (BC) registered in four different times, at the beginning of the study (m1), at the second third of pregnancy (m2), at the third (m3), and on 112 (m4). Two equations were employed to calculate the body fat (BoF) and the protean mass (PM). The data analysis was carried by means of orthogonal contrasts, and for the body condition a non-parametric test Kruskal-Wallis test was used.

Results
As for weigh and BF no differences were found throughout pregnancy (p > 0.05); however, the total weight gain showed some differences (p=0.001) in contrast “management effect” (O-C, O-A vs. C-C), with O-C (26.15±19.3 kg), O-A (10.62±14.7 kg) and C-C (48.5±11.9 kg). The BF measurements did not showed differences between groups (p > 0.05), until m4 in which the contrast “feed effect” (O-A vs. O-C) (p=0.035) obtained for C-C (21.16±1.69mm) was higher in comparison to O-C (20.7±2.2mm) and O-A (18±2.12 mm). The body composition (BoF, PM, the relationship between them and maternal gain MG), did not show differences (p>0.05); however, maternal fat gain showed differences for both contrasts (p<0.05) with O-C (9.8±5.7 kg), O-A (1.55±6.24 kg) and C-C (17.27±1.7 kg).

Discussion
Sows maintained with organic management showed less weight gain, from which a considerable portion was BoF. Despite the diets were formulated according to the established requirements of NRC 1998, they were not sufficient to satisfy the energetic demands of the animals, principally at the end of pregnancy, period of greatest nutrient demand of the products owing to their fast growth. Therefore, it can be concluded that it is possible to maintain an adequate body condition and composition with an alternative diet during the transition period to organic, as long as the feed’s energetic contribution is increased but not the protein, in such a way that these can be adjusted to the activity and thermoneutrality in this system.

Effect of two different feed phosphates on the content of phosphorus and calcium in blood and bones of finishing pigs

Zbigniew Dobrzański¹ Roman Kołacz¹ Daniel Korniewicz²

1. Wrocław University of Environmental and Life Sciences, Wrocław, Poland; 2. LNB POLAND Ltd, Kiszkowo, Poland

Introduction
Phosphorus (P), except calcium (Ca), is the most important component of an organism. Pigs body contains about 0.45 % of phosphorus, and 80% of that amount is present in bones, considerable concentration is in blood (6).

Mono- (MCP) and dicalcium phosphates (DCP) are the most often used in pigs feeding, but phosphorus digestibility is very differentiated, e.g. 51-80 %. (5). Very important, except P, is calcium content in feed (1, 3).

The aim of the present study was to determine an influence of two different feed phosphates (MCP and DCP) on P and Ca content in blood serum and thigh bones of finishing pigs.

Materials and Methods
The material were 40 piglets (sow – Large Polish White x Polish Landrace) x boar (hampshire x pietrain) The fattening lasted 85 days, i.e. to the body mass of about 110 kg. Group I was given MCP (Ca(H₂PO₄)₂, Finnish product) while group II – DCP (CaH₂PO₄x2H₂O, Polish product). The contribution of particular feed phosphates resulted from the optimization of P content in feed mixtures. It was assumed that mineral phosphorus makes up 30% of the demand for an overall phosphorus. The nutritional value of starter, grower and finisher mixtures, with mineral components was similar in I and II group (3).

Blood for analysis was collected at 85th day of pigs life from the zygomatic vein. When determining the level of inorganic phosphorus, the UV-VIS method was used, and while determining calcium level – photometric method was applied.

Thigh bones were collected after the slaughter. Ring shaped samples of a thickness of 3 mm were collected from each bone. Double weighted amount, of a mass of 0.5 – 0.6 g each, were prepared. Samples subjected to analysis were mineralized using a microwave furnace. Determination of P and Ca content was conducted using atomic emission spectrometry (ICP – OES). The results were worked out statistically (Duncan’s test).

Results and Discussion
The feed phosphates used differed considerably as regards their physico-chemical features (2), but the level of P (and Ca as well) was similar in pigs diet (3). Phosphorus level in blood serum of pigs was similar in both groups (about 2.5 mmol/l), what was also observed in the case of calcium (about 3.1 mmol/l) (Table 1). The values were close to an upper limit of reference values (8).

In the case of a bit lighter pigs (85 kg) the considerably higher values of P were obtained (over 4 mmol/l), but similar ones of Ca (7). Statistically higher (p<0.05) content of P (142,2) and Ca (261,2 g/kg) was in thigh bones in II group (DCP) as compared to group I (MCP). Another data in this range may be found in the literature (1,4), that proves numerous factors influencing P accumulation in pigs bones.

Table 1. The content of P and Ca in pigs blood serum (n=12) and thigh bones (n=10) (x ± SD)

<table>
<thead>
<tr>

</tr>
<tr>
<td>P</td>
<td>3.03 ± 0.14</td>
<td>3.09 ± 0.38</td>
</tr>
</tbody>
</table>

Generally it should be stated that the two different phosphates used in the experiment did not significantly influence the differentiation of P and Ca of blood of pigs, while the highest concentrations P and Ca in thigh bones of pigs that were given DCP may prove the better bioavailability of those building elements in pigs, that is of a special significance in the fast-growing animals.

Decreasing pork’s carbon footprint: greenhouse gas emissions savings from feeding ractopamine (Paylean®) to the US swine herd

Garth Boyd1 David B. Anderson2 Allen L. Sutton3 Casey V. Hogan1 Marks-Callahan Amy4
1. Camco, Broomfield, CO, USA; 2. Elanco Animal Health, retired, Loveland, USA; 3. Purdue University Department of Animal Sciences, West Lafayette, IN, USA; 4. Elanco Animal Health, Greenfield, USA

Introduction
In response to global concern about climate change, there is pressure on the pork industry from the retail sector to measure, and over time, reduce the carbon intensity of pork. The National Pork Board is currently assessing the carbon footprint of US produced pork. Ractopamine (RAC; Paylean®) is a feed ingredient that when fed the last 28 days to finishing pigs results in enhanced feed efficiency, increased growth rate, and increased leanness(1). These benefits impact pork production by decreasing feed utilization, days to market and by reducing the population of pigs needed to supply the same quantity of protein produced from non-RAC-fed pigs. The purpose of this study was to quantify the cradle-to-gate GHG emissions savings resulting from the theoretical feeding of RAC to the 109.2 million head of pigs harvested in the US in 2008.

Materials and Methods
Using 2008 U.S. pork production statistics, the environmental benefits associated with the production efficiency of RAC were quantified and assumed implementation of RAC in all finishing pig diets in the U.S. at 5 or 10 mg/kg diet(2). The derived benefit of the increased leanness per pig resulted in fewer animals needed to produce the same amount of pork protein. In addition, pigs experienced greater feed efficiency as a result of RAC, and reach their market weight sooner for harvest(2). The model used to assess GHG emissions savings followed the same methodology as a ‘cradle-to-gate’ Life Cycle Assessment and included all upstream and on-farm GHG emission savings.

Results and Discussion
The leanness response of 109.2 million head of finishing pigs being fed 5 or 10 mg/kg RAC resulted in the same amount of pork protein being produced in 2008 with 5.8 and 6.9 million fewer finishing pigs and 310,000 and 369,000 fewer sows, respectively. The RAC-fed pigs reached market weight in 3.00 or 2.76 fewer days for the 5 or 10 mg/kg dose respectively.

The reduced population of sows and finishing pigs, improved feed efficiency, and reduced number of days to market, resulted in GHG savings measured on a CO2-equivalent basis for the three major categories of production activity changes shown in Table 1.

The avoidance of methane emissions from manure was over 60% of the overall GHG emissions savings for both the 5 and 10 mg/kg dose of RAC (due to its 25 times higher global warming potential compared to CO2). Over 30% of the GHG savings associated with both doses resulted from decreased upstream emissions resulting from reduced feed needed. The avoided emissions from pig housing energy demands was the third most substantial contributor to the over GHG savings for both doses with approximately 4% of the total savings. Overall, this is a very conservative estimate of the GHG emissions savings because none of the downstream GHG emissions savings were included such as post farm transport and processing of pigs. The carbon footprint of the manufacturing and distribution of Paylean to the entire pig population resulted in a fraction of GHG emissions attributable to pork production.

A comparative study on route and number of times of iron administration in piglets on hematological values

Pariwat Poolperm; Prapha Songjinda; Piyapol Tiangladawong; Peerapat Krittanan; Patthanan Paprakorb; Wimwiga Sakchainanon; Yaowaluk Panavajkitkul; Apichart Subsiribhaiboon
Kasetsart University, Nakornpathom, Thailand

Introduction
Piglets are most likely to develop anemia after birth since the iron requirement for red blood cell production is about 7-10 mg/day while there is insufficient amount of iron at 1 mg/day available in sow milk (1). Therefore, the supplementation of iron to piglets at a few days of age is of importance for anemia prevention. The iron supplementation can be given by oral or parenteral route, and its effectiveness was varied. Two doses of intramuscular injection showed higher hematocrit and hemoglobin than two doses of oral administration and one dose of injection (2). The larger dosage of iron intramuscular injection promoting haemoglobin formation was also confirmed (3). In the other hand, Miller, et al (4) showed that oral administration gave significantly higher hematocrit than intramuscular injection.

The aim of this study was to investigate the effect of iron administration methods (oral versus intramuscular route) and number of times of iron supplementation (1 time versus 2 times dosage) on hematological values of piglets. Hematocrit (Hct), haemoglobin concentration (Hb) and erythrocyte count (RBC) were determined.

Materials and Methods
In this study, new born piglets (n=45) were randomly assigned into 5 groups. Each group was given iron supplementation as follows: control group received no iron supplementation (C, n=5); piglets intramuscularly injected with iron dextran (AbideX®) 200 mg on day 4 (IM1, n=10), on day 4 and 18 after birth (IM2, n=10); piglets given 200 mg ferrous sulfate (Ferrous Booster®) orally on day 4 (OR1, n=10), on day 4 and 18 after birth (OR2, n=10).

Blood from the piglets were collected weekly in EDTA, as anti-coagulant, for the period of 4 weeks. The blood samples were then examined for hematological indices including hematocrit, haemoglobin concentration and RBC count using Automated hematology analyzer (Abacus Junior Vet, Austria). The results were statistically analyzed by repeated measures analysis of variance.

Results
The hematological values of all the treatment groups were significantly different from that of the C group (P<0.05), except the RBC count of OR2 group. Meanwhile, Hct and Hb were similar for all treatment groups. Compared within route of iron administration, one-time and two-times administration had the same hematological values.

a,b,c = significant difference within column (p < 0.05)

Discussion
The results from this study indicated that iron supplementation to piglets was benefit to piglet health on haematological values regardless of routes or number of times that piglets received iron supplementation. Oral administration of iron might be compromised with animal welfare for those piglets.

Serum micro-element reference values for gestating and lactating sows
Frédéric A. Vangroenweghe1 Tamara Vandersmissen2 Ellen Van Driessche1 Dominiek Maes3 Ellen De Jongh3
1. DGZ-Vlaanderen, Torhout, Belgium; 2. DGZ-Vlaanderen, Lier, Belgium; 3. Faculty of Veterinary Medicine - Ghent University, Merelbeke, Belgium

Introduction and Objective
The measurement of serum macro-element parameters of farm animals can provide important information on health and metabolism of several organ systems (1,2) Recently, an episode of reproductive problems was observed in several pig herds in Flanders, although no specific infectious causes could be identified. Besides infectious causes, feeding strategies and feed composition could have an impact on reproductive performance of the sows. Several components such as vitamin E, selenium (Se) and minerals (Ca, Mg, Mn, Cu and Zn) could have an influence on reproduction (1). However, to interpret the obtained results in serum macro- and micro-element analysis, reliable reference values should be available. Therefore, blood was collected from primiparous and multiparous sows in several farms with no reproductive problems in order to establish reference values for several minerals and vitamin E. The effect of stage of reproductive cycle was also evaluated.

Materials and Methods
Seven pig farms with at least 100 sows in a batch management system (BMS) were selected based on the absence of reproductive problems. Samples were collected from the same sows at 60 ± 5 d of gestation, 3 ± 1 d after farrowing and at 3 ± 1 d after weaning. Analysis was performed as follows: Se (μg/l) and Mn (μg/l) using an atomic absorption technique and vitamin E (mg/dl) using HPLC-analysis.

Results
Results expressed as mean and range (2.5-percentile and 97.5-percentile) are given for primiparous and multiparous sows in Tables 1-3.

Table 1. Reference values for serum macro-elements of the parity-one sows (n = 14) and parity ≥ 2 sows (n = 31) from 7 commercial pig herds at 3 ± 1 d of lactation

Discussion and Conclusions
It is difficult to compare the obtained results with previous results due to differences in analytical techniques (3). The reference values obtained for vitamin E were lowest at parturition and increased at weaning. Selenium reference values had a quite stable kinetics with slightly higher values at 3 d after weaning. For Mn, the lowest reference values were observed at 3 d of lactation. Due to one farm with very high Mn-levels at 60 d of gestation, the reference value and range is much higher in multiparous sows. Overall, primiparous sows had lower reference values as compared to multiparous sows in all three production stages.

Introduction and Objective

The measurement of serum macro-element parameters of farm animals can provide important information on health and metabolism of several organ systems (1) and is a practical diagnostic tool for assessing pathological conditions in the live animal or for monitoring the health status of groups of animals (2). Recently, an episode of reproductive problems was observed in several pig herds in Flanders, although no specific infectious causes could be identified. Also no major shortcomings were observed regarding management and housing conditions. Besides infectious causes of the reproductive problems, feeding strategies and feed composition could have an impact on reproductive performance of the sows. Several components such as vitamin E, selenium (Se) and minerals (Ca, Mg, Mn, Cu and Zn) could have an influence on reproduction (1). However, to interpret the obtained results in serum macro- and micro-element analysis, reliable reference values should be available. Therefore, blood was collected from primiparous and multiparous sows in several farms with no reproductive problems in order to establish reference values for several minerals and vitamin E. The effect of stage of reproductive cycle was also evaluated.

Materials and Methods

Seven pig farms with at least 100 sows in a batch management system (BMS) (3-4 or 5-week BMS) were selected based on the absence of reproductive problems. The herds had between 200-450 sows. Samples were collected from the same sows at 60±5 d of gestation, 3±1 d after farrowing and at 3±1 d after weaning. All samples were stored at -20°C until the end of the sampling period and analysed subsequently in one single batch. Analysis was performed as follows: Na (mmol/l), Cl (mmol/l), K (mmol/l) using Vetlyte (Idexx), P (mmol/l) using Vettest (Idexx), Fe (μmol/l) using Diasys nl Iron FS Ferene (Konelab TX20) and Mg (mmol/l) using Siemens Medical Solutions (Konelab TX20) and Ca (mmol/l) and Mg (mmol/l) using Rapidox (Konelab TX20) and Zn (μg/dl) using an atomic absorption technique.

Results

Results expressed as mean and range (2.5-percentile and 97.5-percentile) are given for primiparous and multiparous sows in Table 1-2. The results of 3 d after weaning were comparable to those at 60 d of gestation and were therefore not presented here.

Discussion and Conclusions

It is difficult to compare the obtained results with previous results due to differences in analytical techniques (3). The reference values obtained for most of the determined elements were slightly higher at 60 d of gestation as compared to 3 d in lactation. Moreover, the ranges are higher and narrower at 60 d in gestation, indicating less variation within the animal population. Overall, primiparous sows had higher reference values as compared to multiparous sows in lactation and during gestation.

Growth performance response to different sources and batches of Ractopamine

Diego Brana Varela¹ Cesar A. Mejía Guadarrama¹ Jose J. Lopez Espinoza ²

1. INIFAP, National research institute for Forestry, Agriculture and Livestock, Queretaro, QRO, Mexico; 2. Elanco, Guadalajara, JAL, Mexico

Introduction

Ractopamine (RAC) is a phenethanolamine β-adrenergic receptor agonist that is commercially available (Paylean®, PAY) for enhanced muscle protein growth in pigs. After the success of RAC hydrochloride (PAY®), several companies have commercialized generic versions of the product. This trial was done to study growth performance and consistency of response between brands of Ractopamine (generic “GEN” vs. PAY), and also to determine the uniformity of response when comparing different production batches of the same brand.

Materials and Methods

The experiment was conducted as a Randomized Complete Block Experiment. RAC source and batches (treatments) were present in all the blocks. A total of 240 pigs (half gilts and half barrows), were individually contained providing 2.09 m² space per pig and were fed one of the RAC products (at 5 ppm) or a Control diet (C; with the same formula) during the last 28d of the finishing period. There were 48 pigs for the control diet and 24 for each of the 4 product batches within RAC source. Thus the Ractopamine source effect included 96 experimental units, and the source * batch (lot) interaction, 24. All Treatments were present in 4 blocks (block=week of birth). Animals were individually feed twice a day, weighed every week, and average fat free lean tissue growth (FFLTG) was estimated by real time ultrasound (Aloka 550 SD) measurements. Data was statistically-analyzed under the restriction of a complete random block model, with 9 treatments and 4 blocks. General Linear Models (GLM, SAS) were used. Least square means from the variance analysis were presented.

Results

Initial body weight (76.6 ±8.32 kg) was similar (P<0.9) between Treatments. After 28d, average daily gain (ADG) differed between brands (1030; 1153, and 1115±202g/d; P<0.0001) respectively for C, PAY and GEN. Interestingly, ADG response was not the same within the GEN batches: (C: 1033; PAY: 1161; 1149; 1171; 1138; GEN: 1128; 1169; 1076; 1089±32g/d), respectively for the mean of each one of the production batches within Trt. Similar response was observed for feed efficiency (gain over feed; FE), where overall the use of RAC improved FE, but the response was dependent not only on the brand, but also was dependent on the production batch for the GEN (C: 361; PAY: 394; 404; 406; 407; GEN: 382; 390; 374; 373±8.4; P<0.0001). The FFLTG was improved by RAC (C: 355; PAY: 415; RAC: 394±6.8g/d; P<0.0001).

Discussion

Overall treatment responses were consistent (P<0.0001) for ADG, FE and FFLTG, although the response was better and more consistent when the PAY product was used. But the evaluation should also be done in probabilistic terms. Interestingly, two batches of the GEN product out of four, when compared to the Control, where not different (P>0.6); meaning that the response to the GEN product could not be observed in 50% of the times. Differences in feed intake and ADG can be relatively small and hard to detect at the farm because of the variation inherent to the process. Feed efficiency is a more sensitive and reliable variable. Additionally, in times of expensive feed, feed efficiency is one of the most relevant variables in profitability. Finally, as demonstrated in this trial, product consistency is a feature that producers should consider when evaluating different products.
This study explored the effect of pre-slaughter fasting on the pigs' carcass value and weight.

The optimum time of feed withdrawal before slaughter was determined. Findings will be useful to the pork industry in minimizing the decrease in carcass value particularly weight and therefore increase the amount of money a producer may receive, without compromising carcass value.

Ninety (90) market weight pigs were divided into 3 treatments: 0, 12 and 24 hour feed withdrawal prior to slaughter without restriction to water access. Each treatment was allocated with 30 pigs irrespective of sex. The experiment was conducted in 6 slaughter days, wherein 15 heads were slaughtered on each slaughter day. Carcass weight was recorded, along with the weight of body organs and digestive tract full and emptied. Meat pH was also measured 45 minutes post-slaughter to determine the effect of feed withdrawal on meat.

There was an observed 2.6 kg body weight loss in the first 12 hour of fasting which increased to 4.7 kg after 24 hour of continued feed withdrawal. Total shrinkage of 55.3% occurred during the first 12 hours, which was reduced to only 44.7% in the next 12 hours of fasting. Dressing percentage was observed to be higher in fasted animals compared to pigs not fasted before slaughter (P<0.01). It was estimated that the weight loss for every hour of feed withdrawal was 0.2791 kg loss. This study found that a considerable live weight loss occurred when pigs are fasted over a 24 hour period. This loss translates to monetary losses to the producer. Within 12–24 hour period of feed withdrawal, carcass losses also entail monetary losses on the part of the buyer.

Regarding the current trend of buying and selling of finishing hogs in the market today, it seems that a lot of money is wasted due to improper fasting time of finishing pigs. In order to avoid unnecessary monetary losses, pigs should be fasted not more than 12 hours before the actual time of slaughter. It is also important to note that this study is limited to the effect of feed withdrawal only, so it could be assumed that additional weight losses can be incurred if transportation parameter is included. Ordinarily buyers purchase their pigs at long distances so drastic losses are expected. Highly significant differences (P<0.0001) were observed in fasted and non fasted groups for the digestive tract, (full and emptied), residual gut fill, and liver weight.

After 24 hour of feed withdrawal, when the digestive tract is fully empty, there was a progressive loss in liver weight with increased fasting time. Except for the liver being significantly bigger in barrows than in gilts, there were no other carcass traits observed to be significant between genders. No significant changes were observed among body organs in the three treatments. There are also no significant differences in the initial pH of the meat at 45 minutes post-mortem among fasted and non fasted animal.
Introduction
The steady increase in demand by the world population explosion, the unbalanced regional distribution and various forms of pollution have made water a scarce and precious resource. Nowadays, the use of water is an issue of great concern in all human activities due to its growing scarcity. Therefore all efforts are relevant to optimize its use. Unfortunately, there is very little information on water use in swine production.

Aims
To determine the amount of water needed to produce a finished 100 kg live weight pig, taking into account the water used by the pigs and cleaning activities on the farm.

Material and Methods
The study was conducted at the experimental farm of the Universidad Nacional Autónoma de México, which is a 120 sows farrow to finish operation located in central Mexico, with an average temperature of 18°C and average rainfall of 608 mm. The feed were based on sorghum and soybean meal. The pigs in the weaning and finishing stages are fed ad libitum. In all areas of pigs were used nipple type drinkers and had free access to water. Water meters were used for metrological class C, which measure 100 ml fractions. The washing of the pens was made with a pressure washing machine. Only in the area of early gestation was performed daily washing with a hose. During the study, said there were no leaks in the hydraulic installation of the farm. In the areas of breeding pigs, gilts, gestation and lactation was measured amount of water used and calculated how much each area contributes to produce a 21 days weaned pig. In the stages of weaning and fattening, was calculated the individual average water used by a pig during each stage. The amounts were added to the average water used for washing pig facilities in each stage, to finally get the amount of water used for production of a pig of 100 kg. The results were analyzed with descriptive statistics.

Results
Table 1 shows the average water used per individual in each stage of production and the individual average of water used for washing facilities. The average water used to produce a 21 days weaned pig was 894.23 liters. The average water used by the weaning and finishing pig was 1705.44 liters. The sum of these amounts represents the average water used for production of a pig of 100 kg, which was 2599.67 liters.

Discussion
The results obtained should not be taken as a universal measure, but as a reference for estimating water needs for a pig farm, and to seek to reduce water consumption by specific strategies. Results of the study discovered areas where water use is too high, which allows to identify critical points in which to work to establish corrective actions. These measurements can be implemented relatively easily in pig farms. Future studies will be necessary to include the water used in bathrooms and offices of the pig farms to obtain more complete information. It is suggested to perform jobs that are water ways to optimize every step of the production process of the pigs, which is an important objective in relation to water use in the swine industry worldwide.

Table 1. Individual average daily liters of water used in each stage of production (AWP) and average water used for washing facilities (AWF).

Effect of feeding newborn piglets with a fermented bioprotein (Lianol®) in mortality before weaning

Daniel Villalba¹ Guillermo Cano² Ruddy Forier³ Ramon Gatnau⁴ Alberto Morillo²

1. University of Lleida, Lleida, Spain; 2. Tests and Trials, Lleida, Spain; 3. Ardol, Susteren, Netherlands; 4. Molimen, Barcelona, Spain

Introduction and objectives
Piglets with low weights at birth are related with a decreased livability falling into hypothermia, starvation and death¹. Lianol® (a fermented bioprotein by Ardol, The Netherlands) is supposed to have a positive effect in newborn piglets from an increase of circulating IGF-I. The aim of the study was to evaluate the effect of supply orally Lianol® at first day of live in mortality from born to weaning in piglets and to evaluate if this improvement could be done by and increase of serum IGF-I.

Material and Methods
391 newborn piglets were tagged, weighed and assigned to one of two groups during the first 12 hours after birth depending on BW: piglets with BW higher or equal to 1.2 kg (BIG) or with BW lower than 1.2 kg (SMALL). Treatment were: i) 2 ml of Lianol® given orally in the mouth during first 12 hours after birth (Lianol2), ii) 1 ml of Lianol® during first 12 hours after birth plus 1 ml 24 hours later (Lianol1+1) and iii) a negative control group (Control). Piglets were randomized to be assigned onto each treatment within BW group and sex. All animals were weighed again on days 3, 7 and 20 of live.

181 randomized piglets were bled at the day 1, 7 and 20 of live. Number of piglets in every group and treatment is shown in table 1. Blood samples were tested by enzyme-linked immunosorbent assay (ELISA) using established methods.

Piglet was the experimental unit. IGF-I, BW and ADG were analyzed with ANOVA. Mortality was analyzed using a logistic regression. Piglet uniformity was assessed from the coefficients of variation of the individual BW and differences between treatment groups were analyzed using F test. The level of significance was 5%.

Results and Discussion
Table 1 shows number of piglets included and mortality levels. Mortality was not statistically different between treatments. However, we have observed a relevant reduction of 50% between Control and Lianol2 in BIG group and 46% between Control and Lianol2 in SMALL group. These values were not statistically different but are a relevant data under commercial situations.

We found no statistical difference in BW nor in ADG. Piglet uniformity was not different between treatments at day 20.

Implications and Conclusions
The supply of Lianol® after birth did not improve mortality statistically but the numerical improvement was relevant under commercial situations mainly in BIG piglets. IGF-I values, BW and ADG were not improved. More investigations should be done in order to know the relationship between IGF-I levels and piglet performances.

Effect of dietary cysteamine on growth performance and growth hormone of starter-finishing pigs

Jamlong Mitchaothai1 Chanathip Thamnakarn2 Suaysuda Ninlaworn3
1. Faculty of Veterinary Medicine, Mahanakorn University of Technology, Nong Chok, Bangkok, Thailand; 2. School of Animal Production Technology and Fisheries, Faculty of Agricultural Technology, King Mongkut’s Institute of Technology Ladkrabang, Bangkok, Thailand; 3. Technical and Product Department (Veterinarian), Grandsiam Co., Ltd., Bangna, Bangkok, Thailand

Introduction

Cysteamine (CS) can be used as a feed additive for improving growth performance of growing pigs. Pigs obtaining CS would lead to lower level of somatostatin, resulting in elevation of growth hormone (GH) level (1). It has been known that GH increases muscle growth (2) and decreases deposition of fat in pigs (3). In finishing pigs, dietary CS supplementation improved protein deposition (4). However, the effects of dietary supplementation on growing pigs raised under field condition have not been reported. Thus, the current study aims to determine effect of dietary supplementation on growth performance and serum GH of starter-finishing pigs.

Materials and Methods

Three hundred and seventy five starter pigs were randomly selected from a commercial pig farm for the current study. All experimental pigs were equally allotted into three groups; the control (CT), recommended level of CS (RC) and high level of CS (HC). Each experimental group contained 125 pigs, equally housed in 5 pens. The pigs in the CT were offered control diet, which is normally used in the farm, while the pigs in the RC and HC were offered the control diet with supplementation of CS at 300 and 500 ppm, respectively. The pigs were fed ad libitum. Live body weight of the pigs of each pen was measured at the start and the end of the study. Feed intake of the pigs was recorded throughout the experiment. Blood samples of 10 pigs from each group were randomly collected at 13.00 hours in order to quantify level of GH with RIA method. At the conclusion of the study, ADG, FCR and feed cost per body weight gain (FCG) were calculated. The statistical analysis is one way ANOVA with Duncan’s multiple comparison.

Results

The results of the growth performance have been demonstrated in the Table 1. There was no effect of dietary CS supplementation on ADG and FCG. However, the pigs fed on the RC diet had significant lowest FCR (p<0.05), whereas the pigs fed on the CT and HC had no significant difference. The levels of GH have been shown in the Table 2. The change of GH was greatest (42%) in value for the pigs fed on the CT diet, while the GH change in the pigs fed on the RC (22%) and HC (18%) diets were around half of the change of the CT group.

Discussion

In the current study, the FCR of the pigs fed on the dietary CS supplementation at recommended level, while there was no effect of the supplementation at recommended and high level on ADG and FCG. The difference of the results of ADG from earlier report (Yang et al, 2005) might be the results of wider range of pig age and uncontrollable environment conditions in the current study. However, dietary CS supplementation at recommended level had the best improvement of growth performance values, which it is the similar direction with reports previously (1,4). Serum GH levels in this study was dramatically lower than previous experiments (5). This would be the results of more light exposure during blood sample collection (6). However, dietary CS supplementation at both levels had smaller values in decreasing GH, which might be used to explain improved values of growth performance.

The effects of a naturally contaminated diet with and without a mycotoxin deactivator on blood parameters of weaning piglets

Ursula Hofstetter; Sabine Masching
Biomin Holding GmbH, Herzogenburg, Austria

Introduction

When ingested, mycotoxins cause insidious losses, ill thrift and increase disease incidence due to their immune-suppressive effects. In spite of all efforts to prevent formation of mycotoxins in feeds, significant contaminations still occur. While the use of products based on aluminosilicates gave good results in counteracting aflatoxins (1), the adsorptive deactivation of other toxins failed under field conditions (2). A further efficient way of detoxification of non-adsorbable mycotoxins is microbial or enzymatic biotransformation. It has been reported that an anaerobic rumen bacterium (Eubacterium BB5H797) is able to deactivate trichothecenes by biotransformation of their epoxide ring (3). A trial with weaning piglets was carried out to investigate the negative effects of deoxynivalenol (DON) on blood parameters and immune globulins and to prove the efficacy of a feed additive based on different strategies to counteract these effects.

Materials and Methods

The trial was conducted at the Center for Applied Animal Nutrition (CAN) in Austria with 14 pens for 10 piglets each, equipped with slatted floor, cup drinkers and a computer – operated feeding system (Spotmix). Directly after housing all piglets were fed a prestarter for approx. 3 days and afterwards changed over to the experimental diets. A 2-phase feeding system was used, where starter diet was fed between d4-14 and grower diet from d15. Water and feed were provided ad libitum.

CG(-) Negative control group; no detectable mycotoxins, no additive.
ToG Toxin group; 2 ppm deoxynivalenol (DON).
TG Trial group; 2 ppm DON and 2 kg/mt feed additive.
CG(+) Positive control group; no toxin but 2 kg/mt feed additive.

Table 1 shows all blood parameters with statistically significant differences between the groups. The hematocrit value is an indicator for the concentration of erythrocytes and general water balance. In general all groups revealed hematocrit values close to the lower level of the reference values. This may be due to interference in water balance caused by diarrhea. The hemoglobin value is an indicator for the concentration of the iron-containing blood pigment. The high level of DON in the naturally contaminated diet caused an extreme activation of the immune system. In the toxin group the IgA value was significantly increased. IgA is with approx. 15% the main immune globulin in serum. In the trial group the immune suppression caused by DON was counteracted.

Discussion

Hematocrit values in the non-contaminated group with the feed additive were significantly improved compared to the control and the naturally contaminated group. Hemoglobin values in the feed additive group were significantly better compared to the control and all other groups. In the toxin group, DON activated the immune system and significantly increased the IgA values. The feed additive counteracted the immune suppression caused by deoxynivalenol.

Early feeding of flaxseed leads to a permanent retention of n-3 fatty acids in pork tissues

Hector R. Martinez-Ramirez1 John K. Kramer2 Cornelius F. de Lange1
1. University of Guelph, Guelph, ON, Canada; 2. Agriculture and Agri-Food Canada, Guelph, ON, Canada

Introduction
Value added pork products may be produced by enriching pork with health benefits providing n-3 fatty acids (FA), such as eicosapentaenoic acid (EPA; 20:5n-3), docosapentaenoic acid (DPA, 22:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) when these n-3 FA are incorporated into inter- and intra-muscular fats depots.

Several experiments have been conducted to assess the extent of incorporation of n-3 FA in pork products. However, little attention has been paid to determine the effect of feeding n-3 FA at different stages of growth to pigs.

Objective
To determine the incorporation of n-3 FA such as 18:3n-3 (ALA) and highly unsaturated n-3 FA (HUFA; 18:4n-3, 20:3n-3, 20:4n-3, EPA, DPA and DHA) in trimmed loin (L) and whole belly (B) of pigs fed flaxseed that contains high levels of ALA.

Materials and Methods
A total of 24 purebred individually housed Yorkshire female pigs, weighing approximately 25 kg BW were allotted in one of three feeding programs (n = 8): T1, diet with 10% FS diet fed between 25 and 50 kg BW, and control diets (C) low in n-3 FA fed thereafter until 110 kg BW; T2, C fed between 25 and 85 kg BW, and diet containing 6% FS fed thereafter until 110 kg BW; and T3, fed C between 25 and 110 kg BW. Feed intake was fixed at 95% of the voluntary feed intake according to NRC (1998). Fat samples were extracted from 5 g of fresh L and B samples using chloroform/methanol (1:1 v/v) and then methylated using anhydrous methanol-HCl 5%. FA methyl esters were analyzed using a gas chromatography (Agilent Technologies Model 6890N) equipped with a 100m CP-Sil 88 fused capillary column. The FA content in the tissues of pigs slaughtered at 110 kg BW was expressed as mg/100 g of fresh tissue. Results were subjected to analysis of variance using the Proc Mixed procedure of SAS v9.1 (SAS, Inst., Cary, NC). Pigs and block (pigs upon arrival, n = 2) were used as a random effect.

Results and Discussion
No treatment effect was observed on growth performance, carcass characteristics or loin meat quality (P > 0.05). Pigs on T1 and T2 consumed equal lifetime amounts of FS (5.1 vs. 5.2 kg, P > 0.10). In L, ALA was higher (P < 0.05) for T2 than T1 and T3 (143, 76.4 and 37.0, respectively). In B, ALA was similar for T1 and T2 (667 vs. 752; P > 0.10) and both were higher than T3 (207; P < 0.01). The main HUFA's were 20:3n-3 (in B similar for T1 and T2, P > 0.10, and higher than T3: 104, 102, 31, respectively; and in L similar for T1 and T2, P > 0.10, and higher than T3: 12.5, 21, 6.0), DHA (in B similar for T1 and T2, P > 0.10, and higher than T3: 10, 8.3, 6.9, respectively; in L no treatment effect, 2.1, 2.0, 1.8; P > 0.05) and DPA (in B similar for T1 and T2, P > 0.10, and higher than T3: 40, 34, 20; in L similar for T1 and T2, P > 0.10, and higher than T3: 9.7, 11, 6.2). Total HUFA content was larger (P < 0.05) for T1 and T2 compared to T3 in L (30, 42, 18) and B (179, 168, 71). In T1 and T2 the n-6/n-3 ratio was lower than T3 in L (5.9, 4.0, 12.7) and B (4.9, 3.8, 13 3; P < 0.001). These results indicate that feeding modest amounts of FS leads to a significant enrichment of ALA and HUFA, in particular 20:3n-3 and DPA, in pork. The enrichment of n-3 FA appears to be independent of time of feeding n-3 FA and provides flexibility as to when n-3 FA can be fed for generating n-3 enriched pork.

Key words: Pork growth, n-3 fatty acid, pigs

Effects of carbohydrates supplementation on gut microbiota and immunology of growing pigs

Joseane Willamii, Judith González1, David Torrallardona2, Pierre-André Geraert3, Estelle Devillard3, Ignacio Badiola1

Exogenous carbohydrates enzymes used in feed to improve animal performance, hydrolyse non-starch polysaccharides (PNA) from raw materials. A study conducted in our laboratory has shown that this type of enzymes modify the intestinal microbiota of growing pigs (dos Santos et al. 2009). These changes in microbiota could play a positive effect on intestinal health as suggested by Kim et al. (2003). The aim of our study was to determine the effects of enzyme supplementation on gut microbiota and immunological parameters of growing pigs.

Thirty-six pigs (25 kg BW.) were fed during 28 days with one of 4 different treatments based on the type of diet (WBR or C) and the supplementation or not (+ or -) with enzymes. The pigs were slaughtered to obtain samples of serum, bile and ileal mucosa for immunological studies. In addition, samples of ileal and caecal digesta and ileal mucosa were collected for microbiota studies. The microbiota composition was studied by RFLP-PCR. The serum IgA, IgG and IgM and bile IgA were examined by ELISA. The terminal ileum was used to study some immunological cellular markers by immunofluorescence (Table 1) and some morphological parameters by HE and PAS stains.

WBR+ diet presented an increase in the mucosal biodiversity and in the villous height:Crypt depth ratio compared to WBR- diet (Table 2). These results are in accordance with the gut health concept: a higher microbiota biodiversity promotes a lower aggression on the mucosa. The corn based diet supplemented with enzymes increased the neutral Goblet cells, a reduction of secretory IgA, intra epithelial lymphocytes (IEL) and CD3+ cells of villi compared to corn based diet without enzymes (Figure 1). An increase of secretory IgA, an increase of IEL and an increase in CD3+ cells can be indicative of a higher aggression of gut mucosa in the corn based diet without enzyme supplementation.

Figure 1. Immunofluorescence of the gut cells CD3+ (A) and s-IgA+SCW8 (B).

The biodiversity degree of ileal mucosa presented significant correlation with the bile IgA concentration (R=-0.42, p=0.001), the IEL of villi (R=-0.43, p=0.008) and neutral Goblet cells (R=0.53, p=0.03).

Our results suggest that a more complex intestinal microbiota could play a positive effect on intestinal health. Changes on microbiota components can be induced by changes of feed components and by the addition of exogenous enzymes. The beneficial effects of enzymes could be related with an improvement of the adaptive capacity of commensal microbiota as a natural barrier against the overgrowth of pathogens.

**Effect of the inclusion of enramycin and bacitracin methylene disalicylate over the productive performance of growing (30-55 kg) pigs**

Erandi Toledo1 Juan M. Palacios2 Francisco Rosales2 Arturo G. Borbolla1

1. Departamento de Producción Animal: Cerdos. Facultad de Medicina Veterinaria y Zootecnia. Universidad Nacional Autónoma de México., Coyoacan, DF, Mexico; 2. Shering Plough Intervet S.A. de C.V., México, DF, Mexico

**Introduction**

The use of feed antibiotics as growth promotants (AGP), in farm animals has been a practice used for several decades. From a production standpoint, these molecules have been consistently shown to improve weight gain and feed efficiency (Gaskins et al., 2002). Despite of these benefits, there has been a tendency to ban AGP in animal feed, which would have important economic implications in the cost of production. In the EU the ban of AGP was related to the alleged selection of antibiotic-resistant bacteria (RB), which might infect human beings and produce non-treatable diseases, particularly with Gram negative bacteria (Butaye et al., 2003). However, the development of RB has not being conclusively related to the use of AGP. The correct use of AGP could reduce the risk of producing RB. Therefore, it is important to evaluate continuously different molecules and administration programs that allow a correct use of APC in farms. The objective of this study was to compare the effect of enramycin and bacitracin methylene disalicylate over some important production parameters in growing pigs (30-55Kg).

**Materials and Methods**

Four hundred and fifty mixed pigs (N=45 animals/pen, 255 pigs/treatment, 5 repetitions/treatment), were assigned randomly to two treatments. Control group (C) was the basal diet plus 500 g of bacitracin methylene disalicylate/ton and the experimental group (E) contained the basal diet plus 120 g of enramycin per ton. The trial was conducted during the first 35 days of the growing phase (30-55 kg). At the beginning of the study, 5 pigs/pen were tagged and weight at the beginning and end of the trial. These data were used to evaluate average daily gain (ADG) average daily feed intake (ADFI) and feed conversion (F:G). These data were used to analyze the main effect of each treatment by mean comparison using the statistical program SPSS Statistics 17, with a level of significance of (P< 0.05).

**Results**

Production parameters are shown in table 1 and figure 1. The initial and final body weights during the growing phase were similar (P > 0.05) for both treatments (31.4 and 54.4 kg vs. 30.0 and 55.7 kg for C and E pigs, respectively). It implies a mathematical improvement of 4 % in weight gain for the E pigs. The ADFI was smaller (P < 0.05) for the C than the E animals (1.5 vs. 1.6 kg/d, respectively). However, the ADG was greater (P = 0.08), for the E group (0.74 Kg/d), than the C group (0.66 Kg/d). Nevertheless, F:G ratio was similar (P> 0.05) for both treatments.

**Discussion**

The addition of bacitracin and enramycin in the diet of growing pigs in this trial showed similar results to those observed by Silva et al. (2003), who reported that the addition of enramycin reduced ADFI and increased ADG; therefore improving F:G ratio. In this study, however, the improvement in F:G was not observed. Therefore, it is conclude that enramycin used as a growth promotant improves the performance parameters of pigs during the growing phase.

**Effect of peroral iron supplementation in piglets on health and production**

Caroline Vanderhaeghe1 Jeroen Dewulf1 Frédéric Vangroenweghe2 Maarten Steyaert1 Ellen de Jong1 Irris Villareal1 Alfonso Lopez1 Ruben Del Pozo Sacristan1 Dominiek Maes1

1. Facutly of Veterinary Medicine, Department of Reproduction, Obstetrics and Herd Health, Merelbeke, Belgium; 2. Animal Health Care Flanders, Torhout, Belgium

**Objectives**

Piglets are born with only minor iron reserves and also sow milk contains very low amounts of iron. Therefore, if piglets in intensive pig herds are not provided with extra iron during the first week after birth, they will become anaemic (1). Iron is commonly provided by means of intramuscular injection. However, if iron could be supplemented orally, it could save labour and also, the stress of manipulating pigs and injecting them could be avoided. The objective of this field study was to investigate the efficacy of peroral iron (Fe) supplementation by means of health, performance and haematological parameters. Additionally, the correlation between the concentration of haemoglobin (Hb) measured in the laboratory and measured on-farm using the HemoCue® test (HemoCue® Diagnostics B.V., Waalre, The Netherlands), was assessed.

**Material and Methods**

Three commercial pig herds (>300 sows) participated in the study. Within each herd, 40 sows with their litters were included. Blood samples of the sows for Hb concentration were obtained one week before farrowing. A droplet of blood was absorbed in a microcuvette by capillary action for quick Hb-determination by the HemoCue®. Within each herd, the litters of the 40 sows were randomly divided in two groups. Group 1 (G1) received the peroral iron supplement (40g for a litter of 12 piglets) (HemOral®, Biofiber-Damino, Gesten, Denmark) on day 2-4, 5-7 and 8-12. Group 2 (G2) received an intramuscular injection with 200 mg Fe3+ on day 2-3 (Bastion 20%®, Intervet, Brussels, Belgium). Within each litter, 3 piglets were randomly selected and blood sampled just prior to iron injection and at weaning. Additionally, a droplet of blood was absorbed in a microcuvette by capillary action for quick Hb-determination (HemoCue®). All piglets were weighted at these two time-points, and the total feed intake was recorded for each group. Farrowing data of the sows and performance of the piglets during lactation were measured. Statistical analysis was performed by means of analysis of variance (SPSS 16.0), in which the effect of the herd was taken into account.

**Results**

The sow farrowing data and the performance of the piglets are shown in Table 1. None of the parameters differed significantly between the two groups (P>0.05). The time needed to treat a litter was significantly lower in the HemOral® (G1) group than in the Bastion 20%® (G2) group (P<0.0001), but the difference was very small.

</tr>
<tr>
<td>Hb concentration</td>
<td>92.4 (24.6)</td>
<td>89.5 (21.0)</td>
</tr>
</tbody>
</table>

The correlation between the Hb concentration measured in the laboratory and measured on-farm using the HemoCue® test (n = 1036 piglets) was 0.79.

**Discussion and conclusions**

The present study did not show significant differences between oral or intramuscular supplementation of iron on performance of piglets during lactation. As oral supplementation is less time consuming and does not require individual injections, it may be the preferential method. It also appeared that the quick on-farm testing of Hb can be used reliably to assess the Hb concentration of the piglets.

Evaluation of three feeding systems during gestation and its effect on reproductive performance of sows

Erandi Toledo1 Alfredo García-Rendón2 Arturo G. Borbolla1 Jorge López1
1. Departamento de Producción Animal: Cerdos. Facultad de Medicina Veterinaria y Zootecnia. Universidad Nacional Autónoma de México., Coyoacan, DF, Mexico; 2. Granjas Covadonga, Estado de México, Mexico

Introduction

In sows, body reserves (protein and fat tissues), at farrowing and feed consumption during lactation determine milk production capacity and future reproductive performance (McNamara and Pettigrew, 2002). Therefore, an inadequate feeding program during the gestation and lactation periods, affects sow productivity and finally, farm output (Gill, 2006). However, in the majority of commercial farms, feed allowance during gestation is generally not focused on sow’s body reserves, but in easiness of delivery. Therefore, most sows are offered a homogeneous amount of feed; practice that in short time, alter the reserves of nutrients in the body. The objective of this study was to evaluate three feeding systems during gestation and their effect on body reserves of sows at farrowing and weaning.

Material and Methods

Four hundred sows from parity 0 to 5 were assigned randomly to three treatments: Tr. 1. feed allowance based on visual body condition. Tr. 2. Feed allowance based on body condition evaluated by weight and backfat using ultrasound (Aloha 500), techniques. Tr. 3. Feeding was based on the expected weight gain (net maternal gain), during gestation established by the modeling software from the NRC (1998). Body condition was determined using Noblet (1990) formulas. The amount of feed distributed to each sow did not consider parity number. These data were analyzed by ANOVA using the statistical program SPSS 15.0, and with a significance level of P < 0.05.

Results and Discussion

In general, sows from Tr. 2 and 1 consumed the same amount of feed over gestation, which was lower than sows in Tr. 3. Weight and protein loss after the lactation period were reduced in sows of Tr. 2 and 3 (Table 1). Fat loss however, was higher in sows of Tr. 2. Reproductive performance seemed to be not affected at farrowing or weaning by any of the dietary treatments (Table 2). However, sows in Tr. 3 shown better (P > 0.05) numbers in total pigs born.

Body weight gain in gestating sows depends highly on the feeding level. Therefore at a higher feed intake there is a higher weight gain. In the present study, however, sows of Tr. 3 had a greater feed intake (P<0.05) than sows of Tr. 1 and 2; but maternal weight gain did not show any differences for the three dietary treatments (Table 1). It was observed however, that sows in Tr. 3 had greater energy retention (fat), which agrees with results reported by Noblet et al. (1990), and Kusina et al (1999). As reported by Revell et al (1998) and Sinclair et al (2001), there were no effects of feeding level and feed intake in gestation over piglets birth weight, because an increase in gestation feed intake enhances maternal weight gain but has little influence over piglets weight.

Galactogeno use (product based organic fennel, and juniper alcarabea) as a stimulant in dairy production sows in maternity

Oscar Huerta Alva; FJC Crespo; N. Vázquez
Laboratorios Sanfer SA de CV, Mexico, DF, Mexico

Introduction

The improvement of productive and reproductive performance in pig farms is the work of every day, sometimes we have to use the tools available to improve results. Milk production allows us to have a good weaning weight of our pigs by ensuring better growth during the fattening.

The galactógena, natural product made from fennel, caraway and juniper promotes glandular environment free of pathogens (bacteria, viruses and fungi) and ensures the rhythmic discharge from the alveoli, increasing milk production and thus improve weight weaning.

Materials and Methods

On a farm with a capacity of 1,200 bellies in western Mexico, it randomly selects a maternity ward with a capacity of 28 deliveries, where the control and treated group received the same diet for 21 days, the treated group was given daily directly in the food 30 grams of galactógeno, divided into two served. The following table describes the groups:

<table>
<thead>
<tr>
<th>Group</th>
<th># of gilts</th>
<th>Average parity</th>
<th># piglets</th>
<th>Initial Weight</th>

<tr>
<td>Total final difference (0.080+0.161)</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td>0.241</td>
</tr>
</tbody>
</table>

As can be seen, the final margin rate was 0.241 g per piglet, considering the total number of piglets weaned, gained 30.9 kg piglet weight at weaning.

The difference in these herds 0.241 gr weaning piglets, has a direct impact on market day, feed conversion and daily weight gain, as demonstrated by Mahan 2005.

Conclusions

Based on the results, where female piglets children were treated with a final weight Galctogeno accumulated 0241 kg, compared to children of female piglets of control, it is concluded that use of this product helps in improving the accumulated weight weaning.

As can be seen, the final margin rate was 0.801 g per piglet, considering the initial and final average, because the piglets in the treated group started with lower weight. Considering the difference of the total initial weight and final weight total (17.5 +53.2) and divide by the total piglets have a difference of 0.693kg of difference for children piglets treated females.

Conclusions
Based on the results, where children piglets galactógena treated females had the most weight at weaning compared to piglets from control female children, it is concluded that use of this product helps in improving the accumulated weight at weaning.

TOPIGS: Feeding pigs according to the (genetic) requirements

Michiel Westerhof
KNMvD, Helvoirt, Netherlands

Introduction

For a major pig breeding company like TOPIGS, it is crucial that genetic progress achieved by breeding is expressed under practical conditions, the so called phenotypic expression. This phenotypic expression is a product of genotype and environment of the pig. The phenotype consists of the observable characteristics or traits, the genotype is the inherited instructions within the genetic code. By selection, TOPIGS is gradually changing the genotype, for instance into the direction of higher growth and a lower feed conversion. The problem is that environment (E) is not controlled by a genetics company, while E is very important to benefit from the genetic progress.

Most important factors in environment of the pig are: farm management, health, feeding and climate. In relation to feeding, TOPIGS decided to redefine the protein deposition capacity of the animals. Protein deposition is defined as PD = f (FI, W, NH| sire line, sex,...) where FI stands for Feed Intake, W for weight and NH for nutritional history. When PD is estimated, one can calculate the lysine and energy requirements and thus the composition of the feed needed to achieve best results. PD is described by the Linear Plateau theory (Whittemore and Fawcett, de Greef), see figure 1.

Figure 1. Protein and fat deposition as function of energy intake.

Materials & Methods

The TOPIGS specific protein deposition model is established by using the records of 15,000 animals in the breeding data base. Since TOPIGS is a worldwide operating breeding company, we collect data for breeding purposes in over 25 countries. At individual animal level, feed intake, back fat and weight is measured and recorded and slaughter house data are available.

Results

Protein deposition for the different sire lines and the sexes were estimated and the lysine and energy requirements were calculated. Figure 2 shows one example, differences between gilts and barrows. In the TOPIGS feeding manuals for finishers these requirements are expressed for the different genetic lines, the different sexes and different age groups.

Figure 2. Protein deposition for barrows and gilts at different age.

Discussion

Feeding is an important aspect of getting optimal expression of genetic potential. If an animal is not fed according to its requirements it is not only unfavorable for economic results but it might also have negative impact on health and welfare. By having good estimations of the protein deposition capacity in different stages of the life of the pig, the feed industry can manufacture feeds to fully exploit the genetic potential.

TOPIGS is in the process of using the data also to predict the effects of health status, of the use of growth promoters, of immuno-castration and of climate on the protein deposition capacity of our animals.

Impact of fineness of grinding of corn and high-moisture corn on growth performance, carcass characteristics and stomach lesions in liquid-fed growing-finishing pigs

Cuilan Zhu; Doug Wey; Robert Friendship; Cornelis F. de Lange
University of Guelph, Guelph, ON, Canada

Introduction
To minimize the energy cost in cereal grain milling and maximize feed utilization, much attention has been drawn to defining the optimum particle size for pig diets. In various studies it has been shown that reducing mean particle size of typical corn and soybean meal based diets to < 600 μm result in improvements in nutrient digestibility and feed efficiency in growing-finishing pigs (Wondra, 1995). Research conducted in the UK indicates that the optimum particle size for barley-based diets used in liquid feeding systems is larger than that in conventional dry feeding (MLC, 2005), and thus reduces energy costs of liquid feed preparation. No research has been conducted to establish the optimum fineness of grinding of dry and high-moisture corn (HMCorn) that is used in swine liquid feeding. Two experiments were conducted to determine the impact of fineness of grinding of corn and HMCorn on growth performance, carcass characteristics and stomach lesions.

Materials and Methods
In experiment 1, a total of 96 Yorkshire pigs with initial BW 32.3 kg (SEM 1.4) were randomly assigned to 6 pens per treatment and 8 pigs per pen. Two complete corn and soybean meal-based diets were formulated with dry corn hammer milled to two different particle sizes. Titanium was added as marker for determining fecal digestibility. Pigs were liquid fed using a computer controlled feeding system according to a two phase feeding program until pigs reached market weight (110 kg). Body weight was monitored at biweekly intervals and fecal samples were collected during the growing period. Carcass quality was evaluated according to the standard Canadian carcass grading scheme.

In experiment 2, 160 Yorkshire pigs with initial BW 33.8 kg (SEM 0.63) were randomly assigned to 10 pens per treatment and 8 pigs per pen. HMCorn was ground to two different particle sizes, transferred to large fermentation tanks, mixed with water to a target of 26% dry matter (DM), and stored for a maximum of seven days until feeding. The feeding program and pig management were as in experiment 1. The pigs’ stomachs were collected at the commercial slaughtering house and scored for lesions: 1=normal, 2=erosions, 3=ulcers, and 4=severe ulcers.

Results and Discussion
In experiment 1, dry corn particle sizes, coarse vs. fine, were 652 μm (±47.5) vs. 525 μm (±22.6). Average daily gain (ADG), average daily feed intake (ADFI), and gain:feed were not affected by fineness of grinding (P>0.5) with means of ADG 1.11 kg/d, ADFI 2.46 kg/d, and gain:feed 2.22. There were no differences (P >0.05) in apparent fecal digestibilities of DM, crude protein, and ash, with means of 85.8%, 76.0% and 58.8%, respectively. Carcass weight and estimated carcass lean yield were not affected by treatment (P>0.05).

In experiment 2, increasing mean particle size of ground HMCorn from 355 to 918 μm, did not impact growth performance (P>0.1), with mean ADG, ADFI and gain:feed of 1.03 kg/d, 2.22 kg/d and 2.15, respectively. Carcass characteristics were not affected (P>0.1) either. However, more severe stomach lesions were observed when pigs were fed finely ground HMCorn. Of the 135 stomachs that were evaluated, for pigs fed the fine diet (65 stomachs), the number of observations for scores 1 to 4 were 9, 11, 14 and 31, respectively; for pigs fed the coarse diet (70 stomachs), the number of observations were 23, 20, 11 and 16, respectively.

In contrast to the conventional dry feed practices (Wondra, 1995), manipulating particle size appears to have little influence on performance of liquid-fed pigs. Coarsely grinding HMCorn has the benefit of reducing stomach lesions.

Implication
The optimum particle size of ground corn is larger in liquid feeding than conventional dry feeding. Increasing HMCorn particle size to 950 μm did not influence growth performance and carcass characteristics, while the incidence of stomach lesions was reduced.

Route of iron supplementation to piglets: effects on hemoglobin, piglet growth and infectious diseases

Dan Rantzer; Mats Andersson; Jos Botermans; Anne-Charlotte Olsson; Jørgen Svendsen
Swedish University of Agricultural Sciences, Faculty of Landscape Planning, Horticulture and Agricultural Sciences, Alnarp, Sweden

Introduction
In modern production systems newborn pigs have no natural access to iron (Fe) in the environment and to avoid iron deficiency they need an Fe supplementation which may be given as an injection or be based on voluntary consumption. It is generally accepted\(^1\) that hemoglobin (Hb) levels in piglets should be above 80-90 g/1000 ml blood and it is considered that higher levels should be aimed for. While early conventional Fe injection is a safe way of securing sufficient iron to all the suckling piglets, there is some evidence\(^2,3\) that early Fe injection as opposed to voluntary oral Fe intake may increase the risk of joint infections and generalized infectious diseases in the piglets. The aim of the present study was to further elucidate the effect the route of Fe supplementation may have on infectious diseases in piglets, and the relationship between Hb levels during suckling and growth from birth to slaughter.

Materials and Methods
The treatments were a) early (d 1-4) and b) late (d 8-12) Fe inj (Pigeron\(^\text{®}\) vet, Leo), 20 litters, c) oral Fe supplementation (Porcofer, Svenska foder, 20 litters, and TorvoJärn Extra, Lantmännen, 20 litters) starting on d 3 and d) oral suppl. (as under c) and an early Fe injection.

Observations: The pigs were individually marked, weighed and blood sampled on d 2, 9, 20 and at weaning (d 33), respectively. Hb level was determined (Hemo Cue\(^\text{®}\)B-Hemoglobin Fotometer [Hemo Cue AB, Angelholm, Sweden]). The presence of joint infections was checked daily and on d 9 more thoroughly. The pigs were individually identified and recorded throughout and at slaughter. Mortality, treatments and morbidity were noted daily and all dead pigs in the trial were post-mortem examined.

Results and Discussion
There were significantly more treatments for joint infections in pigs receiving an early Fe inj. than in the littersmates receiving a late inj. (Table 1). Also, pigs only receiving Fe by oral supplementation (Table 2) had significantly fewer joint infections than littersmates also given an early Fe inj. Hb was significantly higher on d 9 and d 20 in pigs receiving an iron early inj. than in littersmates receiving a late Fe inj. (Table 1) or only oral suppl., respectively (table 2). For the orally suppl. pigs, daily growth to slaughter, and mortality was the same for both treatment groups (Table 2); however, for the inj. groups (Table 1), growth from day 2 to slaughter tended to be lower for the late injection treatment group. The results support the proposal that early Fe inj. increases the risk of piglet joint infections usually occurring in the second week of life. There are no indications in this study that pigs with high Hb levels perform better than pigs with levels of 80-110.

Effect of dietary supplementation of humic substances on the concentration of some elements and antioxidant status in the small intestine of weaned pigs

V. Petrovič1 J. Novotný2 L. Lenhardt3 J. Bernardy4 G. Kováč1
1. University of Veterinary Medicine and Pharmacology, Košice, Slovak Republic; 2. Clinic of Ruminants, Košice, Slovak Republic; 3. Department of Pathological Anatomy, Košice, Slovak Republic; 4. University of Veterinary and Pharmaceutical Sciences, Brno, Czech Republic

Introduction
Humic substances (HS) have relatively high molecular weight and include different amounts of humic acids, fulvic acids and humins. HS contain up to 80% of organic carbon. The variety of molecular structures are presented in HS, such as alkylaromatic, quinoide and aliphatic structures in the core, amino acid and carbohydrates structures and carbonyl-, carboxyl-, phenyl-, hydroxyl groups in the periphery. These functional groups modulate their enzymes activities (Zeichmann 1996; Nardi et al., 2002). In addition, they are capable to alter the bioavailability of nutrients. Herzig et al. (2001) and Laurberg et al. (2003) found the thyroid system affected by HS via significantly reduced iodine bioavailability. The aim of this study was to determine the effect of dietary supplementation of humic substances on the concentration of Se, Zn, Fe, Cu, Mg, Ca and malondialdehyde, the number of Goblet cell and the activity of alkaline phosphatase in the duodenum and jejunum of weaned pigs.

Material and Methods
The twelve piglets Large White, were weaned at the age of 32nd day and were randomly divided into 2 groups. Control group was fed with basal diet for weaned pigs and experimental group of pigs received the same basal diet supplemented with humic substances in the dose 5 g per kg DM for 60 days. At the age of 92 days, the pigs were weighed (the average body mass was 30 kg per animal). After the slaughter of pigs, the samples of duodenum and jejunum were taken, processed and stored under -60 °C till analyzed the concentration of studied elements and malondialdehyde. To obtain reliable microscopic pictures, the small excisions of the proximal duodenum and middle part of the jejunum were immediately harvested from carcass, the lumen rinsed in physiological solution, fixed in 4% formaldehyde for 2 hours, processed for paraffin embedding and sectioned to slides at a thickness of 5-7 microns. The Goblet cells were counted in 10 longitudinal sections of intact duodenal and jejunal villi. Determination of alkaline phosphatase activity was performed by using a cytophotometrical method at a wavelength of 480 nm.

Results
The concentration of Se, Zn, Fe, Cu, Mg and Ca in duodenum did not reveal the statistical difference between both groups of pigs. However, a significantly lower concentration of Fe (p<0.05) was determined in the jejunum of pigs fed basal diet supplemented with humic substances as compared with that of the control group of pigs receiving only basal diet. Similarly, no statistical differences in the number of Goblet cell and in the concentration of malondialdehyde were found in the duodenum of pigs in both groups. Whereas, the higher number of Goblet cell (p<0.01), higher concentration of malondialdehyde (p<0.001) and significantly lower activity of alkaline phosphatase (p<0.001) were found in the jejunum of pigs fed with the diet supplemented with humic substances.

Conclusions
Taken together, the presented data suggest that the supplementation of humic substances into the diet for pigs decreases the concentration of iron in the jejunum. On the other hand, humic substances could possess the property to increase the intermediate metabolism in the jejunum of weaned pigs. A further research on pigs is needed before clearer conclusive statements can be made about the way how humic substances may cause the above mentioned changes.

Introduction and objectives

Storage of semen has an irreversible effect on its quality (1). Boar spermatozoa are very sensitive to "cold shock" (2). If semen temperature suddenly drops below 15°C, most spermatozoa do not survive (3, 4). After dilution, semen is cooled until 17°C. At this temperature, it can be stored without causing damage (5, 6). The purpose of this study was to investigate whether the storage of boar semen at different temperatures and in different packages influences sperm quality.

Materials and Methods

The experiment was performed in April 2009. Ejaculates (dilution with Minitub BTS® until 2.5x10^9 at 26°C) of 6 Piétrain boars from a commercial AI centre (1 ejaculate/boar), were packed in 2 dissimilar assemblages: blisters (most frequently used: 85% market share) and Gédis® (Genes Diffusion: 12% market share). The semen samples were transported to the laboratory of the Faculty of Veterinary Medicine in Merelbeke, kept at room temperature for two more hours and then stored at 3 distinct temperatures: 14°C, 17°C (standard) and 20°C. To determine the quality of the spermatozoa, the following aspects were investigated: motility, progressive motility, percentage normal and percentage live spermatozoa. The first two parameters were analysed using the CASA (Computer Assisted Semen Analyzer) daily from D0 (semen collection) to D4. The percentage of normal and live spermatozoa was also examined daily in a blinded way using eosin-nigrosin staining. Statistical analysis was performed by means of a linear mixed effects model, in which boar was the random effect (S+).

Results

Table I shows the outcomes (mean over the five days) of the four investigated parameters of the semen, stored at different temperatures in blisters. Table II shows the same, but with semen packaged in Gédis®.

Over the five days, a significant lower percentage live and normal spermatozoa was seen in semen packed in Gédis® in comparison to that in blisters at 17°C (p < 0.05).

In case of extended preservation of the semen (> 2 days), a significant decrease in the percentage live (90.3% vs. 86.1%) and normal spermatozoa (84.7% vs. 80.4%), motility (67.1% vs. 57.4%) and progressive motility (45.9% vs. 32.5%) was observed in both packing methods and at all temperatures (p < 0.01).

Discussion and conclusion

These results show that the quality of boar semen decreases when stored for a longer period than two days as well as when it is preserved at temperatures lower or higher than 17°C. The present study demonstrates also a better longevity when spermatozoa are packed in blisters than in Gédis. To investigate the fertility results of semen stored in these conditions, more in vivo studies are needed.

Acknowledgements

The authors are grateful to AI centre Hypor to provide us with boar semen.

Seasonal high temperatures or inadequate nutrition can decrease reproductive efficiency in boars, especially through both a reduction in the number of ejaculate spermatozoal and abnormal morphology. In these situations, animals are under stress, which can be defined as a body reaction to an adverse condition of the environment in an attempt to achieve thermoregulation and homeostasis. Several hormones, including adrenocorticotropic hormone (ACTH), glucocorticoids, catecholamines and prolactin are involved in stress response and can be measured to quantify this response. Environmental factors seem to be primarily responsible for the reproductive performance of boar and, among these factors stands out nutrition. Organic minerals contain a chain of minerals and amino acids and this association enhances the absorption of minerals in the small intestine by protecting the metal in a complex in an inert chemical form due to covalent and ionic bonds between the ligands and amino acids.

The aim of this study was to evaluate the effect of organic and inorganic trace mineral supplementation on adrenocortical activity in boars exposed to high environmental temperatures in Southern Brazil.

Thirteen boars (± 2 years of age) were divided into three groups to receive inorganic (GIn, n=4), organic (GOr, n=4) mineral supplementation or a lactation control diet (GCo, n=5). Inorganic and organic diets were made of a premix of inorganic and organic trace minerals, respectively, with the same quantity of each trace mineral, based on NRC (nutritional requirements for boars). The lactation diet was based on NRC requirements for lactating sows and contained a higher level of inorganic trace minerals, protein and metabolic energy. For the cortisol analysis 124 fecal samples were collected from organic and inorganic groups and 155 samples from the control group. To determine the concentrations of fecal corticoids, samples collected from the latest feces of the day from males from groups GIn, GOr and GCo, weekly, throughout the experiment from 11:00 to 12:00 h.

Even though the fecal analysis represent a pool of concentrations of metabolites, the time of collection was observed to avoid possible changes in cortisol concentration related with circadian variations. The sample processing (extraction and analysis by radioimmunoassay) was performed at the Laboratory of Hormone levels (LDH), University of São Paulo (USP), following the pattern described by Graham et al. (2001). Radioimmunoassay (RIA) was biologically validated for swine feces by administration of adrenocorticotropic hormone (ACTH) in two boars and fecal samples were collected prior to and one day after administration. Feces collection was done at the same as test animals stool collection. Fecal corticosterone metabolites were quantified by radioimmunoassay double antibody, using commercial diagnostic kit, developed to measure corticosterone in human serum. Values of hormone metabolites were corrected for weight and dilution and expressed in nanograms per gram of wet feces (ng/g). Maximum mean environmental temperatures were higher than the normal thermal comfort temperature for boars (26oC) during the experimental period, and were associated with a reduction in semen quality.

Results are expressed as mean ± SEM. Mean fecal corticoid concentrations, assessed by RIA in wet samples, were similar among groups (GIn 10,932.77 ± 12,332.00 ng/g; GOr 9,088.60 ± 8,748.61 ng/g and GCo 9,988.20 ± 10,072.27 ng/g). However, negative correlations were found between fecal corticoids and normal spermatozoa percentage (P<0.05). Percentage of normal spermatozoa, evaluated by humid preparation technique (KRAUSE, 1966), was higher in the Organic group when compared with both Inorganic and Lactation groups (93.31 ± 5.20% versus 78.48 ± 12.15% and 82.59 ± 17.27%, respectively; P=0.00021). Levels of cortisol's metabolites were found in the stools with a significant negative correlation with the percentage of normal sperm (-0.353, P<0.05) so with the increased adrenocortical activity, there is a reduction in the production of normal sperm, with a consequent increase in the number of sperm morphological defects, when boars were subjected to a stressful situation. Organic mineral supplementation did not influence adrenocortical response to the stressor agent (heat stress) in this experiment, but was beneficial to seminal quality, reducing some of the heat stress effects in exposed boars.
Effects of organic selenium supplementation on mitochondrial potential and integrity of plasma and acrosomal membranes in boar sperm

Introduction
Selenium (Se) is an essential element playing an important role in animal reproduction. The selenoproteins participate in regulation of various physiological functions including antioxidant protection, redox regulation of gene expression and sperm structure integrity maintenance. Although there are some studies regarding the influence of the addition of selenium on the quality of boar semen, researchers did not examine the effects of selenium on membrane integrity of sperm cells and mitochondrial potential. Therefore, the aim of this study was to investigate the effects of organic selenium in spermatozoa quality of boars at 0, 24, 48 and 72 hours after diluting with a semen extender.

Materials and Methods
Fifteen boars were kept on the same conditions and were fed the same standard diet during training. The animals were fed with three experimental diets: 0.3ppm sodium selenite (Control); 0.5ppm sodium selenite (Inorganic) and 0.5ppm selenium yeast (Organic). Ejaculates were collected from each boar once per week using the gloved-hand technique. Semen was diluted with standard extender to 3x10⁹ cells/dose and stored for 3 days at 18°C. For flow cytometry assessment of the integrity of plasma and acrosomal membranes and mitochondrial function, semen samples were diluted in a 37°C prewarmed TALP sperm medium at a concentration of 5x10⁶ sperms/mL. Thereafter, two aliquots (150 µL) were transferred to microcentrifuge tubes. One of these tubes was supplemented with 3 µL of propidium iodide-PI (0.5 mg/mL) and 10 µL of fluorescein isothiocyanate-conjugated Pslum sativum agglutinin-FITC-PSA (100 µg/mL) to evaluate the integrity of plasma and acrosomal membranes, whereas the other received 2 µL of JC-1 (153 µM) to evaluate mitochondrial membrane potential. Samples were incubated in the dark for 8 min at 37°C, and then TALP was added to achieve an appropriate sperm concentration (2.5x10⁶ sperm/mL) for the experimental design was a randomised block. Data were analyzed using the PROC repeated from SAS and outcomes were compared among the three treatments by the orthogonal contrast method with p<0.05 level of significance.

Results
Cells with both plasma membrane and acrosome intact (AIMI) did not differ between treatments, but significance was detected according to time. The higher percentage of the AIMI cells was observed in 0 hours. Mitochondrial potential interaction between treatment and time was not observed, but there was a significant effect for time. There was also a lower percentage of cells in the 24 and 48 hours after dilution.

Discussion
Some studies have reported that the diet supplemented with sodium selenite has improved the quality of boar semen. For the reason of environmental and toxicity concerns, however, the FDA allows a maximum of only 0.3ppm Se in swine diets, but studies have shown that 0.5ppm Se has improved the percentage of normal and motile sperm cells of boars. This result is in agreement with our results, but when we assess more specifically the sperm membranes we found that selenium supplementation did not affect these variables. In conclusion, the selenium yeast showed no better results in comparison to others treatments in the seminal analyses.

Sperm production in Duroc, Landrace, Yorkshire, Berkshire and Pietrain boars kept in evaporative cooling system in Thailand

Chanyuth Tretipskul1 Padet Tummaruk1 Seri Koonjaenak2 Mongkol Techakumphu1
1. Department of Obstetrics, Gynaecology and Reproduction, Faculty of Veterinary Science, Chulalongkorn University, Bangkok, Thailand 10330, Bangkok, Thailand; 2. Kasetsart University, Bangkhen Bangkok, Thailand

Introduction
The sperm production of the boars is affected by several factors such as, breed, season, nutrition and housing (1). Since the environmental temperature in Thailand is often over 30°C for several months of the years, a reduction of pig production and the reproductive performance are observed during hot periods. Nowadays, the evaporative cooling system (EVAP) is normally used for housing boars in Thailand. It has been suggested that this system help to reduce the seasonal variation of the sperm production in Duroc boars (2). However, the variation of sperm production among different boar breeds used in Thailand has not been evaluated. The objective of the present study was to determine the sperm production of Duroc (D), Landrace (L), Yorkshire (Y), Berkshire (B) and Pietrain (P) boars kept in EVAP in Thailand.

Materials and Methods
Semen production data from 377 boars used during a period from January 2003 to December 2009 in a commercial boar stud with different breeds (i.e., 184 D, 45 L, 77 Y, 23 B and 48 P) were analyzed. Each boar was kept in each pen (9 m²/boar) and was fed with 2.2-3.0 kg/day of a commercial feed containing 14-18% crude protein, and 3,000-3,200 kcal DE/kg. All boars were accessed to water ad libitum. The data set consisted of 20,643 ejaculates of semen. Semen parameters including volume (ml), sperm concentration (x10⁶ spz/ml) measured by Spermacue®(Minitube, Tiefenbach, Germany), subjective motility and total number of sperm per ejaculates (x10⁹ spz) were evaluated. The sperm production data were analysed using general linear mixed model procedure (MIXED) of SAS version 9.0. The models included boar breeds, year and month in which the semen were collected as fixed eff ect and included boar identity nested within breed as random eff ect. Least-squared means were obtained and compared among breeds using Tukey-Kramer test. P<0.05 was regarded as a signifi cant difference.

Result and Discussion
The sperm production in each breed is presented in Table 1. Across the breeds, volume, concentration, total sperm per ejaculate and subjective motility were 239.6±94.6 ml, 319.8±97.9 x 10⁶ sperm/ml, 71.7±25.4 x 10⁹ sperm/ejaculate and 73.4±8.8% of motility, respectively.

The sperm production of boars differed among the breeds. D and B boars had a lower semen volume and total sperm per ejaculate than L and Y boars. It has been demonstrated that both volume and concentration of the boar semen had a heritability of 0.58 and 0.49, respectively (3). Selection of boars, used in tropical climates, based on sperm production is therefore important.

In conclusions, the semen production of L and Y boars kept in evaporative cooling system in Thailand were superior to D, B and P boars.

Seasonal influence on sperm production in boars kept in evaporative cooling system in Thailand

Chanyuth Tretipskul1 Padet Tummaruk1 Seri Koonjaenak2 Mongkol Techakumphu1
1. Department of Obstetrics, Gynaecology and Reproduction, Faculty of Veterinary Science, Chulalongkorn University, Bangkok, Thailand; 2. Kasetsart University, Bangkhen Bangkok, Thailand

Introduction
Fluctuation of temperature and humidity cause a decrease of semen output in boar (1). It was found that high sperm production was observed in autumn and winter but low sperm production was observed in summer (2). In Thailand, evaporative cooling system (EVAP) is commonly used for boar housing in order to minimize the seasonal effect of the sperm production. An earlier study in Thailand has demonstrated that the total number of sperm per ejaculate was 72.2 x 10⁹ and 74.9 x 10⁹ sperm in boars kept in evaporative and in conventional open housing system, respectively and minor difference in the seasonal pattern was found between the two housing system in Thailand (3). However, high humidity negatively affect both semen volume and total sperm output (3). The objective of the present study was to investigate the seasonal influence on sperm production of boars kept in evaporative cooling system in Thailand.

Materials and Methods
Semen production data from 20,502 ejaculates of 554 boars (164 Duroc, 14 Yorkshire, 23 Berkshire, 31 Pietrain, 54 crossbred Pietrain x Duroc and 268 crossbred Landrace x Yorkshire) collected during January 2006 - December 2009 in a commercial boar station were included. Each boar was kept individual pen (9 m²/boar) and was fed with 2.2-3.0 kg/day of a commercial feed containing 14-18% crude protein, and 3,000-3,200 kcal DE/kg. The boars were accessed to water ad libitum. Semen parameters including volume (ml), sperm concentration (x10⁶ spz/ml) measured by Spermacue®, subjective motility and total number of sperm per ejaculates (x10⁹ spz) were evaluated. On average, the temperature (°C) and Humidity (%) in EVAP from Jan to Dec were 22.5/85.7, 23.8/82.2, 25/81.6, 25/82, 24.9/86, 25.1/85, 25/86.3, 25/85.2, 24.8/85.4, 24.5/86.1, 22.6/85.6 and 21.8/85.5, respectively. The sperm production data were analysed using general linear mixed model procedure (MIXED) of SAS version 9.0. The models included boar breeds, year and month in which the semen were collected as fixed effect and included boar identity nested within breed as random effect. Least-squared means were obtained and compared among breeds using Tukey-Kramer test. p<0.05 was regarded as a significant difference.

Result and Discussion
On average, the semen volume, concentration, total sperm per ejaculates and individual motility were 249.4±97.9 ml, 334.6±96.3 x 10⁶ sperm/ml, 78.7±28.6 x 10⁹ sperm/ejaculate, and 73.9±11.1% subjective motility, respectively. The sperm production by months is presented in Figure 1.

Figure 1 Least-squared means and standard error of total number of sperm/ejaculation by months.

The total number of sperm production in March, August, September and October was significantly lower than April, May and November (Figure 1). Since spermatogenesis spent 35 – 40 days for completing process, short day length during August-October might cause the decrease of sperm production. Furthermore, high humidity during rainy season (Jul-Oct) might also contribute to the seasonal influence on the sperm output of boars kept in EVAP in Thailand. It could be concluded that the seasonal influence on the sperm production was still observed in boars kept in EVAP in Thailand.

Reproductive failure associated with poor AI dilution

John Carr
Portec Australia, Belmont, WA, Australia

Introduction

The preparation of diluent used in artificial insemination is a key component in processing semen.

Failure to achieve the correct osmotic pressure by incorrectly diluting the extender is more difficult to detect during the semen examination. This paper reports a failure to achieve the correct dilution and subsequent effect on reproduction.

Clinical outline

A 32 sow 2 week batch farm practiced on-farm AI. Following a change in stockpeople, the farm suffered a massive drop in farrowing rate.

Problems started in batch 22 and ended in batch 33 with a change in AI practice. Statistical process control clearly demonstrates the production issue.

Detailed analysis of the semen processing revealed that the stockpeople has misread their instructions and were not diluting the extender properly. In general they were over-diluting – adding 1.5 litres of distilled water to 50g of diluents instead of only 1 litre.

AI semen samples were examined without any obvious abnormality being detected. There were no change in live to dead ratios, semen abnormalities or semen movement. Visual analysis of the semen immediately post-dilution, the semen appeared to be stunned and did not move properly. However, within an hour, their movement became visually normal.

The diluents was examined for conductivity mS/cm 17°C where the failure of adequate dilution was confirmed. The conductivity at various dilutions:

<table>
<thead>
<tr>
<th>Water l</th>
<th>0.5</th>
<th>1.0</th>
<th>1.5</th>
<th>2.0</th>
<th>Water</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cond. mS/cm</td>
<td>12.83</td>
<td>8.01</td>
<td>5.88</td>
<td>4.60</td>
<td>0.01</td>
</tr>
</tbody>
</table>

The initial concern was noticed the stockpeople failing to detect 3 and 4 week returns. The stockpeople subsequently mislead management about pregnancy results rather than believe the extreme poor performance.

Consequence and cost of the AI failure

The farm lost 780 weaners associated with this reproductive failure. At $AU 3.40 per kg deadweight costs this resulted in a $75,000 increase in fixed costs – or $9 increase per pig sold over the next year.

Detailed production results

The batch farrowing rate %

The upper line represents the mean, the lower line 2sd below the mean

- Pre-batch 22 Mean 80 Standard deviation 6.6
- Batch 22 to 33 Mean 49 Standard deviation 17

Statistical process control indicates that from batch 23 the system was out of control 10/11 batches. Statistical analysis indicate a p <0.001 difference between batches 22 and 33 and normal.

Piglets weaned per farrowing sow

The middle line is the mean. The two other lines represents 2sd above and below the mean

- Pre-batch 22 Mean 9.1 Standard deviation 1.3
- Batch 22 to 33 Mean 10.1 Standard deviation 2.0

Statistical process control indicates that from batch 22 to 33 the system was never out of control. Statistical analysis indicate p = 0.14. There is no difference in numbers weaned between batches 22 and 33 and normal.

Discussion

Failure to adequately dilute semen resulted in a catastrophic failure of reproduction. The farrowing rate collapsed. The litter size – numbers weaned – did not statistically change. Those sows who became pregnant had normal litters.

The failure of dilution was confirmed by monitoring the conductivity of the diluent. As osmolarity is difficult to measure in the field, conductivity should be included in the standard AI investigation.

The stockpeople did not initially accept their failing and attempted to cover up the problems.

Retrosion rate and boar productivity in two genetic transfer centers managed under an all-in all-out system in central western México

Arturo Juarez-Martinez1 Joaquin Becerril2 Raul Ortega3 Pedro Aceves4 Pedro Vargas4 Jesus Gonzalez1
1. PIC Mexico, Queretaro, QRO, Mexico; 2. LAPISA, La Piedad, MICH, Mexico; 3. Independent Consultan, Morelia, MICH, Mexico; 4. CTG Sinergia, S.P.R. de R.L, La Piedad, MICH, Mexico

Introduction
It has been demonstrated (1, 2), the effect of environmental and genetic factors on the productivity of boars at two Genetic Transfer Centers (GTC), managed under an all-in all-out systems (AI2O), as well as some estimates of longevity, productive life and seminal output repeatability (3). The aim was to obtain comparative estimates for retention rate, live sperm production, and semen doses produced, in two GTC managed under an AI2O system, that were filled with boars sourced from a single genetic supplier.

Materials and Methods
Data was obtained from two GTC established in Michoacan, Mexico, and located at 1020 15'N and 190 50' W. GTC One (GTC1), operated from Sept 1, 2004 until Jan 31, 2007, with an initial inventory of 66 boars. GTC Two (GTC2), operated from Jun 1st, 2006 until Dec 31st 2008, with an initial inventory of 77 boars. Retention rate (RR) was analyzed by trimesters, in order to obtain Lineal Regression Models for each GTC. Sperm production analysis was carried out considering total sperm live concentration per ejaculate (TSLCE) and based on the interval between collections (CI). Annual semen doses production was calculated for each one of the GTC and the boar dose production was carried out by percentile (100, 75, 50, 25). The whole analysis was performed using SAS System SAS (Ver.8.0, 1999).

Results
For GTC1 and GTC2, 10,086 and 11,997 ejaculates were processed respectively. All boars were introduced on the same day and were first ejaculated at an average age of 230.6±28.7 days. For GTC1, the obtained models for RR were 108.49**-7.21** (trimester); R2=0.97, and for GTC2, RR were 109.27**-4.97** (trimester); R2=0.98. The obtained models for TSLCE did not explain the variation observed: GTC1: TSLCE=47114*+95.19* (CI); R2=0.003; and for GTC2: TSLCE = 46840**+194.3** (CI); R2=0.008, although, all coefficients were significatively different we conclude that for a longer collection interval, there will be an increase on doses produced, therefore the importance of follow up an adequate CI protocol. At each GTC, there were also productivty differences between periods and the same happened when doses produced per boar during his lifetime were evaluated (Table 2), where a declining trend was observed between RR, ejaculates processed and total doses produced at each GTC. In a previous study, it was established that a peak of doses produced was reached at 953 days of age, with an average of 20.3 doses per ejaculated (1).

Discussion
For RR and considering regression trend, there was the same direction for both GTC, but not its magnitude, neither on its time-dependent distribution. Also, it was possible to see improvement in GT2, maybe due to a better understanding and more experience gained. Regarding TSLCE and although, all

**High levels of dietary Zn-Methionate increase sperm DNA fragmentation in the boar: A preliminary investigation**

A García-Contreras 1 Y De Loera 2, C García-A 2, A Palomo 2 J Guevara-G 3 J Herrera-H 4 C López-F 5 J Gosálvez 5

**Introduction**

Zinc (Zn) is as a member of metalloenzymes (GP, SOD) whereby it operates as an essential trace element important to a range of the reproductive processes in mammalian species (1). This mineral is necessary for the stability of sperm chromatin and embryonic development (2). Studies have demonstrated an increase in a range of abnormal seminal parameters linked to deficiencies in Zn concentration. The boar is susceptible to the adverse effects of Zn deficiency, so that there is increasing interest to understand the relationship between dietary levels of Zn sources and its effect on fertility. Rojas et al. (3) shown that there is a difference in the bioavailability of Zn source, well as the rate of absorption, transfer mechanisms, metabolism and storage (4). The aim of this investigation was to assess the influence of elevated concentrations of dietary Zn-Methionate (Zn-Met) on sperm DNA fragmentation (SDF).

**Material and Methods**

This experiment was conducted using ten individually housed York-Landrace breed boars with an age average of 8 months. Five boars received a standard food ration (SFR) containing 25 ppm Zn and were used as a control. The SFR was balanced according to NRC requirements (1998) using a premix of grain supplemented with soybean, vitamins and minerals. The experimental group consisted of 5 boars that were fed on a SFR containing a supplement of 200 ppm Zn (Zn-Met200). Boars were assessed for sperm DNA fragmentation (SDF %) over 6 consecutive weeks. The levels of SDF were measured using the Sperm-Sus-Halomax assay (DNA Halotech SL, Madrid, Spain). SDF mean values were compared with Tukey's test.

**Results and Discussion**

Fig. 1 shows the effect of increased dietary Zn on the SDF of boar semen collected over 6 consecutive weeks. On average the level of SDF for the control group was 2.91 ± 3.04%; this value is likely to be with the normal range for this species, i.e. <5% (5,6). However, boars receiving the Zn-Met200 diet showed average values for the SDF of greater than 15.01 ± 3.10 %, which was in the order of four times more intense that those values found in the Control (P=0.003) and values previously reported for boars (6). An interesting unexpected observation was the weekly rhythmic (10 to 20%) expression of SDF throughout the collection period (Fig.1). Although dietary Zn-Met200 in this experiment resulted in significant damage to the sperm DNA during the period of feeding, further studies are required to determine whether this effect is reversible if the animal is returned to a normal diet or whether the initial exposure to high levels of dietary Zn may interfere with future normal sperm development. Since a diet containing 200 ppm of organic Zn (Zn-Met) resulted in a significant increase in boar sperm DNA damage, new ongoing experiments have been conducted to investigate the maximum level of Zn which does not interfere with the baseline level of SDF.

**Fertility of sows inseminated with extended semen stored at +5°C or +17°C**

Caterine Braga\(^1\) Maristela Palhares\(^1\) Amanda Siqueira\(^1\) Mário Moraes\(^2\) José Monteiro Silva Filho\(^1\)

1. Federal University of Minas Gerais, Belo Horizonte, MG, Brazil; 2. DB-Dan Bred, Patos de Minas, MG, Brazil

**Introduction**

Cooling boar semen to lower temperatures is necessary for transport over long distances and exchange of material genetic as sperm cryopreservation remains suboptimal in this species. Moreover, temperature reduction has been used to prolong the sperm viability, as a result of decreased cellular metabolic processes and bacterial growth reduction. However, there are few studies related to the preservation of boar sperm at +5°C and its effectiveness "in vivo", involving the measurement of fertility parameters, such as farrowing rate, return to oestrus and litter size. Thus, the objective of the research was to evaluate the reproductive performance of sows inseminated with semen diluted in glycine-egg yolk extender (1) and cooled to +5°C.

**Material and Methods**

A total of 70 primiparous and multiparous sows were distributed uniformly, after grouping by breed and parity, into two treatments: TI (n=35) – sows inseminated with semen diluted in BTS® extender, submitted to stabilization period at room temperature (23±2°C) for 2 hours, with subsequent storage at +17°C (control treatment); and TII (n=35) – sows inseminated semen diluted in glycine-egg yolk extender (1), submitted to a stabilization period at room temperature (23±2°C) for 4 hours, before cooled at +5°C in previously described container (2). The females of both treatments were inseminated with doses containing 3x10\(^9\) viable sperm. The first insemination was performed 12 hours after the onset of oestrus, and the subsequent every 12 hours, for up to three insemination. If still in oestrus within 24 hours of the third insemination, the sows also received a fourth insemination. The data were analyzed using the statistical program "Statistical Analysis System", Version 5 - Microsoft ©, with a significance level of 95% (p <0.05). The data were submitted to the procedure GLM (General Linear Models) and the quantitative variables analyzed by SNK or Student’s t test, and proportional variables, by chi-square test (\(\chi^2\)).

**Results**

The semen extended in glycine-egg yolk (TII) was superior (p<0.05) with regard to the maintenance of the physical characteristics (motility and vigor), after 19.79±7.06 hours of storage (TI=68.17±5.83% and 3.19±0.43; TII=75.47±3.78% and 3.60±0.42). Regarding the sows reproductive performance, there was an influence (p<0.05) of treatment on the farrowing rate, from 77.14% with semen diluted in glycine-egg yolk and stored at +5°C in special container to 97.14% when using the semen diluted in BTS® and kept at +17°C. However, there were no significant differences (p>0.05) between treatments regarding the average of total number of born piglets (14.87±2.85 vs. 10.72±3.94) and born alive (13.26±2.89 and 10.12±3.53), for TI and TII, respectively.

**Discussion**

Studies related to cooling boar spermatozoa at +5°C showed a farrowing rate of 85% (4) or 63% (1). Thus, the results found here are in agreement with those showed in the literature. Boar spermatozoa are sensitive to cooling below +15°C (3), and membrane damages increasing with the storage time reducing the sperm longevity (5). Thus, one alternative to use of cooled boar semen will be the change in the site of sperm deposition in the female genital tract as have been made with cryopreserved semen in this specie.

**Conclusion**

The use of swine semen cooled to +5°C proved to be viable using the glycine-egg yolk extender and container proposed (2). However, caution is recommended when used on a large scale in commercial herds, especially considering the excellent reproductive performance of sows submitted to intracervical insemination with sperm diluted in BTS® and kept at +17°C.

Main bacterial species isolated from commercial seminal doses and antibiotic activity

René Mozo-Martín; Yahya Dahmani; Carmen Larraz' Juan Luis Úbeda
R&D department, Magapor SL, Ejea de los Caballeros. Zaragoza, Spain;

Introduction

Presence of bacterial contamination in pig seminal doses occurs with some frequency in artificial insemination centres, and may have a negative effect on its durability, even using ejaculates with good spermatic quality. Normally the source of this contamination is the own boar. However, distilled water used to elaborate the seminal doses can also be an important source of bacterial contamination. To overcome this problem it is essential to have a good hygiene and disinfection protocol. Moreover it is necessary to use extenders with an effective antibiotic combination. The aim of this study is to observe the main bacterial species isolated from seminal doses and to assess the activity of antibiotics commonly used against these microorganisms, in the seminal doses production and swine reproductive infections.

Material and Methods

The study was carried out with more than 170 diluted sperm samples from artificial insemination centres located throughout the Spanish geography. The sample cultures were routinely performed within 24 hours post-dilution (without any previous manipulation). Bacterial isolation and identification were performed in TSA agar (incubation 24 hours at 37 °C ± 1 °C). A kit API-20E was used to identify isolated bacteria, while the antibiogram was performed by diffusion in Mueller-Hinton agar (incubation 24 hours at 37 °C ± 1°C). The antibiogram test was carried out using antibiotics routinely included in the elaboration of seminal doses or pig reproduction pathology chemotherapy. Statistical analysis was developed with relative frequency description for bacterial isolates (StatView 5.0 statistical package) and Chi-Square for antibiotics activity (WinEpi: Working in Epidemiology).

Results

The most commonly bacterial species isolated in extended semen samples were those shown in Table 1.

Figure 1 show the frequency which bacterial isolates present sensitivity (S), resistance (R) or intermediate-acting (I) against antibiotics commonly used in pig reproduction (differences among antibiotic activity: p<0.0001)

Discussion: Isolation of bacteria in seminal doses treated with antibiotics, indicate that it is produced a selection of bacterial species according to their susceptibility (resistance) to this antibiotics (i.e.: S. marcescens). Therefore, we consider essential to make an accurate bacterial type diagnostic and quantification, in addition to, a proper antibiotic selection to use. Taking into account frequent apparition of bacterial species with resistance or intermediate susceptibility to some antibiotics, no randomly selected antibiotic combination with synergic activity may support a proper tool to guarantee the minimum detrimental effect caused by bacterial contamination in the seminal dose conservative period. In short, With the objective of find more efficient antibiotic combinations, we consider essential assessing the activity and the MIC (Minimum Inhibitory Concentration) to each antibiotic about no treated seminal doses.

Correlation between sperm quality traits in seminal doses distributed by boar stud to farms in Spain

Yahya Dahmani; René Mozo-Martín; Carmen Larraz; Juan Luis Úbeda

R&D Department, Magapor SL, Eje de los Coballeros. Zaragoza, Spain

Introduction
Fertilizing potential assessment of an ejaculate or semen doses destined for swine artificial insemination (AI) includes evaluation of sperm quality traits like morphology, concentration, motility and functionality of sperm membrane. Nowadays, in Spain there are more than 60 boar stud supplying boar semen doses for farms, and in some cases, the distance between centres and farms is large. Nevertheless, semen doses should exhibit adequate fertilizing predictive parameters comply with standard limits. The aim of the present study was to assess sperm quality traits of seminal doses supplied by boar studs in Spain during last 5 years, and to investigate the correlations between these sperm parameters.

Materials and Methods
8728 semen doses were obtained from 56 commercial AI boar studs between January 2004 and December 2009. Semen quality parameters: Motility, Concentration, Whole acrosoms, functionality of sperm membrane (Host), sperm abnormal forms (head, tail, mid-piece, proximal and distal droplets) and temperature of semen doses reception in laboratory were checked. All analyses were carried out by the same person. Data were processed by StatView 5.0 software (1). Model of Multiple Regressions was used to test the correlation between all parameters and ANOVA test was applied to confirm differences of variances. Significant differences were considered when p<0.05.

Results
All sperm parameters analyzed were acceptable and according standard limits, excluding, sperm abnormal forms which expressed mean value of 32 ± 7, superior to standard limit value (30%). Regression coefficients between parameters are illustrated in table 1. Motility showed a correlation (R= 0.4) with whole acrosoms and negative slight correlation with total sperm abnormal forms and with abnormal tails. A great logical correlation was observed between sperm abnormal forms and abnormal tail, proximal droplets and distal droplets.

In what concern temperature of semen doses reception in the laboratory, ANOVA analyses showed increased values from June until September, and decreased values from December to Mars. In parallel, functionality of sperm membrane (Host) changed similarly and inversely (P<0.0001, figure 1). Correlation between both parameters was negatively significant R = - 0.4 (Table 1).

Discussion
In this study, we observed some correlations between different sperm quality parameters. Motility demonstrated a correlation with intact acrosoms and negative correlation with total sperm abnormal forms and specifically with spermatozoa with abnormal tails which appear coherent with requirements for propulsion and movement of sperm. Furthermore, sperm abnormal forms were clearly correlated with abnormal tails and presence of proximal and distal droplets. This finding corroborate that any change or influence of total abnormal forms of sperm can be explained by these three classes of sperm morphoanomalies: abnormal tails, distal and proximal droplets. It’s of utmost importance the good checking of abnormal forms, because negative association between morphological anomalies and fertility was observed in several studies (2, 3). Other parameter which showed a significant variation is the temperature reception of seminal doses. Some differences found in Host values could demonstrate the importance of minimize the temperature variation during sperm processing and transportation, even the temperature inside de boar stud, because a significant fall in this parameter during hot months can take place. Any change in this area can affect functionality of sperm membrane and consequently the potential fertility of semen doses.

Fertility and prolificacy of boar semen extended with Duragen® and BTS

René Mozo-Martín; Yahya Dahmani; Carmen Larraz; Juan Luis Úbeda
R&D department, Magapor SL, Ejea de los Caballeros, Zaragoza, Spain

Introduction
The productivity of the swine industry is highly dependent on artificial insemination and consequently on the production and transport of boar semen. Technologies of swine reproduction have developed semen extenders based mainly on salts and sugars denominated short term extenders, long-term and extra long-term extenders. Many of the commercial extenders have been investigated in vitro for their fertilizing potential using some sperm parameters like motility.

Duragen® is an example of these extenders, and it’s the unique extender which can preserve sperm parameters for 2 weeks. It has been demonstrated that Duragen® maintains a high degree of sperm fertility for more than 12 days and increase the farrowing rate also at 1 day of sperm extension. Some studies in vitro about quality of sperm motility in extended semen with Duragen® (data not shown) suggest a down-regulation of sperm motility at 24 hours, since it was observed that sperm exhibit value of average head orientation change (AOC) lower than 5, being characterized as immotile. The aim of this study is to investigate the fertilizing potential of extra-long term extender Duragen® after 24 hours of semen extension.

Materials and Methods
The sperm rich fraction of ejaculates from fertile boars were collected, evaluated and pooled. Seminal heterospermic doses of 3 billion spermatozoa in 90 ml were prepared with Duragen® and BTS extenders, and stored at 17°C before being used for artificial insemination at 24 hours. 4464 multiparous crossbred sows (Landrace x Large White) were randomly divided in tow groups. Group1: BTS N=2303 and Group2: Duragen®, N=2161. Cervical Insemination was performed at 0 and 24 hours after external estrus signs observation. 2303 inseminations were carried out with semen extended with BTS and 2161 with Duragen®. Farrowing rate (FR) and total born piglets were checked. Data were processed by StatView 5.0 software. ANOVA test and post hoc analyse were performed to confirm differences in variances of FR. Significant differences are considered when p<0.05.

Results
1996 sows inseminated with semen extended with BTS get to farrows, showing a fertility rate of 86,67%. In parallel to this data, 1917 sows inseminated with semen extended with Duragen® a higher significant fertility rate 88,7% (P= 0,03) Tabe 1. In what concern total number of piglets and mean of born piglets per sow, no differences was found between both groups Duragen® and BTS (P=0.13).

Discussion
Fertility rate of sows inseminated with semen extended for 24 hours with BTS and Duragen® was higher in Duragen® group. This funding demonstrate that Duragen® can be used at 24 hours as short-term extender, even it is developed for extra-long term conservation of boar sperm. In addition, this exhaustive study with 4464 sows, demonstrate strongly the functionality of Duragen® at 24 hours excluding any doubt about fertilizing potential of Duragen® at 24h even the observation on quality of sperm motility at 24h.

Boar semen cryopreservation: effects of straws types, number of spermatozoa, insemination site

Pierre Thilmant
Centre Provincial liégeois e de productions animales, Argenteau, Belgium

Introduction
The objectives of this study are to check 2 types of French straws for boar semen cryopreservation: medium or 0.5 ml versus fine or 0.25 ml; the number of straws per dose (10, 5, 4 or 3); 2 insemination sites: intracervical versus intrauterine (corpus); 2 insemination volumes (100 versus 50 ml) with intracervical insemination. The goal is to decrease the number of spermatozoa per insemination dose and to have good results on the field.

Materials and Methods
210 sows have been inseminated with frozen semen in 2 farms. 24 ejaculates of 7 Pietrain boar have been frozen with own method (1, 2). Each 0.5 and 0.25 ml straws contained respectively 0.72 x 10^9 and 0.32 x 10^9 spermatozoa. The 0.5ml straws were thawed by immersing in a hot water bath at 55°C during 12 seconds and the 0.25 ml straws in a water bath at 38°C during ± 60 seconds (no risks of overheat). After that, the contents were directly poured into BTS at 38°C. Semen was thawed just before the insemination. Double AI has been made 5 days post weaning during the standing reflex. We have used a foam tip insemination catheter for intracervical insemination (IC) and the same catheter equipped with a flexible tube for the post cervical insemination (IU). 2 parameters have been measured: pregnancy rate with an ultrasound scan between 23 - 42 days post AI and the litter size or total piglets born per litter. Three trials were successively performed. The first tested the effect of straws types and number of spermatozoa per dose (from 3.6 to 1.0 x 10^9); the second and third trials tested these same alternatives and insemination sites (trial 2) or insemination volumes (trial 3) on sows' pregnancy rates and litters size.

Results
With IC insemination and 100ml insemination volume, the pregnancy rate (92.9%; n=141) was not influenced by the straws types and the number of spermatozoa. However it has significantly decreased when IU inseminations were performed (60.0; n=30 versus 91.7%; n=180; p<0.05) and particularly with 1 x 10^9 spermatozoa or 3 fine straws (50.0; n=10). There was no significant difference between the 2 volumes when IC inseminations were performed 92.9; n=141 versus 87.2%; n=39) whatever the straws type and the number of spermatozoa per dose. The litter size was significantly higher when sows were intracervically inseminated using 3.2 x 10^9 (10 fine straws) versus 1.0 x 10^9 spermatozoa (12.3 ± 0.6; n=20 versus 10.6 ± 0.5; n=31; p<0.05). In the same way, the litter size tended to decrease when IU rather than IC insemination was performed (11.5 ± 0.2; n=156 versus 10.2 ± 0.7; n=16; p= 0.08). There was no significant difference between results obtained when using 100 ml insemination volume (11.5 ± 0.2; n=139) versus 50 (11.0 ± 0 5; n=33) when IC inseminations were performed, whatever the straws type and the number of spermatozoa.

Discussion
With IC insemination, the pregnancy rate is always above 86.8% despite the spermatozoa number and straw type, lower litter size is with 1 x 10^9 spermatozoa / dose. The IC insemination is not influenced by the volume (100 or 50 ml). With IU insemination, pregnancy rate and litter size are lower than IC insemination.

So, with frozen semen, we recommend intracervical insemination with a minimum 1.3 x 10^9 spermatozoa / dose or 4 fine straws / dose

Using autologous and heterologous boar sperm supernatant from freezing processes as post-thawing solution: its effect on sperm motility

Kampon Kaeoket1 Panida Chanapiwat1, 2 Padet Tummaruk2 Mongkol Techakumphu2 Annop Kunavongkrit2
1. Faculty of Veterinary Science, Mahidol University, Phutthamonthon, Nakorn-pathom, Thailand;
2. Faculty of Veterinary Science, Chulalongkorn University, Bangkok, Thailand

Introduction
Cryopreservation process damage the sperm plasma membrane by a number of reason, e.g. cold-shock effect, osmotic stress and oxidative stress from reactive oxygen species (ROS) which result in a decrease of sperm motility, viability and fertilizing ability (Kaeoket et al., 2008). It is evidence that seminal plasma able to arrest or reverse cryoinjury and perhaps extend the longevity of the sperm by inhibiting or reversing capacitation and acrosome reaction, and also by its antioxidant activity (Vadnais and Roberts, 2007). The aim of this study was to evaluate the effect of post-thawing dilution with autologous and heterologous sperm supernatant on motility of frozen-thawed boar spermatozoa.

Materials and Methods
During the cryopreservation, sperm supernatant (a combination of seminal plasma and semen extender, 50% v/v) or seminal plasma from 9 boars (Duroc, Large White and Landrace; 3 in each) was collected by centrifugation and stored frozen until using as post-thawing solution. Sperm pellet were further processed and cryopreserved using control rate freezer and was thawed at 50°C for 12 sec. After thawing, frozen thawed semen was diluted with seminal plasma (group A), supernatant from Landrace (group B), supernatant from Large White (group C), supernatant from Duroc (group D) and Modena® semen extender (group E). Post-thawing motility was evaluated using a phase contrast microscope after thawing at 1, 10, 20 and 30 min. The present results show that at 1 min, a significantly higher percentage (P ≤ 0.001) of progressive motility was found in groups B (53.3%) and C (53.9%) than the other groups. At 10 min, the highest (P ≤ 0.001) progressive motility was found in groups B (65%) and C (61%). At 20 and 30 min, a significantly higher percentage (P ≤ 0.001) of progressive motility was found in groups B (58.9%), C (53.5%) and D (45.6%) than groups A (3.9%) and E (20.6%).

Discussion
It is clearly showed, in the present study, that using autologous or heterologous sperm supernatant from cryopreservation process as post-thawing solution yielded a superior frozen-thawed boar sperm motility (as high as 70%). This is in accordance with the studies in dog (Rota et al., 2007) and boar (Okazaki et al., 2009) in which seminal plasma and prostatic fluid, respectively, were added in post-thawing solution.

Conclusion
It can be concluded that supernatant from freezing processes (consisting of seminal plasma and Modena®, 50% v/v) had beneficial effect on post-thawing progressive motility of frozen boar semen.

References
Introduction
Since 2000 when Gil et al. (1) published the first reproductive results obtained by using Post Cervical Artificial Insemination (PCAI), it was proved that the number of sperms that guarantees similar reproductive results to those used in the standard AI is 1.0 billion (2). Also it is possible to obtain excellent results using doses of 15 ml and half billion sperms, but it is necessary to increase the inseminated volume by infusing 15 ml of extender after the semen introduction (3).

In 2006 we improved the technique by adding the cervical stimulation (4). The results obtained confirm that this management improves litter size.

After semen introduction, cervical stimulation could help the preovulatory pulsatile LH release that lead to the ovulation process (5) and advance the ovulation or perhaps promote passive sperm transport by enhancement of uterine contractions.

Is it possible to inseminate less than 30 ml and obtain good results when stimulating the uterus by cervical stimulation? This paper shows the results.

Material and Methods
The trial was carried out in a 1700 sows farm. In this farm PCAI was used in weaned sows in a habitual way. After standing oestrus control, sows were randomly allocated to three treatment groups. In group Mono-phase 30 (MPh30), sows were inseminated with doses of 30 ml and 1.0 billion sperms. In group Bi-phase 30 (BPh30) sows were inseminated with doses of 18 ml and 0.6 billion sperms and 12 ml of extender added after the infusion of the dose. In group Mono-phase 18 (MPh18) sows were inseminated only with doses of 18 ml and 0.6 billion sperms.

To apply the semen it was used a combined catheter-cannula kit (Soft & Quick, Import-vet, Spain). In all groups, the sows received a cervical massage. After the infusion of the dose in groups MPh30 and MPh18 or the dose and the extender in group BPh30, only the cannula was removed and then with the catheter, still placed in the cervix, shaking it in a rotational way, the neck of the womb was massaged during five to ten seconds. Once the massage was finished the catheter was also removed.

Results
Table 1 shows that there isn’t relationship between the treatments with the fertility and prolificity levels. Farrowing rate is very similar in all groups, 89.74%, 92.11% and 89.74% in MPh30, BPh30 and MPh18. The best litter size, 12.20 total born and 12.11 born alive, takes place in the MPh18 group, being very similar, + 0.17 total born and + 0.25 born alive, in MPh30 group and being considerably better, + 0.51 total born and + 0.65 born alive, than the BPh30 group, 11.69 total born and 11.46 born alive.

Table 2 shows the percentage of litters according to the number of total born. It attracts our attention the difference in percentage of short litters, 11.5% vs. 5.8% in BPh30 and MPh18 respectively. The smaller number of short litters in MPh18 group increases the percentage of large litters 28.6% vs. 20.10% in BPh30 group.

Discussion
The reduction of the percentage of short litters leads up to improve the litter size in MPh18 group.

These results suggest us that isn’t necessary a large volume so the uterus can absorb the semen when it’s properly stimulated. Cervical stimulation seems to promote passive sperm transport and allow excellent reproductive results with small doses of semen.

Post cervical artificial inseminastion use of different volumes and sperms number with cervical stimulation

Javier Gil1 Ana M. del Valle2 Antonio Roset3

1. JGPasesor S.L.P., Segovia, Spain; 2. Pinsos YAK, Lleida, Spain; 3. ARVET Veterinaria S.L., Lleida, Spain

Introduction

Since 2000 when Gil et al. (1) published the first reproductive results obtained by using Post Cervical Artificial Insemination (PCAI), was proved that the number of sperms that guarantees similar reproductive results to those used in the standard AI is 1.0 billion (2). Also it is possible to obtain excellent results using doses of 15 ml and half billion sperms, but it is necessary to increase the inseminated volume by infusing 15 ml of extender after the semen introduction (3).

In 2006 we improved the technique by adding the cervical stimulation (4). The results obtained confirm that this management improves litter size.

After semen introduction, cervical stimulation could help the preovulatory pulsatile LH release that lead to the ovulation process (5) or perhaps promote passive sperm transport by enhancement of uterine contractions.

Is it possible to inseminate less than 30 ml and obtain good results when stimulate the uterus by cervical stimulation?

Material and Methods

The trial was carried out in a 760 sows farm. PCAI was used in gilts and weaned sows in a habitual way. The trial was conducted in three consecutive periods. In the first, from 09/02/09 to 15/03/09, sows were inseminated with doses of 45 ml and 1.4 billion sperms. In the second, from 16/03/09 to 19/04/09, sows were inseminated with doses of 20 ml and 0.6 billion sperms.

In the third, from 20/04/09 to 21/05/09, sows were inseminated with doses of 30 ml and 0.9 billion sperms. In all groups the first insemination was done half a day after heat detection. In the first group sows were inseminated three times every half a day. In the other groups sows were inseminated four times every half a day.

To apply the semen it was used a combined catheter-cannula kit (Soft & Quick, Import-vet, Spain). In all groups, the sows received a cervical massage. After semen infusion only the cannula was removed and then with the catheter, still placed in the cervix, shaking it in a rotational way, the neck of the womb was massaged during 5-10 seconds. Once the massage was finished the catheter was also removed.

Results

Table 1 shows that the fertility level and the farrowing rate are very similar in all groups, 90.55%, 89.29 and 91.79% respectively. However, there is a difference in litter size according to the treatment. The best litter size, 12.55 total born and 11.58 born alive, takes place in the 20ml group, followed by 45ml and 30ml groups with 12.02 and 11.78 total born and 11.20 and 10,98 born alive respectively.

Table 2 shows the litter size by parity. In 45ml and 20 ml groups litter size was very similar in each parity. In group 30ml litter size was also very similar to other groups from 3 to 6 parities but was considerably lower in parities 1 and 2.

Discussion

Inadequate management of nulliparous and primiparous sows during the period of 30ml group may have been responsible for this drop in production in parities 1 and 2.

The 20ml group results, better than those obtained in group 45ml, suggest us that isn’t necessary a large volume so the uterus can absorb the semen when it’s properly stimulated. Inseminate with low number of sperm in a normal dilution ratio, without the need of increasing the total volume, greatly facilitates the success of PCAI with low number of sperms.

Use of P.G. 600® in replacement gilts with unknown reproductive status: Ovarian, estrual and fertility responses

Robert V. Knox
University of Illinois, Urbana, IL, USA

Introduction
Effective methods to induce and synchronize estrus in replacement gilts are essential for controlling costs related to size of the gilt pool, days from entry to service, and fertility. We performed two experiments to evaluate ovarian and estrual responses to use of P.G. 600® in gilts with known or unknown reproductive status.

Materials and Methods

Experiment 1
PIC gilts (n=15) >6 mo. of age and ~140 kg but of unknown reproductive status, were treated with MATRIXTM for 14 days. Following last MATRIXTM feeding (LMF) gilts were checked for estrus and ovarian status determined using ultrasound. All gilts diagnosed with or without corpora lutea (CL) were treated with P.G. 600® (d 0). Ultrasound was performed every other day for the next 6 days and estrous detection was performed for the next 22 days. Reproductive tracts were assessed at day 25. Experiment 2
This study was performed in replicates using 123 prepubertal PIC terminal-cross gilts. All gilts were given P.G. 600® for initial induction of estrus at 168 d of age and 114 kg. Estrous detection was performed daily. Ten days following P.G. 600®, gilts were synchronized using MATRIXTM. In replicates 1-3, gilts received no P.G. 600® following LMF, and in replicates 4-6, all gilts received an injection of P.G. 600® 24 h following LFM. Estrous detection began after LMF and transrectal ultrasound was initiated at estrus to observe follicles and time of ovulation. Numbers of follicles >5.0 mm were counted and digitally recorded at estrus for confirmation of follicle number. All estrus gilts were inseminated and reproductive tracts collected at d 35.

Results

Experiment 1
For gilts displaying estrus following LMF, all (12/15) had CL on their ovaries at time of P.G. 600® (d 0). None of these gilts had large follicles at time of treatment (d 0) but 75% developed large follicles over the next 6 days. All gilts maintained their CL for the next 6 d. Two gilts had cysts on d 0, and 3 had cysts on days 2-4, but none had cysts by day 6. None of the gilts showed estrus within 6 days. The interval from P.G. 600® to estrus averaged 12 days and cyclic gilts treated with P.G. 600® showed an inter-estrus interval that averaged 22 days. The two gilts that did not display estrus following LMF and did not have CL on their ovaries, developed large follicles, ovulated, and expressed estrus within 3 days of P.G. 600®. The one gilt that failed to show estrus following LMF, but that did have CL at time of P.G. 600® treatment, developed large follicles, but did not display estrus until 13 d after P.G. 600®. At the end of this study, 92% of all gilts had expressed estrus, and 100% were cyclic.

Experiment 2
Initial induction with P.G. 600® was 66% with an interval to estrus of 100 h, and an estrous duration of 42 h. All gilts were treated with MATRIXTM regardless of whether they expressed estrus or not. In replicates 1-3, gilts received no treatment following LMF but in replicates 4-6, P.G. 600® was given at 24 h following LMF to improve estrous synchrony. Expression of estrus following LMF was >85% for all replicates. Use of P.G. 600® following LMF shortened the interval from LMF to estrus (P<0.0001) in replicates 4-6 (130 h) compared to replicates 1-3 (148 h). P.G. 600® following LMF also shortened the duration of estrus (P<0.0005) in replicates 4-6 (42 h) compared to replicates 1-3 (52 h). However, the interval from onset of estrus to ovulation was not influenced by P.G. 600® (P>0.20), and averaged 33 h in replicates 1-3, and 34 h in replicates 4-6. The number of large follicles (>5 mm) counted using ultrasound at estrus was highly correlated to the digital recording (r=0.90, 19 follicles), but was unrelated to the final number of CL at slaughter (17). There was no effect of P.G. 600® following LMF on pregnancy at slaughter (74%).

Discussion
The results suggest that P.G. 600® can be used in gilts of unknown reproductive status which are cyclic or acyclic gilts to improve farm estrus expression and synchrony without detrimental effect on fertility. Also, use of P.G. 600® in a puberty induction program and followed by MATRIXTM regardless of estrus induction results in estrus expression and synchrony in >85% of replacement females.
Single fixed-time insemination protocol in weaned sows: synchronizing ovulation with porcine luteinizing hormone

Louisa J. Zak\textsuperscript{1} Jennifer Patterson\textsuperscript{2} George R. Foxcroft\textsuperscript{2} John Hancock\textsuperscript{3} Dragan Rogan\textsuperscript{1}

1. Bioniche Animal Health, Belleville, ON, Canada; 2. University of Alberta, Edmonton, AB, Canada; 3. Picton Animal Hospital, Picton, ON, Canada

Introduction

Optimal sow fertility is achieved when insemination occurs up to 24 hours before ovulation. In practice, multiple inseminations are necessary to ensure good sow fertility as estrus to ovulation interval is unpredictable and depends on the wean to estrus interval (WEI) and estrus duration (ED).

The inability to predict the moment of ovulation causes inefficiencies in current artificial insemination (AI) technology. Multiple inseminations necessitate extensive labor demands and result in inefficient use of semen – which directly limits the wider application of genetically superior boars. Variation in the timing of the pre-ovulatory luteinizing hormone (LH) surge relative to onset of estrus causes the variation in time of ovulation. Ovulation is synchronized in sows\textsuperscript{1} and gilts\textsuperscript{2} by administration of porcine LH (pLH; Lutropin, Bioniche Animal Health, Belleville, Ontario, Canada), and occurs 38\pm2.8 h later\textsuperscript{1}. Recently Zak et al.,\textsuperscript{3} showed that administration of Lutropin at onset of standing heat (SH) in the weaned sow, followed by a double fixed time AI (FTAI) within the period of optimal sow fertility, resulted in more pigs born compared to a conventional AI protocol. The present study in the sow, compared effectiveness of combining Lutropin administration at first detection of SH followed by a single FTAI to results from sows conventionally managed and inseminated until they were no longer in SH.

Materials and Methods

Sows were randomly assigned to treatment at weaning. Twice-daily boar exposure facilitated estrus detection (8AM and 2PM). As was usual farm practice, untreated control sows (CONT) were inseminated at least twice, based on WEI and ED. Treated sows (LUT) were administered 5 mg Lutropin IM concomitant with detection of SH. Sows in estrus in the morning or afternoon were inseminated once, 24 hours after Lutropin injection. Semen was <3 days old when used, and contained a minimum of 3*10\textsuperscript{9} live spermatozoa per 80-mL dose. Effect of treatment on WEI, number of inseminations, total pigs born and litter weight were analyzed using a linear mixed effect model. Proportions of sows that were bred and farrowed were analyzed using a chi-squared test.

Results

Results are shown for sows having a WEI between 3 and 7 days. Lactation length ranged from 14 to 24 days. Quality for all inseminations was routinely excellent.

Table 1. Reproductive traits for sows bred according to a conventional insemination protocol (CONT) compared to sows administered Lutropin at onset of SH and inseminated once 24 hours later (LUT).

Figure 1. Total number of pigs born per AI dose for sows bred multiple times (CONT) or once (LUT). \textsuperscript{ab} differ P <0.001

Discussion

The control of ovulation using Lutropin followed by a Single-FTAI is a breeding technology that can be easily applied at the farm level. Single-FTAI saves on labour and semen usage. It is a tool that increases the number of females bred per boar, allowing wider application of the best boar genetics within a breeding pyramid.

Introduction
Gilt management should be a major focus for commercial sow farms. Too often, gilts are neglected and their reproductive performance is poor, resulting in inefficiencies. P.G. 600® is often incorrectly used to compensate for “poor gilt performance”, compounding the poor performance and a vicious cycle ensues. This scenario results in lost confidence in gilts and P.G. 600®. Proper gilt management is even more essential with start-ups, depop-reops, breeding projects and parity segregated production. This paper describes implementation of gilt development and estrus induction with P.G. 600® to improve gilt utilization and performance in a parity segregated commercial gilt herd.

System overview
The farm was a 1,000-gilt one-site farrow-to-finish commercial unit. The farm internally multiplied all replacement animals. It was essential that gilt breeding remain predictable, consistent and efficient. This was not the case the first year of breeding internal gilts, leading to poor gilt utilization, inefficient use of employee time and poor reproductive performance.

Gilt development and selection
All matings were with maternal semen, thus all progeny were potential replacements. Every 3 weeks, 180, 22 to 24 week old gilts were selected from finishing, sized into three equal groups, assigned to a “synch” week and moved to an acclimation barn. The heaviest group was the first to be induced, allowing additional grow time for smaller groups. Gilts remained on a development diet until breeding. A key component to the program was the controlled lack of boar exposure to insure that gilts are pre-pubertal prior to entering the next phase.

Estrus induction and synchronization
Each Wednesday, a new “synch” group was moved from acclimation into a “synch” barn. Pens of gilts (10-15) were taken to an Intense Boar Exposure area (IBE), based on the BEAR system.1 In each IBE, 2 boar crates were placed in the middle of the pens, allowing 360 degree gilt-boar exposure. Boar exposure was given from entry to Friday (3 days) for 15-20 minutes. Each gilt was observed for signs of heat during this period and recorded. On Friday, all gilts received a 5ml dose of P.G. 600®. It has been shown that 2-3 days of boar exposure may improve the percentage of gilts responding to P.G. 600®.2 The group of gilts received casual boar exposure over the weekend. The following week, each pen of gilts would return daily to the IBE for 15-20 min. Daily heat scores were recorded for each gilt (0 = no response; 1 = slight interest; 2 = interest, swollen vulva, no locking stance; 3 = full locking heat). Gilts achieving a score of 2 or 3 were identified as Heat No Service (HNS) and remained in groups for 2 weeks before being moved to the breeding barn. Gilts scoring <2 were mixed and provided physical boar contact until in heat was identified or culled.

Results
Key performance parameters were compared between 52-weeks of the old program and the new “synch” program (Table 1).

Discussion
Under the “Synchronization” system, gilt flow, pig flow and downstream P1 supply was more predictable, consistent and efficient than the previous system. The reproductive improvements seen were most likely due to several factors associated with the P.G. 600® induction program. Estrus was induced and synchronized in large numbers of gilts, allowing for more predictable time and number of matings per week. Heat detection and timing of insemination was more accurate with induced HNS. Under this program P.G. 600® was being utilized consistent with the label, in gilts with a known reproductive state and not being misused or wasted.

Use of a new GnRH to control reproduction in gilts

Silke Engl¹ Ralf Bischoff² Wolfgang Zaremba¹

1. Veyx-Pharma GmbH, Schwarzenborn, Germany; 2. Veterinary Practice for Farm Animals, Lammersbrink, Germany

Introduction
In pig production units controlling reproduction is widely used to optimize farm work flow and fertility performance of animals. This leads to better hygiene, supervision, health and output capacity. A new GnRH has been discovered in the sea lamprey (l-GnRH-III, INN: Peforelin) with proven selectivity for FSH release from male pigs' hypophysis (1). Peforelin was registered last year in Europe and in some other countries for the indications oestrus induction in gilts after cycle blockade and in sows after weaning. This paper reports about some experiences with Peforelin in mature gilts following a cycle blockade.

Materials and Methods
This surveillance was conducted from August 2008 to May 2009 in a 220 sows unit in Germany. In total 110 sexually mature, healthy gilts (Danish landrace x Yorkshire) were included. Each gilt received 20 mg of Altrenogest per day orally for a period of 18 d and was then randomly allocated to either Group I (n = 52): 48 h after last treatment 150 μg Peforelin (= 2 ml Maprelin®) i.m. or Group II (n = 58): no further hormonal treatment. Oestrus detection was performed starting d 3 after cycle blockade twice daily in the presence of a mature boar. Gilts were artificially inseminated up to 3 times in intervals of 12 h. Sonographic pregnancy detection was performed 4 wk after insemination. Oestrus rate (OR₈d  on heat by d 8), last Altrenogest-to-oestrus-interval (AO₈d on heat by d 8 and AO₈d all = all gilts), oestrus duration (OD), pregnancy rate (PR = percentage of mated sows that have been sonographically detected pregnant), farrowing rate (FR = percentage of inseminated gilts that farrowed), total born piglets per litter (TBP) and piglets born alive per litter (PBA) were recorded.

Results
OR was higher and AO was lower in group I than in group II (p ≤ 0.05; see table) and the distribution of first inseminations was more concentrated in group I (see figure). Taking into account only those gilts displaying oestrus within 8 d after cycle blockade the AO₈d was shortened by 0.45 d. AO₈d all was shortened by 1.88 d (p ≤ 0.05). There were no significant differences in PR between the groups; however, there was a tendency for higher PR in group I. From all sows inseminated (AO₈d all), 9 gilts of each group returned to oestrus, 3 had abortions in group I and 5 in group II (PCV and PRRS were diagnosed). From the gilts on heat by d 8, 38 litters were born in group I and 32 in group II. The FR did not differ between the two groups and was at a low level. The litter size (TBP and PBA) was similar in both groups (p > 0.05).

Discussion
In comparison to untreated animals after the inhibition of cycle the Maprelin®-treatment yielded a significantly higher oestrus rate, a significant reduction of last Altrenogest-treatment-to-oestrus-interval and thus an induction of oestrus with a clear concentration of insemination times. These results confirm previous results (2, 3). In the following period a suitable vaccination programme was established that yielded in a considerably decreased number of returns and abortions.

Practical experience with Peforelin in a large sow herd: data from primiparous sows

Silke Engl1 Heiko Zepperitz2 Reinhold Rath3 Wolfgang Zaremba1
1. Veyx-Pharma GmbH, Schwarzenborn, Germany; 2. Veterinary Practice Zepperitz, Neubukow, Germany; 3. Tierzucht Gut Losten GmbH & Co. KG, Bad Kleinen, Germany

Introduction
Primiparous sows (first litter sows) represent an age group of animals with special needs. Particularly in the summer time they may show a depression in fertility performance. Thus, especially in large sow herds, this group is often treated with pharmaceuticals to control reproduction. For oestrus induction a new GnRH is available. The substance originates from the sea lamprey (l-GnRH-III, INN: Peforelin) and has proven selectivity for FSH release from male pigs’ hypophysis (1). Peforelin is registered in Europe and in some other countries for inducing oestrus in gilts after a cycle blockade and in sows after weaning off the piglets. This paper reports about practical experiences from primiparous sows and shows an example of a large farm.

Materials and Methods
The herd consists of sows of Danish genetics and is managed in a weekly-batch-farrowing system with 3 wk of lactation (weaning: Thursday, 10.30 h). The farm managers used to apply equine chorion gonadotropin (eCG) for inducing oestrus in the weaned sows and started using the new Peforelin for this indication in January 2009. Thus, here a comparison of two production periods is presented. The data of a total of 3498 primiparous sows are included.

**Group I**: From January to July 2008 the sows received 24 h after weaning 1000 IU eCG (Pregmagon®) i.m. (n = 2062).

**Group II**: From January to July 2009 the sows received 24 h after weaning 37.5 μg Peforelin (= 0.5 ml Maprelin®) i.m. (n = 1436).

The following parameters were recorded: Oestrus rate (OR = proportion of sows with standing reflex on Tuesday or Wednesday after weaning), farrowing rate (FR = percentage of inseminated sows that farrowed), total born piglets per litter (TBP), piglets born alive per litter (PBA) and piglet index (PI_TBP = TBP/100 inseminated sows; PI_PBA = PBA/100 inseminated sows). The results were compared between the groups and in addition between 2 seasons (A = insemination January to mid May, B = insemination mid May to July).

Results
In group II OR was significantly higher than in group I. The farrowing parameters including litter sizes were similar in both groups.

In the comparison between seasons both groups had better results for OR in the cold compared to the warmer, while the farrowing parameters including litter sizes did not differ between seasons. There was a tendency for better results for group I in the cold season and for group II in the warmer season.

Discussion
The results show at least equal efficacy of Peforelin in comparison to eCG and are in line with previous results yielded in Peforelin treated animals (2). In addition, Peforelin seems to be highly potent to overcome a possible depression of fertility performance in the warmer season.

Of course, the comparison of two years is limited for a scientific evaluation, because, e.g., climate and feeding conditions may vary between years. But it is a comparison of practice and should be allowed, because a producing company will always make comparisons between two years of production in order to assess its progress.

References
**Introduction**

Controlling reproduction is crucial for economic success especially in large sow herds. Application of management tools like optimized feeding, batch farrowing, light regimes etc. alone are not in every case sufficient to meet the high performance expectations of farmers. Thus, pharmaceuticals to control reproduction are widely used to increase fertility performance of animals and to optimize economics. Today, a new GnRH is available for inducing oestrus in gilts after a cycle blockade and in sows after weaning off the piglets. The substance was discovered in the sea lamprey (l-GnRH-III, INN: Peforelin) and has proven selectivity for FSH release from male pigs’ hypophysis (1). Peforelin is registered in Europe and in some other countries. This paper reports about practical experiences from pluriparous sows on a large farm.

**Materials and Methods**

The herd consists of sows of Danish genetics and is managed in a weekly-batch-farrowing system with 3 wk of lactation (weaning: Thursday, 10.30 h). The farm managers used to apply equine chorion gonadotropin (eCG) for inducing oestrus in the weaned sows and started using the new Peforelin for this indication in January 2009. Thus, here a comparison of two production periods is presented. The data of a total of 11852 pluriparous sows (more than 1 litter born) are included.

**Group I:** From January to July 2008 the sows received 24 h after weaning 800 IU eCG (Pregmagon®) i.m. (n = 6430).

**Group II:** From January to July 2009 the sows received 24 h after weaning 150 μg Peforelin (= 2 ml Maprelin®) i.m. (n = 5422).

Sonographic pregnancy detection was performed 4 wk after insemination. The following parameters were recorded: Number of sows showing standing reflex on Tuesday or Wednesday after weaning (SR), Oestrus rate (OR = percentage of sows showing standing reflex on Tuesday or Wednesday after weaning), Pregnancy rate (PR = percentage of inseminated sows that have been sonographically detected pregnant), number of litters born, farrowing rate (FR = percentage of inseminated sows that farrowed), total born piglets per litter (TBP), piglets born alive per litter (PBA) and piglet index (PI_TBP = TBP/100 inseminated sows; PI_PBA = PBA/100 inseminated sows).

**Results**

OR and PR were significantly higher in group II than in group I. The farrowing parameters including litter sizes were similar in both groups.

Introduction
At the moment the discussion strikes large waves around the fertility rate of different breeds. But, the goal must be to use the achievement potential of each existing genetic optimally. So, a method (AI monitoring) was developed to examine and improve the success of the artificial insemination.

Material and methods
The AI monitoring represents a control of the insemination times by the evaluation of the rate of farrowing sows (based on the number of inseminated sows), litter size total and alive born piglets and piglet index in sows inseminated at certain times (HOY 2007). The precondition for a meaningful application of the AI monitoring is an accurate execution and documentation of the result of heat detection (standing: yes or no). The heat controls should begin at the third day after weaning. When weaning is accomplished on Thursday morning the heat detection has to begin on Sunday afternoon or evening! The determination of the duration of heat is the crucial condition to estimate (afterwards) whether the insemination took place in the biologically optimal period (16 h before to 4 h after the ovulation). AI monitoring was tested in 8 farms with approximately 3000 inseminations. It is to be recognized that actually in each farm specific conditions are prevailed. All data provided by the farms were registered into an Excel table and statistically analysed. The AI data were divided in categories: too early, optimally, too late. Beyond that we computed three goal sizes:

- percentage of sows with farrowing (based on all sows inseminated),
- litter size total and alive born piglets and
- piglet index for the sows with different time of AI (too early, optimally, too late – at least related to the first AI).

Results
Exemplarily the results of a farm are presented, which provides a very good documentation. A total of 829 inseminations of sows and 195 of gilts were evaluated. It could be shown that sows inseminated within the optimal time window (for AI 1) yielded the best fertility – both related to the farrowing rate (89.4 %) and to the litter size (11.3) thus leading to the highest piglet index (1006). A comparatively small difference of approximately 3 percent in the farrowing rate led together with a lower litter size (around 0.83 piglets) to a difference of more than 100 alive born piglets per 100 inseminated sows (comparison: too early and at the optimal time inseminated sows). At this farm despite altogether very good achievements in the analysis period almost a fifth of the sows was nevertheless inseminated too early - with appropriate effects on the fertility rate. The frequency of AI which was too late was low, led however also to clearly worse achievements (farrowing rate = 66.7 %, piglet index = 760)(p < 0.05).

A further evaluation was concentrated on the number of inseminations because about 12% of the sows (n = 97) was inseminated three times. Sows, which were inseminated twice, obtained the best achievement. With three inseminations the farrowing rate, litter size and therefore also the piglet index were lower than with two AI. However, this must not be the case in each farm.

The first evaluations at 195 AI in gilts showed, that gilts inseminated three times had clearly worse performance data (farrowing rate = 70.9 %, piglet index = 749) than gilts inseminated twice (farrowing rate = 76.5 %, piglet index = 832). Here, further investigations must be done to analyse the cause.

Discussion
Clear differences between the farms occurred in the insemination management (times, quality and documentation of heat detection; times and number of AI). The heat control (standing reflex) (including also the registration of a possible standing after the last insemination as the precondition for the calculation of the duration of heat) is (more or less) in need of improvement at the farms but at the same time a compelling requirement for the AI monitoring. The determination of farrowing rate, litter size and piglet index related to the onset and duration of heat and to the insemination date (in particular AI 1) allows clear statements for the optimization of the AI.

Reference
Introduction
The effect of a progestagen (Regumate®) induced prolongation of the lactation anoestrus to reproductive parameters in the subsequent parity was evaluated. The objective of the monitoring was to find out whether Regumate® is indicated for the synchronisation of sow groups in a protocol to change the production rhythm and to analyse the effect of the blockade on the fertility performance in the subsequent parity considering the lengths of lactation.

Material and methods
In a 800 sow farm the change from a 1-week-group-management-system to a 2-week-group-management-system was monitored. The total of 20 groups was reduced to a total of 10 groups. This was realized by blocking the first oestrus after weaning in every second group with a progestagen (Regumate® - Altrenogest) given up to one day before weaning the consecutive group. The application started 24 h before weaning. The dosage was 20 mg Altrenogest per day (= 5 ml Regumate®/day) applied 8 times. All sows of the new established group were artificially inseminated in their first standing heat. Data records of 9 groups including 517 sows in the final 2-week-system were analysed. As a benchmark fertility records out of an insemination monitoring programme conducted over 2 previous years in that farm including 659 sows with lengths of lactation between 19 and 23 days were used. Statistical analyses were obtained by using the SPSS 15.0 statistical programme. The differences between the groups concerning litter size were tested by the multiple t-test. Differences in farrowing rates were tested by the Pearson's chi-square test. The analysis of variance (ANOVA) was used to test the parameter litter size total born piglets under consideration of Regumate® treatment (yes/no), parity and length of lactation as independent factors to evaluate also interfering effects.

Results
Regumate® treated animals reached a significantly higher farrowing rate (+8.5 %, p < 0.05) and an increased litter size (+ 0.65 total born piglets, p < 0.052) compared with non-treated sows. The difference in piglet index was +157 in favour of the treated sows. The litter size of progestagen treated primiparous sows was significantly higher in comparison to non-treated primiparous sows (+ 2.02 total born piglets, p < 0.07). The farrowing rate of the treated primiparous sows was increased by 12.8 % in contrast to the untreated primiparous sows (p > 0.05). Referring to the piglet index with Regumate® treated primiparous sows generated 300 total born piglets more per 100 first inseminations in contrast to the not synchronized animals. In the group with very short length of lactation (< 21 days) treated sows realized a 12.8 % higher farrowing rate compared to the not treated sows. Treated sows with more than 21 days length of lactation performed 3.7 % more in the farrowing rate in relation to the not treated animals (p > 0.05). Pharmacologically synchronized sows generated 193 total born piglets more per 100 inseminations after a lactation length of 13-20 days than not-estrus-blocked sows. No differences in estrus behaviour or weaning-service interval between the treated and untreated group were found.

Discussion
The conclusion is that Regumate® is indicated for the cycle synchronisation of sows in a protocol in order to change the production rhythm. The prolongation of the lactational anoestrus by applying Regumate® can also be recommended to ensure fertility performance after a previous very short length of lactation especially in primiparous sows. This study confirms that a prolongation of the lactation anoestrus can be induced by starting the Altrenogest application one day before weaning. This result is in accordance with the results of other authors. It has to be respected that Regumate® is not registered for that indication. Local or national guidelines must be considered by veterinarians and by farmers.

A descriptive questionnaire on weaning management in commercial pig herds in Belgium

Ellen de Jong1 Jeroen Dewulf1 Maria Laanen1 Jan Jourquin2 Dominiek Maes1
1. Ghent University, Faculty of Veterinary Medicine, Department of Reproduction, Obstetrics and
Herd Health, Merelbeke, Belgium; 2. Janssen Animal Health, Beerse, Belgium

Introduction and objectives
Suboptimal reproduction results in modern pig herds are not only disease related. Many different non-infectious factors such as length of lactation, body condition, season, and weaning management practices have an influence on the fertility of sows (1). The purpose of this epidemiological study was to investigate how weaning management influences different reproduction parameters in commercial pig herds in Belgium.

Materials and Methods
In August 2009, a questionnaire was sent by conventional mail to 150 randomly selected pig herds in Flanders, Belgium, with exclusion of farms smaller than 80 sows. After one and a half months, all farms were contacted by phone and asked whether they were willing to cooperate. All cooperating farms were then visited individually by the same interviewer, starting in October 2009. This paper shows the data gathered until January 2010. The questionnaire contained a variety of questions, related to gilt management, batch management system, weaning practices, heat stimulation and detection, insemination, farrowing, housing, climate, feeding, hygiene, vaccinations and fertility parameters. Each visit lasted approximately one hour.

Results
Table 1 shows the descriptive results of important parameters of 30 herds located in three provinces in Flanders. These provinces represent 94% of the Belgian pig production. Of the 30 herds, 37% were farrow-to-finish farms. An equal number of farms purchased gilts or selected their own gilts. Farm size distribution was as follows: 10% less than 150 sows, 63% between 150 and 300 sows and 27% more than 300 sows. The majority (57%) of the farms used a batch management system, mainly 3 and 4 week systems.

Table 2 shows the mean, standard deviation and range (minimum, maximum) of the major fertility parameters.

Discussion and conclusion
As these are preliminary results on a limited number of farms, correlations are not yet clearly visible. By mid 2010, the study will be finalized and the final results and a risk factor analysis will be presented.

**Introduction**

Weaning to estrus interval is a major measure of reproductive efficiency in a breeding herd. Failure to return, or delay in returning to estrus, after weaning increases the number of non-productive days, resulting in economic losses. Many studies have shown that the use of PG600® (400 IU of PMSG and 200 IU of hCG) at weaning increases the number of sows returning to fertile estrus and shortens the estrus to weaning interval (1). In Spain, there are other commercial products with the same composition and indication as PG600®. Previous data have shown that products with the same composition do not always perform as well as each other (2). The aim of this study was to compare the efficacy of PG600® in terms of the rate of return to estrus with two other commercial products with the same composition and indication.

**Materials and Methods**

The trial was undertaken in July, August, September and October in two breeding herds of 750 and 3500 sows, in the northeast of Spain. Due to the high summer temperatures in this area, these farms had a history of extended weaning to estrus intervals during these months. In an attempt to address this, all sows were routinely treated at weaning with PG600® during the summer months.

A total of 1910 multiparous sows were included in the trial over the period. Every week, sows were divided into three study groups, equalized for parity, in total numbers as follows:

- **PG600 Group**: 856 sows treated with PG600.
- **Group A**: 728 sows treated with product A (400 IU of PMSG and 200 IU of hCG)
- **Group B**: 326 sows treated with product B (400 IU of PMSG and 200 IU of hCG)

All products were administered on the day of weaning.

The number of sows in estrus in the 10 days following treatment was recorded, as well as the number of induced estrus which proved fertile and the number of piglets born at the farrowing following the induced estrus.

The data obtained were subjected to statistical analysis using the Fisher's exact test.

**Results**

Sows treated with PG600® at weaning came into estrus in statistically significantly greater numbers than the sows treated with either of the other two commercial gonadotropins (p<0.001) (Table 1).

a, b: values with different superscripts in the same row represent statistically significant differences (p<0.001)

Sows treated with PG600® also exhibited significantly better fertility rates than those treated with product A (p<0.001), and better than those treated with product B, though the latter difference was not statistically significant (p=0.26).

**Discussion**

The results obtained in this trial are evidence that PG600® administered at weaning is the most effective treatment to induce estrus in multiparous sows in herds with increased weaning to estrus intervals due to high temperatures. Estrus induced by PG600® are also more fertile than those induced by the two other tested products with the same composition, with consequent improvements in the economic performance of the herd. PG600® is thus the best choice when induction of estrus is required in these circumstances.

Improving sow fertility to insemination with aged semen

Am-in Nutthee 2 Wichai Tantasuparuk 1 David Sprecher 1 Roy Kirkwood 1
1. Michigan State University, East Lansing, MI, USA;
2. Department of Obstetrics, Gynaecology and Reproduction, Faculty of Veterinary Science, Chulalongkorn University, Bangkok, Thailand

Introduction

Semen quality deteriorates during storage which can result in poorer sow fertility to artificial insemination (AI). To counter this, the usual recommendation is that semen should not be used beyond 48-72 hours from collection. This has a negative economic effect since it may result in the discarding of semen doses. When using aged semen, fertility affects can be reduced by inseminating am/pm, which increases costs from semen and labor but also implies that the semen doses do have viable sperm but presumably fewer of them. We hypothesized that the application of technologies that allow for AI of fewer sperm, such as intrauterine insemination (1), will permit the maintenance of fertility with once daily AI of aged sperm. The aim of this present study was to test this hypothesis.

Material and methods

In 3 replicates, sows were induced into estrus by PG600 to remove confounding effects of WEI and sows estrous on days 4 or 5 after weaning were assigned by parity to cervical AI on consecutive days with 1 and 2 or 2 and 3-d old semen (Control, n=29), or cervical AI with 4 and 5 or 5 and 6-d old semen (group 1; n=30) or intrauterine (Deep Golden Pig; IMV) AI with 4 and 5 or 5 and 6-d old semen (group 2; n=29). Semen was extended in BTS and semen quality was assessed for days 2 to 6 after collection. Sow performance was compared on the basis of pregnancy rate and subsequent litter size (at writing only 2 replicates farrowed) using Fisher’s exact test and ANOVA in SAS 9.1.

Results

On days 2, 3, 4, 5, and 6, percent sperm motility was 83, 73, 63, 63 and 60%; percent live sperm was 94, 83, 77, 74, and 72% and percent normal sperm was 93, 93, 84, 84, and 83%, respectively. Compared to the Control group, pregnancy rate of sows receiving a cervical AI of aged semen was lower (P=0.05). However, sows receiving an intrauterine AI with aged semen maintained their pregnancy rate (Fig. 1). Based on limited farrowings, litter size was lower (P=0.06) for sows receiving aged semen (11.4±0.6, 8.7±1.0 and 8.6±0.8 for control and groups 1 and 2, respectively).

Discussion

The results of the present study confirm that measures of sperm quality are lower by 2 or 3 days after collection and further declined to reach lowest quality by 4 days when extended in a short-term extender such as BTS. As noted by others (2) this age-associated effect on sperm quality was further evidenced by depressions in sow fertility when the sperm were deposited conventionally (ie. intra-cervical) and sperm was 4 days from collection. One explanation for this effect is that as the sperm age there is a growing proportion of sperm that are less able to support a normal fertilization, possibly because of age-associated DNA damage such as may result from inadequate anti-oxidant capacity (Am-in et al. unpublished data). That viable sperm were still available in 4 and 5-day old semen is supported by the normal pregnancy rates when aged sperm were inseminated intrauterine. We suggest that this is similar to the effect documented previously (1) whereby conventional insemination of fewer sperm resulted in poorer performance, which effect was prevented by intrauterine insemination. Interestingly, based on incomplete data collected to date, litter size was reduced in both aged semen groups. The etiology of the differential effects on pregnancy and litter size are not known.

Energy intake and exogenous gonadotrophins (eCG and LH) on embryo viability

Octávio H. Eckhardt¹ Felipe C. Horta¹ Larissa J. Parazzi¹ Esther R. Afonso¹ Simone M. Martins¹ Flávia R. Barros² Carolina I. Silva¹ José A. Visintin¹ Aníbal S. Moretti¹

¹. Laboratory of Swine Research, University of Sao Paulo, Depto. Nutrição e Produção Animal (VNP), Pirassununga, SP, Brazil; ². Laboratory of In Vitro, Cloning and Animal Transgenesis, University of Sao Paulo, Depto. Reprodução Animal (VRA), São Paulo, Brazil

Introduction

Greater energy intake during late gestation have been linked to lower feed intake during lactation¹, which in turn can lead to lower gonadotropin secretion² and an unsatisfactory reproductive outcome. The aim of the study was to investigate the effects of gestational energy intake and exogenous gonadotropins at weaning on primiparous sow’s reproductive performance.

Materials and Methods

Twenty three out of thirty hybrid gilts, with 75 days of gestation, were fed according to 2 treatments until farrowing: (P, n=12) 2,9kg of a pre-lactation diet (3203 kcalME/kg, 17,25%CP), and (G, n=11) 2,5kg of a gestation diet (2930 kcalEM/kg, 16,43%CP). At weaning, animals were split into 2 other groups: (H; n=12) administration of 600IU of eCG and, after 72 hours, 2,5mg of LH, and (C; n=10) control group, without hormonal protocol. Animals were weighed at the beginning of the trial, before and after parturition and at weaning (23,7±2,2 days after farrowing) and were fed to appetite during lactation. Pos-weaning estrus was determined by standing reflexes in the presence of adult boar, following artificial insemination. After 4,56±0,92 days, sows were slaughtered and had their reproductive tracts collected. Ovulation rate was established and embryos were recovered and stained with Hoechst 33342 and propidium iodide for evaluation of viable embryo cells through epifluorescence microscopy. Experimental design was entirely casualized in a 2x2 factorial arrangement, analyzed with the PROC GLM of SAS5

Results

Gilts fed the gestation diet (G) weighed 186,4±9,6 and 220,1±13,7 kg at the beginning of the trial and at farrowing whereas treatment P gilts weighed 183,8 ± 7,1 and 229,1±10,2 in the same periods (p>0,05). Daily weight gains during late gestation were 0,915±0,159 and 1,23±0,158 kg/day for G and P, respectively (p<0,001). Post farrowing and weaning weights were, respectively, 194,1±10,4 and 197±15,2 for treatment G and 199,7±8,8 and 195,3±12,2 for P (p>0,05). Mean lactational weight change was -4,7±-12,2kg for G and -5,3±-9,3 for P. Post weaning performance and embryo evaluation is presented in Table 1. The results indicated an interaction between factors for the percentage of fecundated structures, with values of 98, 55%, 78, 97%, 96, 88 and 99, 09 for GC, GH, PC and PH, respectively

Discussion

The level of energy intake did not interfere on lactation weight losses, although researches have shown different results¹,². Unlike other reports³,⁴, hormonal treatment did not influence WEI or enhance the ovulation rate. The literature⁴ mentions that an increase in the serum gonadotropins levels due to eCG and LH administration, could have led to the ovulation of immature follicles, resulting in oocytes and, hence, embryos of lower quality. At the same time, the higher weight at farrowing could have provided sufficient body reserves for the sows to cope with the metabolic demands of lactation, resulting in a lower impact of the hormonal protocol on the reproductive outcome signaled by the percentage of fertilized structures. Similar findings were reported previously⁴ when using the same hormonal protocol combined with flushing in gilts. In conclusion, the condition associating body reserves at weaning and hormonal pattern in primarous sows can affect embryo viability. Further information is needed regarding the mechanism involved.

Improving oestrus behavior with peforelin, a specific FSH releasing GnRH

Jan Arnauts, Jan Jourquin, Lieve Goossens

Introduction

During oestrus, the expression of the oestrus symptoms is very important for the heat detection and timing of insemination. Oestrus symptoms are induced by the estrogens from the growing follicles. They prepare the sows for mating. During follicle growth, the oestrus production in the follicles increases and will eventually cause a luteinizing hormone (LH) peak that leads to ovulation. Follicular growth is regulated by the hypothalamus. Gonadorelin releasing hormones (GnRH) induce the release of follicle stimulating hormone (FSH) and LH from the pituitary. These hormones are responsible for the recruitment, selection and growth of the follicles. Peforelin (Maprelin®) is a synthetic GnRH that specifically induces the release of FSH in pigs (1). The product is used for the induction of oestrus (2). The aim of this study was to measure the effect on the timing and intensity of the heat symptoms in a high productive farm.

Materials and Methods

In a 2400 sows farm, 224 sows and 224 gilts were included in the study. All gilts were synchronized with a daily dose of 20 mg altrenogest (Regumate®) during 18 days directly in the mouth. The last dose of altrenogest was given the day before weaning of the sows. 48 hours after the last altrenogest dose, 112 randomly chosen gilts were injected intramuscular with 150 μg of peforelin (2 ml Maprelin®) and 112 randomly chosen sows were injected with peforelin 24 hours after weaning. Primiparous sows received 37.5μg peforelin (0.5 ml Maprelin®) and multiparous sows received 150 μg of peforelin (2 ml Maprelin®). From day 3 after weaning, twice daily oestrus control was carried out. A score from 1 to 5 was given: 1 no heat, 2 first heat symptoms, 3 pre-oestrus, 4 oestrus but not yet perfect and 5 for perfect oestrus. The weaning to oestrus interval (WOI) and the weaning to insemination interval (WII) was recorded. At the moment of submission of this abstracts, only partial pregnancy information testing and no farrowing data were available yet. The Wilcoxon Mann-Whitney U test between groups was performed in SAS® (version 9.1).

Results

The numbers of gilts coming in heat within 7 days after last altrenogest dose was 95.5% for the peforelin treated group versus 92.0% for the non-treated group. In multiparous sows, 96.4% of both groups came on heat within 6 days after weaning. The pregnancy rate was slightly better for the peforelin treated group, both for the gilts (85.7% vs. 84.0%) and sows (92.4% vs. 91.0%). The WOI and WII of sows and gilts coming in heat within the set range are shown in table 1.

Discussion

The results of this study show that the peforelin treatment has a positive effect on timing and intensity of oestrus in high performing farms. Improving results in high productive farms is a challenge. Early onset of a good quality oestrus facilitates the breeding management and often results in improved reproductive performance. With only few animals remaining one week after weaning or synchronization, it is easier to cull and to reduce empty days. While in gilts, the use of peforelin seems to reduce the number of gilts not bred, this is hardly possible in the sows on this farm. In sows, WOI is shortened and more concentrated after the use of peforelin.

References

Introduction

Examination of the reproductive tracts of infertile sows and gilts is recognised as a valuable diagnostic aid (1,2). Between 2006 and 2008, Scottish pig farmers were offered examinations of reproductive tracts of sows and gilts culled for infertility reasons, including multiple returns to oestrus, pregnancy failure/not in pig and suspected anoestrus. The aims were three-fold; firstly to assist farmers and their veterinary advisors with understanding the causes of infertility on their units, secondly to improve the reproductive performance of herds and thirdly, to carry out surveillance for any previously unrecognised or any new and emerging reproductive conditions.

Materials and Methods

After slaughter, the tracts were bagged, sealed, identified by herd and animal number and delivered to one of two diagnostic laboratories within 24 hours. Similar protocols were used by both laboratories including inspection of all parts of the reproductive tract and bladder (if present), counting the number of follicles, and other features on the ovaries (corpora lutea, corpora albicans, corpora haemorrhagica, cystic lesions), testing oviducts for patency, examination of uterine horns for pregnancy, inflammation or other lesions, the cervical structure, the vagina and bladder for inflammation or abnormalities. Swabbing of the uterine body anterior to the cervix for bacterial culture was done routinely by one laboratory, and only in the event of gross inflammation or abnormal uterine contents, by the other. Selected cases were tested for *Chlamydia* species by PCR. Representative samples were collected for histopathology.

Results

In total, 142 tracts were examined from 31 units. No abnormalities were evident in 58 of the tracts (23 units). These tracts showed normal ovarian activity with presence of corpora lutea. Nineteen tracts were pregnant (14 units); 11 were in early pregnancy (up to 6 weeks gestation), 4 were in mid-pregnancy (7 – 13 weeks gestation) and 4 were in late pregnancy (14 weeks or more, gestation). Two gilts were found to have congenital defects of the cervix or uterine horns. Twelve sows had cystic ovaries (10 units). Uterine bacterial infection was detected in 32 tracts (13 units). Some cases showed gross inflammatory changes associated with infection. Infections involved were as follows: *E.coli* (8 tracts, 5 units), *Strep. dysgalactiae* (6 tracts, 3 units), other *Streptococcus* species (3 tracts, 3 units), *Actinomyces pyogenes* (6 tracts, 1 unit), other infections including mixed environmental-type organisms, *Fusobacterium* species or *Clostridium perfringens* (8 tracts, 6 units). Abscessation of the uterine wall was present in one sow. Evidence of anoestrus was found in 17 tracts (7 units). One anoestrus sow also had totally blocked oviducts. Two sows had severe cystitis. Both yielded the same bacterial isolates from their uterus and bladder suggesting a link between cystitis and the endometrial infection. No *Chlamydia* sp. were detected in any of the uteri tested.

Discussion

This study allowed reports to be provided for individual sows and gilts including assessments in relation to last oestrus and service dates. Where the cause of infertility could not be determined from the slaughter examination, other means of investigation including serology were suggested. The culling of pregnant animals highlighted the need for better pregnancy testing and/or training on some farms. In herds with endometritis, there was a tendency for particular organisms to be prevalent, for example streptococci or *A. pyogenes*. Coliforms and other environmental bacteria associated with endometritis suggested hygiene issues on some units. Happily, the study did not demonstrate any previously unrecognised or any new and emerging conditions on the farms.

Effect of different sexual stimuli on the estrous cycle and reproductive performance of artificially inseminated sows

Flavea Reis1 Ronaldo Reis1 Maristela Palhares1 Amanda Siqueira1 G. B. Mourão1 C. Malm1 José Monteiro Silva Filho1
1. Federal University of Minas Gerais, Belo Horizonte, MG, Brazil; 2. Elanco Animal Health, São Paulo, Brazil

Introduction

Deficiencies in management, particularly concerning estrus detection, have been reported as the main cause of low reproductive performance when using artificial insemination (A.I.). It is known that the boar influences many physiological and reproductive processes in the female, thus having a positive effect on reproduction. Aiming to use the copulative and seminal plasma stimuli, while loosing none of the genetic benefits of A.I., many studies have been conducted to assess the effectiveness of teaser or infertile males on increasing the fertility rates of inseminated females. The objective of this study was to evaluate the influence of using vasectomized boars or boars with deviated preputial on estrus detection and reproductive performance of artificially inseminated sows.

Material and Methods

A total of 110 primiparous and multiparous females (parity 1 to 11) and 12 boar teaser were used (five were vasectomized and seven had preputial ostium deviation). Four fertile boars were used as semen donors. The vasectomized males presented olfactory, visual, auditory and tactile (external and internal - by penis penetration) stimuli, in addition to the action of the seminal plasma. The males with preputial ostium deviation, on the other hand, provided no internally contact or seminal plasma. The females were randomly distributed to the three pre-insemination treatments: TI (n = 35) - females inseminated without direct male stimulation (control); TII (n = 38) - female stimulated and mated by males with preputial ostium deviation, immediately before each insemination; TIII (n = 37) - female stimulated and copulated with a vasectomized male, immediately before each insemination. Estrus detection was done three times a day - in TI was done with the females housed in individual pens, by the back pressure test in the presence of a boar (nose-to-nose contact); in TII and TIII the boar was kept in physical contact with the sows in the pen. Were performed up to three inseminations using insemination doses of 3x10⁹ viable sperm, diluted in the MR-A® extender and stored at 17°C for up to 12 hours. The data were analyzed by Analysis of Variance, and the averages compared by SNK test.

Results

The average duration of estrus was 67.53±16.42 hours, showing a numerical superiority when identified in the male's pens (treatment II and III). The average weaning-estrus-interval was 3.98±0.85 days, with a significantly higher percentage (p<0.05) of females showing estrus between 1-3 days after weaning in the treated groups (24.66%), compared with the controls (8.57%). The percentage of females that showed estrus in the morning was 69.09%. Regarding sows reproductive performance, no statistically significant differences (p>0.05) were found in any of the parameters measured. The farrowing rate was 88.18% and the average total number of piglets born was 11.22±2.77.

Discussion

The combination of the tactile, visual, auditory and olfactory stimuli increased the proportion of females in heat in accordance with others studies (1). The group exposed to vasectomized males presented the worst dates. Probably the amount of seminal plasma altered the sperm concentration in the doses and reduced the fertility. Also, these females had full contact with the boars and so, were exposed to stressful conditions (2).

Conclusion

The contact with the teaser boars immediately before the insemination not resulted in improvements in the reproductive performance in the females. Probably, the effect of vasectomized boar use is not evident in farms that use artificial insemination and show rates of fertility and prolificacy close to ideal.

The rate of gilts become pregnant at the age of 220-240 days

Marijan Sviben1 Pero Gnjidic2
1. Freelance consultant, Zagreb, Croatia; 2. Biotim KG, Z’upanja, Croatia

Introduction
Gilts may be covered naturally or inseminated artificially when they reached the live weight of 130 kgs being old 220 days at least (Hühn, 1999). Recently it was recommended the gilts would be covered old 220-240 days in order to farrow at the age of 335-355 days (Zootechnical Dpt., Biotechnical Faculty, University of Ljubljana, 2009). We decided to establish how many gilts became pregnant at the age of 220-240 days.

Materials and Methods
Data collected at the Family Farm Glavas’ic’ in Bizovac, Republic of Croatia, were the material used during this research. The farm bought 65 hybrid PIC gilts from farm “Belje” where they had been born during the period of August 21st till September 14th 2008. Gilts were covered naturally or inseminated artificially with the boar’s semen obtained from the A.I. Center in Osijek so that they became pregnant during the period from February 18th till September 14th 2009. Litters from those females dropped in the period from June 11th 2009 till January 7th 2010. It was accounted how many days particular gilts was old at the start of her successful pregnancy and how many days particular female was old at the 1st farrowing. Numbers were elaborated using the methods described by Serdar (1959).

Results
Ten gilts from 65 or 15 38% of all observed females became pregnant at the age of 225-240 days giving the average of 234.9 days.

Discussion
Gilts became sows as yearlings covered at the age of 225-240 days or at the age of 172-386 days but in former case less than 16% of all females in our research. Successful pregnancy of 65 gilts in 2009 started at the age what was observed with the data on the age at the first successful services of gilts born in 1960-1962 (169-401 days - Sviben, 1967), when gilts reached 89 kg at the age of 212 days on an average. Contemporarily bred pigs in appropriate circumstances reach the live weight of almost 140 kg on an average at the age of 154-175 days (Sviben, 2007) when gilts are sexually mature. Pigmen have an interest to service gilts as early as possible what means at the age of six months (Legault and Dagorn, 1973).

6.  Zootechnical Dpt., Biotechnical Faculty, University of Ljubljana, 2009: Plodnost pras’ic’ev. Domz’ale
Introduction
Reproductive failure continues to be one of the most common reasons for culling sows from pig farms. Reproductive slaughter checks have been conducted to determine the causes of urogenital infections, discharging sows and reproductive failures. Nevertheless, a few studies have been done on the presence of gross reproductive lesions at slaughterhouse and their application to solve reproductive problems in pig farms. The aim of this paper was to develop a systematic protocol to assess reproductive failure by using a spreadsheet as a procedure to analyze and to reduce reproductive problem in farms.

Material and Methods
Three pig farms with historical reproductive failure were selected (Farm A = 4,000 sows, Farm B = 7,000 sows, Farm C = 2,500 sows). A longitudinal study was performed to determine the main reproductive problems in each farm. 20 to 30 culled sows or replacement were examined at slaughterhouse during April – November 2009 period. A systematic monthly or every two-three weeks inspection was performed to each pig farm to assess the evolution of each case. Post-mortem examination of the genital organs was carried out immediately after slaughtering. A detailed protocol was used to examine every part of the organs by using a technical inspection guide. Sample of several tissues were taken for histopathological and bacteriological studies. The inspection outcome were transferred to a specific spreadsheet designed to analyze the pathological findings.

Results
Nine reproductive inspections were performed in 244 sows or replacement belongs to the three pig farms. The pathological findings are shown in the Table 1. The main problem we found was a high percentage of pregnancy (13.5%), followed by inactive ovaries (13%) and pyometra and cystitis (10.6% each one). 8.6% of ovary inspected had multiple large cysts. Lithiasis was a non-expected finding for us since it was higher in Farm A than the other ones (Fig 1). Farm C had the mayor reproductive problems with a high percentage of pyometra and pregnancy (data not shown). E. coli, Streptococcus spp and Proteus spp were the predominant bacteria isolated, respectively.

Discussion and Conclusion
The results were similar to those previous reports, however, the prevalence of pregnancy, cystitis and pyometra were higher. The systematic evaluation conducted in the reproductive tract on sow from the three pig farms in this study showed to be a worth tool to detect the main reproductive problems in those farms and to introduce management strategies to reduce the reproductive problems in this herds.

Figure 1
Responses to delayed breeding protocols in weaned parity 1 sows

Jennifer Patterson1 Ana Paula Mellagi2 Merel Verhoeven1 Meghan McCarty1 Tanja Minder1 Barbra Behiels1 George Foxcroft1
1. University of Alberta, Edmonton, AB, Canada; 2. Setor de Suinos, Porto Alegre, RS, Brazil

Introduction
In today's well managed sow farms, approaching 90% of sows can be detected in estrus within 3 to 5 days after weaning and pregnancy rates in these sows can be better than 90%1,2. However, the results of our recent studies suggest that although modern, primiparous sows can be consistently bred soon after weaning, the emerging pre-ovulatory follicles are of poorer quality, which may affect both the number and quality of pigs born. This study examined the effect of delayed breeding after weaning in primiparous sows, using either "skip-a-heat" breeding or treatment with oral progestagen, on subsequent reproductive performance.

Materials and Methods
In this study, 1st parity sows restricted to 60% of their ad libitum intake, and induced to lose 17.0 ± 4.1 kg of body weight during the last week of a 21-d lactation, were allocated as trios to one of 3 breeding strategies at weaning (weaning weight = 160.2 kg): 1) CON (n=25) bred at the first post-weaning estrus; 2) SKIP (n=23) bred at second post-weaning estrus; 3) ALT (n=23) oral progestagen (altrenogest: ALT) treatment for 14 d starting the d of weaning and bred at the first, but delayed, post-weaning estrus after ALT withdrawal. After weaning, sows were heat checked twice daily and bred by AI (using single sire AI doses, evenly assigned across trio). At day 30 of gestation, reproductive tracts were recovered after euthanasia and dissected on-site.

Results
At breeding, SKP and ALT accumulated more non-productive days as measured by the wean-to-service interval (WSI) but the proportion of sows bred was similar (PBRD). ALT sows were bred as a more synchronous group (VAR) than either SKP or CON. Sow body weight at weaning, and total energy balance during lactation did not differ among treatments. The longer delay to breeding resulted in greater weight at breeding (ALT: 169.4 ± 21.4; SKP: 177.1 ± 22.3; CON: 162.1 ± 21.0 kg) and a more positive energy balance at breeding (ALT: 423.9 ± 12.2; SKP: 633.3 ± 14.0; CON: 196.2 ± 11.5) in SKP and ALT sows. Pregnancy rate (PR) was improved in SKP and CON sows. An improvement in follicular quality and corpus luteum function (total luteal weight (CLWT) and progesterone concentration (PCON)) was observed in ALT sows. Delaying breeding from 1st to 2nd estrus in SKP sows increased the size of the pre-ovulatory follicle (FOLL). At d30 of gestation, no differences in ovulation rate (OR), live embryos (LE), embryo survival, embryo size (LEWT), or placental fluid volume (PVOL) were detected (Table 3). A Fertility index (FI) was calculated as the percent of sows bred and pregnant per 100 sows weaned x live embryos at d30.

Results show that as a result of the exceptional performance of CON sows, the FI of ALT (1179) and SKP (1215) did not meet the performance achieved by CON (1406) sows.

Discussion
Delayed breeding allows for additional time for the sow to recover weight lost due to lactation catabolism. Altrenogest treatment effectively synchronizes estrus after weaning and reduces the number of days in the breeding week. Delayed breeding, improves follicular quality, corpus luteum function and the synchrony of sows bred. In the present study, the performance of Control sows, as measured by the Fertility Index was exceptional and no gain in estimated productivity was achieved by delaying breeding after weaning in sows.

*P≤0.07, **P≤0.03
**Introduction**

Local pig farming is an important source of livelihood in many rural communities of Western Kenya (1, 2). Sows are important in sustaining this important sector. Data on their performance is currently lacking. Such information is crucial for the pig farmer to identify target areas for farm improvement. Studies on the performance of pigs have only been done on commercial farms keeping exotic breeds (3). The purpose of this study was to provide baseline information on the reproductive performance of sows raised by small-holder pig farmers in rural villages of Busia and Kakamega districts, Western Kenya.

**Materials and Methods**

We studied a random sample of 288 local pig farmers in the two districts of Western Kenya. Farms were randomly identified and visited three times in the course of the study period (June 2006 to October 2008). Information on sow productivity was gathered by means of questionnaires administered to sow owners in face to face interviews. All data were managed and analysed in Stata® statistical software. Student’s t-tests were used to compare data between districts.

**Results**

The mean number of sows owned per farm per visit was 1.3 (SD=0.62) on farms where at least one sow was present when the farm visit was made. Farmers in Kakamega bred their sows more times (2.4) compared to farmers in Busia (1.8) (p<0.05). The average prices for sows purchased as piglets (≤ 4 weeks), growing pigs (4 - 8 weeks) or adults were Ksh 619 (SD=178), Ksh 813 (SD=457) and Ksh 3060 (SD=684) respectively. Piglets were cheaper in Busia (Ksh 509 SD=57) than in Kakamega (Ksh 777 SD=174) (p<0.05). Pigs were weaned at an average age of 5.4 (SD=3.3) weeks. The mean number of piglets born alive was 7.87(SD 2.67) and the mean number of piglets weaned was 6.60 (SD 3.25). A median and mean pre-wean mortality of 0% and 13% (SD=26) was reported. The median and mean age for sows at first breeding was 6 and 8.25 (SD=4.8) months, respectively. Sows were bred 1.95 1.64 months after piglets were weaned. Sows were sold at Ksh 2286 (SD=934), Ksh 2603 (SD=996) and Ksh 2830 (SD=1114) for the lowest, highest and expected price respectively. Most sows (91%; 74/81) were sold to pork butcher men who slaughtered them for immediate local consumption. Many sows were sold immediately after their first litter (56%; 33/59). Sources of breeding boars included; boars that were borrowed from a neighbour (77%), farmer’s-own boar (14%), group-owned boars (0.4%) and boars that were free-roaming in the villages (2%).

**Discussion**

This study has provided important production data that was previously lacking. Increasing the productivity and profitability of small-holder pigs directly contributes to the social and economic wellbeing of households in low-income countries. Some of the opportunities that may increase sow productivity include; improved sow feeding, shorter wean to breed interval, breeding more than one in an estrus, keeping sows for more than one litter by lowering the female culling rate, introduction of improved genetics with better litter size. There is need for more detailed research particularly on potential management factors influencing sow productivity (number of born alive piglets, farrowing rate, sows age at first farrowing and piglet mortality).

Reproductive parameters in pregnant sows adapted from a conventional system to an organic system

Roberto G. Martinez; Yadira Miranda; Jorge R. Lopez; Roberto Martinez-Rodriguez; Mario E. Haro
Facultad de Medicina Veterinaria y Zootecnia. Universidad nacional Autonoma de Mexico, Mexico, DF, Mexico

An alternative to the industrial pork production is the development of market niches. An example of this is the production of organic pork meat, in order that a product goes through one system to another, it is necessary a conversion process. However, there is not study that indicates any change in breeding parameter with sows which have been adapted from one system to the other. It is known that sows in conventional system could have breeding problems when there are some food changes or environmental changes; that why the reason of knowing the breeding behavior in sows which have been adapted from a conventional system to an organic one.

Material and Methods

It was carried out in a pig farm localized 100 km northeast from México City in a separated area from the rest of the farm (term established by IFOAM). Six yard with concrete floor (28.26m2 each one) and an outside area with land floor (197.62m2) were used for this research. This space fulfills the specifications that are established by certifying organizations (2.5m2/sow in inside area, and 1.9m2/sow in outside areas). It was used 17 adult sows, 11 of them were placed in yards with outside area and the other 6 in confinement.

At the moment of weaning they were separated in 3 groups. A. 6 sows in an organic management and also organic food; B. 6 sows in equal conditions but conventional food. C. 6 sows in an intensive management.

It was registered number of births, number of services, length of estrus, length of gestation, physical conditions at the moment of birth, dorsal grease at the moment of birth, length of the birth, internal between birth, number of mail piglets meconium, total number of newborn piglets, number of dead piglets and weight at the moment of birth. Each variable was analyzed using AND-EVA in a new design completely randomized.

Discussion

The sows in the organic system with both types of diet had similar parameters to the control sows, except with parameters related with the length of birth, they were higher than the controls; the previous is related with less stress conditions at birth.

The removal of gilts and primiparous sows from swine breeding herds in Thailand

Atthaporn Roongsitthichai1 Em-on Olanratmanee1 Seri Koonjaenak2 Mongkol Techakumphu1 Padet Tummaruk1
1. Chulalongkorn University, Bangkok, Thailand; 2. Kasetsart University, Bangkok, Thailand

Introduction

In general, the removal of sows from breeding herds consisted of planned (i.e., old and low productivity) and unplanned (e.g., reproductive failure, lameness, sudden death) reasons (1). It has been demonstrated that at least three litters are required from sows before a positive cash flow could be obtained (2). Unfortunately, 15–20% of the removal sows produced only one litter (1, 2) and most of these were culled due to unplanned reasons (1). The objective of the present study was to evaluate the pattern and reasons for culling gilts and primiparous sows in swine herds of Thailand.

Materials and methods

Data from 38,323 gilts and sows culled from eight swine herds in Thailand between 2006 and 2009 were included. The herds are located in the eastern, western, middle, and northeastern parts of Thailand between latitude 14–17 °N and longitude 102–103 °E. The sow on production in the herds was between 1,600 and 4,000 sows. The sow breeds were chiefly Landrace x Yorkshire (LY) crossbred and some were L and Y. Conventional artificial insemination (AI) was used in all herds. Most gilts and sows were housed in a conventional open-housing system with water sprinklers and fans. They were kept in individual stalls during gestation and in individual farrowing pens during lactation. All herds produced replacement gilts within the herd by their own grandparent (GP) stocks (L and Y). In general, the gilts were mated at ≥32 weeks of age with ≥135 kg of body weight at the second or later observed estrus. Vaccination for gilts and sows included foot-and-mouth disease, classical swine fever, Aujeszky’s disease, porcine Parvovirus, and arthrophic rhinitis. The gilts and sows received ad libitum water via water nipples. The feed was provided once or twice a day (about 1.5–3.5 kg/day/head during gestation and 5.0–7.0 kg/day/head during lactation). The feed was rice-maize-soybean-fish base containing 150–180 g crude protein, 12.1–13.4 MJ metabolizable energy and 8–10 g lysine/kg. Generally, the planned removal was performed after the sows reached the sixth parity.

Results and Discussion

Of all slaughtered females, 14.5% (n=5,543) and 13.8% (n=5,302) were removed as gilts and primiparous sows respectively (Figure 1). Of all the removed females, 93.2% was sent to slaughterhouse, 6.8% was found dead, and 0.02% was euthanized. The reasons for culling of gilts and primiparous sows are demonstrated in Table 1.

The present study indicated that reproductive disorders are the most common reason for culling gilts and primiparous sows, in agreement with earlier studies (1,2). Most of the reproductive problems of the female included anestrus, not pregnancy, vaginal discharge, and abortion. In addition, it also indicates that at least 28.3% of the female produced only one litter or less when they were culled.

References

Introduction

An alternative to increase the profitability of hog farms is to increase the length of productive life (PL) of sows, which is interrupted by different causes that affect their productivity. The establishment of the causes of removal of sows is critical in the culling and replacement programs to implement preventive measures. The aim of this study was to determine the effect of farm, number of piglets born alive at first farrowing (NBA) and age at first farrowing (AFF) on the length of the PL and number of parity (NP), and the main causes of removal sows.

Materials and Methods

We used data from four pig farms representative of the central area of Yucatan Mexico. The farms are of the intensive system and technically. Production records to estimate PL and causes of removal of sows were the year 2003-2009 and were obtained from Pigchamp program. The variables used were: identification of farms and sows, NP, NBA, AFF, date and cause of removal. The PL was defined as the number of days between first farrowing and removal, or termination of data collection (1). To determine the length of the PL and NP will use a model with fixed effects of farm, NBA and AFF. The data of the causes of removal were analyzed in general and by NP using descriptive statistics.

Resulted and Discussion

Table 1 shows the results for PL and NP of sows per farm, NBA and AFF. Other studies also reported an effect of these factors on the PL and NP (1, 2). The main causes of removal were reproductive problems (26.75%), which agree with other studies (3, 4). The highest percentage of removal occurred in the parities 6 to 14 with 28.7%, of which 83% were removal because of advanced age. In the party 0 the 51.3% of sows were removal for reproductive reasons (Table 2). Similar results have been reported by other authors (3).

In conclusion difference was found between farms, NBA and AFF on the length of the PL and NP of the sows. The main causes of removal of sows were reproductive problems.

Relationship among age, body weight and number of ovulation in Landrace x Yorkshire crossbred replacement gilts

Padet Tummaruk; Sawang Kesdangsakonwut; Atthaporn Roongsitthichai; Annop Kunavongkrit
Chulalongkorn University, Bangkok, Thailand

Introduction
On average, Landrace x Yorkshire (LY) crossbred gilts in Thailand attain puberty at 196 days and 106 kg body weight (1). In practice, replacement gilts are usually mated at the second or later observed estrus, about 7-9 months of age. The objective of the present study was to investigate the relationship among number of ovulation, age and body weight in LY crossbred replacement gilts in Thailand.

Materials and Methods
Genital organs from 316 culled LY replacement gilts from 6 swine herds in Thailand were collected at slaughterhouses between May 2005 and September 2008. The organs, including ovaries, oviducts, uteri, cervixes and vaginas-vestibules-vulvas were collected, placed on ice and transported to the laboratory within 24 h after culling. Historical data included herd, gilt identity, breed, date of birth, culling date and body weight at culling were collected. Age at culling was calculated. The ovaries were weighed by using an electronic balance (Precisa Instruments Ltd., Switzerland). Corpora lutea (CL) and corpora albicantia (CA) were counted. Number of ovulations was defined as total number of CL from both ovaries. Number of CA was regarded to the number of ovulations in the previous reproductive cycle. The gilts were classified according to body weight (Table 1) and age at culling (Table 2). Number of ovulations was compared among groups by using one way analysis of variance.

Results and discussion
On average, the gilts were culled at 302.4±51.5 days of age and the body weight at culling was 144.0±20.8 kg. Of the 316 gilts, 23 gilts (7.3%) had multiple cysts, 17 gilts (5.4%) had single cyst, 2 gilts (0.6%) had unilateral ovo-testis and 7 gilts (2.2%) had miscellaneous abnormalities. Gilts with abnormal ovaries were excluded and 261 gilts (82.5%) were remained for further investigation. Of these gilts, 107 gilts did not ovulate (86 pre-pubertal and 21 follicular phase) and 154 gilts (59%) having at least one CL were investigated. On average, the number of ovulations was 15.9±3.5 and the number of CA was 15.3±6.1. The number of ovulations in relation to body weight of gilts is presented in Table 1. Gilts with body weight of 92-130 kg and 131-140 kg had 3.2 and 2.0 ova, respectively, which were less than those of 141-150 kg (Table 1). Number of ovulation of gilts with a body weight of 141 to 205 kg did not differ significantly (Table 1). The relationship between age at culling and number of ovulation are presented in Table 2. Gilts aged 30-35 weeks had a lower number of ovulations than gilts aged 40-50 weeks (Table 2). The present study indicated that maximal number of ovulation of LY gilts in Thailand was obtained at >141 kg body weight and at >36 weeks of age. Therefore, to achieve high prolificacy, the gilts are recommended to be bred at a body weight of at least 141 kg.

Association between lived weight and size of the uterus in Landrace x Yorkshire crossbred gilts

Padet Tummaruk; Sawang Kesdangsakonwut; Atthaporn Roongsitthichai; Annop Kunavongkrit
Chulalongkorn University, Bangkok, Thailand

**Introduction**

In Thailand, replacement gilts are usually mated at the second or later observed estrus, about 7-9 months of age. The objective of the present study was to investigate an association between lived weight and size of the uterus (i.e., weight and length) in Landrace x Yorkshire (LY) crossbred replacement gilts in Thailand.

**Materials and Methods**

The study was conducted between May 2005 and September 2008. Genital organs of 316 LY crossbred replacement gilts from six swine commercial herds in Thailand were examined. The herds, where the samples were collected, were located between latitude 13˚ and 17˚ N and between longitude 100˚ and 104˚ E. The gilts entered the gilt pool at body weight of 80-100 kg and were housed in an open-housing system. The genital organs were collected, placed on ice and transported to the laboratory within 24 h after culling. Data including herd, gilt identity, breed, date of birth, culling date and body weight at culling were collected. Age at culling was calculated. The genital tract including ovaries, uteri and cervixes were dissected from the mesometrium and examined macroscopically. The uterus from uterotubal junction to the uterine body was dissected and weighed by using an electronic balance. The length of the uterine horns was measured by using a metrical scale plastic tape. The measurement was done by placing one end of the plastic tape at the junction of the uterine horn and uterine body and threading the tape along the horn between the thumb and fingers. The measurement was performed on both sides of the uterine horn and the uterine body. The sum of the length of each part was regarded as total length of the uterus. Stages of the reproductive cycle were defined according to an appearance of the ovaries, i.e., corpora lutea (CL), corpora albicantia (CA) and follicles (F). The gilts were classified according to their lived weight at culling (Table 1). Weight and length of the uterus were compared among groups by using multiple ANOVA.

**Results and discussion**

Of the 316 gilts, 36 gilts (11.4%) had endometritis, 15 gilts (4.8%) had congenital abnormalities and 9 gilts (2.9%) had miscellaneous abnormalities. Gilts with abnormal uterus were excluded; therefore 255 gilts were remained for further analyses. The average age at culling was 297.0±46.5 days and the body weight at culling was 144.6±20.5 kg. Of these gilts, 147 gilts (57.6%) were in luteal phase, 31 gilts (12.2%) were in follicular phase and 77 gilts (30.2%) were in pre-pubertal phase. The weight of the uterus was 689.0±219.0, 727.6±315.0 and 127.7±70.8 g in luteal, follicular and pre-pubertal phases, respectively. The length of the uterus was 263.2±61.2, 200.4±35.2 and 123.3±25.4 cm in luteal, follicular and pre-pubertal phases, respectively. Since both weight and length of the uterus in pre-pubertal gilts was significantly lower than in cyclic gilts, they were not included in the analyses. The weight and length of the uterus in relation to body weight at culling in cyclic gilts is presented in Table 1. Gilts with body weight of 92-130 kg had smaller uterus than those of 141-150 kg (Table 1). Gilts with body weight of 161-205 kg had significantly heavier and longer uterus than those of 92-160 kg (Table 1). The present study indicated that the maximum size of the uterus of LY gilts in Thailand was obtained at body weight of >161 kg. Therefore, breeding gilts at body weight of >161 kg may increase the number of piglets born per litter since a maximum uterine capacity was achieved.

Effect of genotype of sows kept under the same housing conditions on piglet litter size

Mario Ostovic1 Anamaria Ekert-Kabalin1 Sven Mencik1 Tomislav Balenovic1 Dinka Milic2 Zeljko Pavicic1
1. Faculty of Veterinary Medicine University of Zagreb, Zagreb, Croatia; 2. Dubravica Pig-Breeding Farm, Ltd, Dubravica, Croatia

Introduction
Litter size in pigs is an important component of production efficiency (1) and sow genotype is one of the factors demonstrated to have significant effect on piglet litter size (2). However, other non-genetic factors including sow housing can cover up this benefit. The aim of this study was to determine association between piglet litter size and genetic type of sows kept under the same housing conditions in order to eliminate the possible influence of housing conditions.

Material and Methods
Data were collected at a commercial pig farm and included two groups of 40 sows (Swedish Landrace, SL and Segers hybrid, SG) representing a part of the farm population (groups 1 and 2). Group 3 of 28 sows (Swedish Landrace and Large White crossbreeds, SL*LW) represented the whole population of this genotype on the farm. All sows were kept under the same housing conditions during pregnancy and lactation. The average length of lactation was 25 days. Semen from the same boars was used for insemination of sows in all groups. Data on litter size included six parity records and were expressed as number of piglets born in total (NBT), number of live-born piglets (NBA) and number of still-born piglets per litter (NSB). Statistical analysis was performed using the Statistica 8.0 (Statsoft Inc., 2008) statistical software and methods of variance analysis (one-way ANOVA and ANOVA Repeated Measures).

Results
Results are presented in Table 1.

Discussion
NBT was highest in the SL*LW sow population in sixth parity and significantly differed from sixth parity of sow groups 1 and 2 (P<0.05). Group 3 NBT differed significantly in sixth parity due to the first parity NBT in the same group (P<0.05). In all groups, NBA and NSB differed within the six parity cycles observed due to the sow genotype. Study results indicated the genotype of sows kept under the same housing conditions to influence the piglet litter size.

Assessment of sow births synchronised with oxytocol and long-acting oxytocol (carbetocin)

Carlo Cerati2, 3 Alessandro Palese1 Fausto Gamba2, 3 Paolo Benaglia4 Paolo Bonilauri4 Lucio Nisoli1
1. Bayer HealthCare, Milano, Italy; 2. Bompi Farm, Piubega, Mantova, Italy; 3. Gruppo Suinicolo Mantovano, Mantova, Italy; 4. Istituto Zooprofilattico Sperimentale Reggio Emilia, Reggio Emilia, Italy

Introduction
The purpose of farrowing synchronisation in sows is to concentrate births into a short period of time, benefiting both production and farm management. Grouping births during working hours is useful to enable proper assistance, reducing perinatal piglet mortality [1] and improving fostering. The duration of farrowing influences the rate of stillbirths: a prolonged farrowing (>3 h) is more likely to result in stillborn piglets than a shorter farrowing [2]. This study compared two synchronisation protocols, using a long-acting oxytocin (carbetocin) and a synthetic oxytocin in association with prostaglandin.

Materials and Methods
The test was carried out in a 2,700 sow farm with weekly births in the Po valley in Italy. Births from 240 sows were analysed: the sows were divided into 3 groups (80 sows per group) at random:

- Group 1: 2 mg of alfaprostol (Gabbrostim®) i.m. at 11 am on the day before the expected birth date (approximately day 113 of gestation) and 0.35 µg of carbetocin (Hypohysin® LA) i.m. at 7 a.m. the next day;
- Group 2: 2 mg of alfaprostol (Gabbrostim®) i.m at 11 am on the day before the expected birth date and 10 iu of oxytocin i.m. at 7 a.m. the next day;
- Group 3: 2 mg of alfaprostol (Gabbrostim®) i.m. at 11 am on the day before the expected birth date.

The following parameters were analysed: duration of farrowing (from expulsion of first piglet until expulsion of placenta), interval between administration of the drugs and time farrowing started, number of liveborn piglets, weight of litter/number of liveborn piglets, stillborns, mummified foetuses, inspections during farrowing (vaginal palpation if birth per piglet was more than 30 min) and mortality during lactation.

Results
The duration of farrowing was significantly longer in group 2 than in the other groups. The mean duration in group 1 was 3 h 41 min, the mean duration in group 2 was 4 h 40 min, and the mean duration in group 3 was 4 h 4 min. The interval between administration of the carbetocin or oxytocin and the start of parturition was 1 h 59 min and 2 h 47 min respectively. The mean numbers of liveborn in groups 1, 2 and 3 were: 11.83, 11.66, 11.63, respectively. The mean weight of the litter/number of liveborn piglets in each of groups 1, 2 and 3, expressed in kg, were 1.70, 1.69 and 1.52 respectively. The mean number of stillbirths and mummified foetuses per group was 0.68, 0.88 and 0.74, for groups 1, 2 and 3, respectively. The mean number of stillbirths per litter for groups 1, 2 and 3 were 0.39, 0.55 and 0.61, respectively. Inspections during farrowing were significantly fewer in group 1 (p<0.01) with 14 inspections during 80 farrowing compared to 55 and 33 inspections in 80 farrowing for groups 2 and 3 respectively. The mean number of piglets that died during lactation in groups 1, 2 and 3 were: 0.40, 0.56 and 0.65.

Discussion
The use of carbetocin in a birth synchronisation protocol showed a significant reduction in duration of farrowing and number of inspections, compared to oxytocin. Besides this, there was a tendency for less stillborn piglets per litter after using carbetocin (3.11%, 4.38%, 4.93% in Groups 1, 2 and 3, respectively). This test confirmed [3] the efficacy of this molecule in inducing farrowing and positively influencing the productive performance of the sows.

1. Bayer HealthCare, Milano, Italy; 2. Suivet, Reggio Emilia, Italy; 3. Il Girasole Farm, Reggio Emilia, Italy; 4. Istituto Zooproﬁlattico Sperimentale Reggio Emilia, Reggio Emilia, Italy

Introduction
In maternity units, synchronising farrowings is undoubtedly advantageous. Concentrating farrowings into working hours and attendance at the farrowings reduces stillborns [1] and means that a higher number of sows are available for matching operations. The objective of this study was to compare two farrowing synchronisation programmes (prostaglandin associated with oxytocin or long-acting oxytocin), examining the most important production parameters, and specifically, weight at weaning, a fundamental piece of information for sites 1 (maternity unit).

Materials and Methods
The test was carried out in a 360 sow farm in the Po valley in Italy operating three weekly batch farrowing. A randomised double blind study was planned, in which the sows were divided into two groups:
• Group 1 (n = 52): intramuscular cloprostenol (Estrumate®) was administered the day before the scheduled farrowing day (approximately day 113 of gestation), and 35 μg of intramuscular carbetocin (Hypophysin® LA) the day after (24 h after cloprostenol).
• Group 2 (n = 59): intramuscular cloprostenol (Estrumate®) was administered the day before the scheduled farrowing day (approximately day 113 of gestation), and 20 IU of intramuscular oxytocin (Izossitocina®) the day after (24 h after cloprostenol).

The following parameters were evaluated: duration of farrowing (the time from expulsion of ﬁrst piglet until expulsion of last piglet of the litter), number of liveborn piglets and weight on weaning; the weight determinations were performed every three batches, and the litters were selected randomly. A total of 33 litters of piglets were weighed. The differences observed in duration of farrowing, number of liveborns and mean weight at weaning between the two groups were compared within ANOVA and the Kruskal-Wallis test with a level of significance of p<0.05.

Results
The mean duration of farrowing was 122.12 minutes and 127.21 minutes in group 1 and group 2 respectively; the mean number of liveborns was 13.71 and 12.73 in group 1 and group 2 respectively (table 1). The mean piglet weight on weaning was statistically (p<0.05) higher in group 1 than in group 2, with 7.43 and 6.80 kg respectively.

ab: indicates that the groups differ signiﬁcantly (p<0.05)

Discussion
In this test, synchronising farrowings with prostaglandin associated with long acting oxytocin resulted in a weight at weaning that was signiﬁcantly higher than the association with oxytocin. An appropriate farrowing synchronisation protocol combined with the assistance required as necessary can increase piglet survival [1,2]; in addition, the short duration of birth ensuring the litter receives higher quantities of immunoglobulin, protein and fat, may explain the increased weight of the litter. This hypothesis could be tested in the future.

Comparison of the effects of cloprostenol (Planate®) and dinoprost on the smooth muscle of sow’s uterus

Maria V. Falceto1 Juan Luis Ubeda1 Divina Murillo2 Ruth Menjon3 Marta Jimenez3 Jesus M. Bollo3 Jesus V. Lopez3
1. Dept. of Reproduction. Faculty of Veterinary Medicine, Zaragoza, Spain; 2. Faculty of Veterinary Medicine, Zaragoza, Spain; 3. Intervet/Schering-Plough AH, Cantabria, Madrid, Spain

Introduction
Besides its luteolytic effects, prostaglandin F2α (PGF2α) exerts contractile effect on uterine smooth muscle due to reduction of intracellular cyclic-AMP levels and increase of intracellular calcium concentration (1). In sows, these contractions can be useful in facilitating elimination of uterine secretions and prevention of vaginal discharge (2). Aim of present study was to compare effects of cloprostenol (Planate®), a synthetic analogue of PGF2α, on uterine smooth muscle of the sow with dinoprost, a product used for this indication.

Materials and methods
Seven 8-month old LDxLW prepubertal gilts were included in the study. After induction of first estrus with 400 IU PMSG and 200 IU HCG (PG600®), gilts were humanely killed on first day of estrus (confirmed by standing reflex). Effects of cloprostenol and dinoprost on uterine smooth muscle was evaluated using in vitro organ bath technique.

Eight 10 x 5 mm strips of myometrium were removed from each gilt, using the same protocol, and placed in Petri dishes in sterile saline. After recording exact weight and length of each strip, four were mounted in direction of the longitudinal fibers and four in direction of circular fibers, and placed in the organ bath vessels attached to an isometric transducer (Pioden UF1, Graham Bell House, Canterbury, UK). Krebs Ringer solution (5ml) was then added to each vessel. The following protocol was followed:
1. Study of spontaneous motility of longitudinal and circular uterine smooth muscle in Krebs Ringer solution. After the stabilization period, the spontaneous motility of the preparations was recorded over about 10 minutes
2. Study of the longitudinal and circular smooth muscle motility in response to dinoprost (571 mcg/ml. 10 minutes) and cloprostenol (Planate®) (10 mcg/ml 10 minutes) (3). The concentration was selected in the light of experience from previous studies, with similar proportions to those used systemically under field conditions for both substances.

The mechanical activity of the preparations was amplified (The MacLab Bridge Amp, AD Instruments Inc, Milford, Mass, EE.UU) and filtered (4). This mechanical signal was sent to an analog-to-digital converter, and the data recorded numerically on computer by a data acquisition and processing program (MacLab System), which was used to measure amplitude, frequency and area under the curve of induced uterine motility per unit of time (interval/time/surface, Maximum-minimum, Interval/time) for all recorded preparations.

The mechanical activity of the preparations was amplified (The MacLab Bridge Amp, AD Instruments Inc, Milford, Mass, EE.UU) and filtered (4). This mechanical signal was sent to an analog-to-digital converter, and the data recorded numerically on computer by a data acquisition and processing program (MacLab System), which was used to measure amplitude, frequency and area under the curve of induced uterine motility per unit of time (interval/time/surface, Maximum-minimum, Interval/time) for all recorded preparations.

Statistical study included the Kolmogorov Smirnov test to assess the goodness of fit of the variables to a normal distribution. An ANOVA test was then performed, and subsequently non-parametric tests (Friedman test and chi-square test).

Results
Contractions of the circular fibers of uterine smooth muscle were quantified (intensity, rhythm and duration) in the first place, and no significant differences were found for any of the parameters studied.

<tr>
<td></td>
<td>p=0.548</td>
<td>p=0.603</td>
</tr>
</tbody>
</table>

Finally, the values obtained for each of the gilts included in the study were compared, and again, no significant differences were found between them.

Discussion
According to these results, cloprostenol produced the same effect as dinoprost on the contractions of uterine smooth muscle of sows, for both circular and longitudinal fibers. This means that cloprostenol (Planate®) is a candidate for post partum use for prevention of vaginal discharge, as has been shown in previous field studies (5). The fact that no significant differences were found between the animals included in the study indicates the consistent repeatability of the results obtained with both treatments.

Effect of the postpartum administration of Cloprostenol (PLANATE®) on production and reproduction performance indices

Juan C. Ezpeleta1 Rut Menjon2 Marta Jimenez2 Jesus M. Bollo2 Jesus V. Lopez2 Maria T. Tejedor3
1. Grupo AN, Pamplona, Spain; 2. Intervet Schering Plough, Madrid, Spain; 3. Dept. of Anatomy, Embryology and Genetics Unit of Genetics - Faculty of Veterinary Medicine, Zaragoza, Spain

Introduction
Among its other properties, such as its luteolytic effect, prostaglandin F2α (PGF2α) induces contractions of the smooth muscle of the uterus. It has been reported that, in the sow, postpartum PGF2α injection may cause a more rapid return to estrus after weaning, may increase prolificacy in subsequent farrowings and prevent uterine discharge, thus assisting in the reduction of premature culling or mortality. Furthermore, it may increase milk production and consequently reduce neonatal mortality(1).

The aim of the present study was to assess the effects of postpartum cloprostenol (Planate®), a synthetic analogue of PGF2α compared with dinoprost (Dinolytic®), another product with the same indication.

Materials and Methods
The study was undertaken on a 1400-sow farm on two sites in Navarra (northern Spain), which transfers two lots of 80 sows per week into the farrowing barn, and practises early weaning at average of 19-21 days of age. The herd was negative for PRRSv, but had severe reproductive problems. In February 2009, the farm records showed that about 17.5% of sows returned to estrus after weaning, and 8-10% exhibited an abnormal postfarrowing uterine discharge.

452 sows were allocated to one of two groups: A Planate® group: 220 sows, injected IM with 2ml cloprostenol (875 μg/ml); and a Dinolytic® group: 232 sows, injected IM with 2 ml dinoprost (5mg/ml). Untreated animals acted as controls using the farm’s historical data. In any week, all the sows which farrowed were treated 24-36h later with one or other product, the products being alternated week by week.

The following parameters were recorded: number of sows with abnormal vulval discharge during lactation and weaning, duration of lactation, number of weaned piglets, weaning to service interval, weaning to fertile service interval, and fertility. Sows were individually identified and cross-fostering was only allowed among sows from the same treatment group. No oxytocics or NSAIDs were used during or after farrowing.

Statistical analysis was carried out using the General Linear Model (GLM-SPSS 15.0 for Windows). The Pearson’s chi-square test and the Breslow test were used for the comparison of means.

Results
A comparison, between groups, of the parities of the sows within them showed that they were fully comparable: 86.45% multiparous and 13.6% primiparous sows in the Planate® group, and 88.8% and 11.2%, respectively, in the Dinolytic® group, (p=0.1522).

Discussion
Postpartum reproductive parameters improved with both treatments, especially fertility, weaning to fertile service interval, and number of weaned piglets, the most notable feature being the nearly complete absence of vulval discharges. As a result, an improvement in prolificacy could be expected in the next cycle (2).

Therefore, the use of PGF2α analogues after farrowing on a farm with a high prevalence of uterine discharge can be a very valuable treatment option, although other factors such as hygiene and general management still require proper attention.

There were no significant differences between the treatment groups, thus it can be concluded that post farrowing treatment with cloprostenol (Planate®) is an option for the prevention of this type of reproductive disorder.

**Introduction**

Paracetamol has antipyretic and antalgic properties but has a specific pharmacological profile\(^1,2\) which explains paracetamol's good level of tolerance in pigs. The demonstration of the paracetamol's safety for gestating and lactating sows\(^3\) has allowed the inclusion of these two categories in the summary of product characteristics (SPC) for Pracetam\(^\circ\) 10% premix. A field trial has been carried out by the University of Parma within a conventional breeding unit to measure the interest of paracetamol during peripartum period.

**Materials and Methods**

A hundred sows have been included in the trial, divided into two batches, control and treated. The treated batch (n = 50) received a medicated feedstuff containing paracetamol (Pracetam\(^\circ\) 10% premix / 30mg of paracetamol per kg of body weight per day) during the peripartum period, over 6 days, 4 days before farrowing and 2 days after. The control batch (n=50) has received the same feedstuff with no paracetamol. The sows have been intensively observed for the 6 days prior to farrowing, on the day of farrowing and during the post-partum period. In order to describe each criterion, they were marked 0, when normal and 1 when they were considered as abnormal. For daily monitoring, the scores were totalled over the entire period covered. Unless stated to the contrary, the statistical analysis used the Mann-Whitney test (Wilcoxon).

**RESULTS**

On the day of inclusion in the study, none of the observed parameters was significantly different between the two batches. In addition, no difference was noted during the monitoring of the farrowing. The lactation anomalies were marked individually and two classes were created: normal lactation and moderately abnormal lactation. For these two classes, there was no difference between the two batches (Chi 2 test, p=0.137). Three classes were created to mark the sows' appetite: the appetite was significantly less disturbed in the batch treated with Pracetam\(^\circ\) than in the control batch (Chi 2 test, p=0.033). In addition, the phenomenon of constipation was significantly less frequent, particularly during the first three days post-partum, in the treated batch (Chi 2 test, p<0.001). Moreover, the number of sows having presented abnormal faeces was significantly lower than in the treated batch (Chi 2 test, p=0.010). The number of sows whose condition required medical intervention is also lower than in the treated batch (particularly during the first three days post-partum, Chi 2 test p=0.044) (see figure 1).

With regard to the piglets, the litters from the two batches presented no significant difference in terms of mortality. Nor was there any significant difference between the two batches with regard to the health of the piglets at three days of age, but there is a trend (Chi 2 test, p=0.07) of better health in piglets born of sows treated with Pracetam\(^\circ\). The same is also valid for the incidence of diarrhoea (Chi 2 test, p=0.059). Moreover, the number of piglets having to receive an individual treatment was significantly weaker in the treated batch, particularly during the first three days of life (55 compared with 36 piglets, Chi 2 test, p=0.037).

**Discussion and Conclusion**

The significant differences observed in the sows from the treated batch (state of health, number of medical interventions) may be attributed to the effects of the paracetamol. As for the significant differences recorded in piglets (state of health, number of treatments), they may be interpreted as a indirect consequent of the positive effects observed in the sows; the sows being in better health in post-partum period (less fever, less constipation, appetite regained earlier), they more voluntarily provided piglets access to the teat, which had a direct consequence on their health and their development.

Porcine circovirus type 2 (PCV2) prevalence in abortions in France

Guillaume Perreul1 Bernard Fily1 Sophie Longo2 Thaïs Vila3 Jean-Bernard Herin1 Julie Venet3 François Joisel3
1. Merial S.A.S., Ancenis, France; 2. BPC, Labruguière, France; 3. Merial S.A.S., Lyon, France

Introduction
The role of porcine circovirus type 2 (PCV2) in reproductive disorders has been studied (1). The present paper reviews the results of the lab diagnosis collected through a MERAL protocol « pack avortons » from June 2008 to June 2009.

Material and Methods
Aborted foetuses or weak piglets (AF-WP) include stillborns and weak piglets which breathed and/or suckled some colostrum before death.

Macroscopic aspect was detailed for 271 AF-WP. Due to poor conservation, 25 AF-WP were not submitted for any analyses.

PCV2, PPV and PRRSV diagnostics were performed on 296 AF-WP from 93 sows in 30 farrow-to-wean and farrow-to-finish non-PCV2-vaccinated herds.

Lab analyses for PRRSV and/or PPV were performed in 15 herds out of 30 on lung pools. In each herd, 1 pool (=3 AF-WP) for each test: all pools were PCR-negative.

Diagnostics for PCV2 were completed in 266 AF-WP as follows:
• by PCR on liver and/or heart for all pooled AF-WP (101 pools : 1 pool=max 3 AF-WP from the same dam)
• in frozen AF-WP which did not drink or breathe totally: anti-PCV2 antibody test performed on 135 AF-WP using thoracic and/or abdominal liquid (SERELISA® PCV2 Ab, Synbiotics, Lyon, France)
• by immunohistochemistry (IHC): 36 IHC were performed from individual AF-WP samples: 11 on livers and 25 on hearts.

A farm was considered as facing PCV2 reproduction disorders when at least 1 AF-WP was PCV2 positive using at least 1 method.

</tr>
</tbody>
</table>

In the 66 PCV2-positive/266 AF-WP (24.8%) PCV2 was found most frequently in hearts, except in stillborn AF-WP in which anti-PCV2 antibodies were found. Anti-PCV2 antibodies were found in all AF-WP types except in mummified AF-WP and in AF-WP with lysed/discoloured liver.

Discussion
The « pack avortons » was put in place to systematically confirm or infirm the involvement of the major reproductive pathogens, i.e. PPV, PRRSV and PCV2 in case they could be suspected. All analysis methods taken together, these results report a high PCV2 prevalence. Indeed PCV2 was evidenced in AF-WP in 40% (often several aborted litters per case) of herds where reproduction disorders were investigated.

In addition, these results enabled to define a diagnosis strategy: mummified foetuses are more likely to be found PCR positive (mummified piglets are often dry so no liquid can be harvested from them to perform ELISA) especially when they are not lysed whereas stillborn foetuses are more often ELISA-positive (i.e. anti-PCV2 antibodies detection). It is well-known that foetuses become immunocompetent from the last third of the gestation, i.e. about 70 days onwards. So age (>70 days of age, i.e. about 17 cm long) and denaturation status of the conspectus could be used as choice criteria for the diagnosis method.

Conclusion
PCV2 appears to be involved in a large number of reproductive disorder cases and has to be included in the differential diagnosis.

Investigation of reproductive failures caused by porcine circovirus type 2 in large pig production units in Croatia

Zoran Lipej; Dinko Novosel; Jelena Balatinec; Besi Roic
Croatian Veterinary Institute, Zagreb, Croatia

Introduction Porcine circovirus type 2 (PCV2) considered the causal agent of PMWS, has also been demonstrated to be involved in reproductive failure [1]. Congestive heart failure, excess fluid in the thoracic and abdominal cavity, dilated and hypertrophied heart, firm and enlarged liver was frequent and the most prominent gross pathological finding in aborted and stillborn piglets [2]. Histologically, there were severe non-suppurative myocarditis and myocardial necrosis with fibrosis [1, 2].

The objective of this study was to investigate role of PCV2 in aborted and premature piglets connected with reproductive disorders on large pig production units in Croatia.

Material and Methods Eight farrow-to-finish farms with previous history of PMWS and reproductive failures were selected for the study. A total of 83 fetuses aborted in the last third of gestation and premature piglets submitted to the Croatian Veterinary Institute, were included in this study. Briefly, a post-mortem examination was performed and samples of heart were collected in 10% buffered formalin for histopathological examination and immunohistochemistry (IHC) and in situ hybridization (ISH). For PCR detection samples of lungs, spleen and liver were pooled and stored on -70°C. Tissue in fixative was routinely processed and stained with H&E. Myocardium sections were proceeded by IHC detection with anti-PCV2 ORF2 monoclonal antibodies (Ingenasa®) according to previously described protocol [3]. In situ hybridization was performed with digoxigenin labelled 41base oligonucleotide probe on myocardium tissue according previously described protocol [4]. For detection of PCV2 ORF 1 is used Q-RT-PCR as previously described protocol [5].

Results Salient gross findings demonstrated in aborted or stillborn piglets were diffuse subcutaneous oedema, oedema and segmental haemorrhages of umbilical cord, hydrothorax, ascites, subepicardial haemorrhages and haemorrhages on kidney cortex. Histopathologically, in 21 (25.30%) fetuses mild myocardial degeneration and mild myocardial necrosis without lymphocytic inflammatory reaction were observed. All of tested samples of heart were negative for presence of PCV2 antigen by IHC and all of tested myocardium tissue was negative for presence of PCV2 genome by ISH. In all 83 tested samples PCV2 genomic DNA is detected.

Discussion In this study gross lesions on fetuses characterized by severe, non-suppurative myocarditis and myocardial necrosis with fibrosis reported as specific for PCV2 associated reproductive failure, were not found.

Positive PCR findings in all 83 samples of myocardial tissue are unexpected and surprising and in contrast with negative IHC and ISH results in same heart tissues. Therefore, all PCR positive results are considered as false positive or result of secondary contamination. Because of that sequencing of PCR products still need to be performed to confirm it. According to absence of specific gross lesions on examined fetuses, no characteristic histopathological lesions and negative results of IHC and ISH in myocardial tissue we consider there is no evidence that PCV2 caused reproductive failure in Croatian large pig production units. Based on our results, the lack of evidence of association between PCV2 and reproductive failure suggests that PCV2 is probably not an important abortifacient pathogen in Croatia. These results are in accordance with Spain researchers [6]

Detection and prevalence of viral pathogens from aborted fetuses and stillborn piglets in Korea

Won Gwnag Lee; Tae Hun Woo; Jeong Hee Han
School of Veterinary Medicine and Institute of Veterinary Science, Kangwon National University, Chuncheon-si, Korea

Introduction
Reproductive disease during the gestation in sows is usually manifested by abortion or stillbirth. Two major classes of reproductive failure are recognised in swine. A first category is represented by infectious agents (considered responsible for 30–40% of abortions, mummified fetuses, and stillbirths) that cause primary infection of the reproductive tract and most of them are viruses. A second group includes toxins, environmental and nutritional stresses, and systemic disease in the sow (considered responsible for the rest of the reproductive failure). A large number of viruses have been reported to affect porcine reproductive performance, and it is likely that any virus capable of causing clinical illness in adult swine, or crossing the placental barrier to infect the porcine conceptus, is a potential reproductive pathogen. This experiment was conducted to investigate the presence of recognised abortifacient viruses from aborted fetuses and stillborn in cases of reproductive failure in sows.

Materials and Methods
A total of 219 samples of aborted fetuses or stillborn, submitted to the Department of Veterinary Pathology of Kangwon National University between 2006 and 2009 May, were collected from 97 commercial swine farms located in the five provinces (Gyunggi, Gangwon, Chungcheong, Jeolla, Gyeongsang) in Korea. Each samples were tested for abortifacient viruses such as PRRSV, PPV, ADV, JEV, EMCV, SIV and PCV2. The presence of virus in fetal tissues was determined by PCR or RT-PCR.

Results
Abortifacient virus infections were detected in 82 out of 219 aborted fetuses or stillborn (37.4%) as well as on 39 out of 97 pig farms (40.2%). The major viral infection were procine circovirus type 2 (PCV2), porcine reproductive and respiratory syndrome virus (PRRSV) and Aujesky’s disease virus (ADV) for which 46 (21%), 19 (8.6%) and 16 (7.3%) were positive, respectively, with 9 fetuses had complicated infection that 4 for PCV2+PRRSV, 3 for PCV2 + ADV, 2 for PCV2 + PRRSV + ADV. As minor viral infection SIV, PPV, JEV for which 8(3.6%), 3(1.3%), 1(0.4%) were detected. And EMCV was not identified.

Conclusions
The result suggest that PCV2, PRRSV, ADV is apparently the most important viral infectious agents associated with fetal infection leading to abortion or stillbirth in Korea. Moreover, SIV, PPV and JEV might have a minor impact on reproductive disease.

Gross morphology of the oviducts in slaughtered replacement gilts

Padet Tummaruk; Sawang Kesdangsakonwut; Paisan Tienthai
Chulalongkorn University, Bangkok, Thailand

Introduction
Retrospective studies based on slaughterhouse materials are a useful tool for the clinical diagnosis of reproductive disturbance in pigs (1, 2). In the pig oviduct, a lot of important reproductive events such as sperm capacitation, fertilization and early embryonic development take place (3). In Thailand, 47% of all culling replacement gilts are culled due to reproductive problems, i.e., anestrus, repeat breeding, not being pregnant, vaginal discharge and abortion (4). The objective of the present study, therefore, was to investigate gross morphology of the oviducts in gilts culled due to reproductive failure in Thailand.

Materials and Methods
Genital organs from 337 replacement gilts from 6 swine herds in Thailand were collected at slaughterhouses between May 2005 and September 2008. The organs, including ovaries, oviducts, uteri, cervices and vaginas-vestibules-vulvae were collected, placed on ice and transported to the laboratory within 24 h after culling. Historical data included herd, gilt identity, breed, date of birth, culling date, body weight at culling and reason for culling were collected. Age at culling was calculated. The reproductive cycle of the gilts were classified according to the appearance of the ovary as inactive, follicular and luteal phases (2). The abnormalities of the oviduct were investigated and analyzed by using frequency analysis. Pearson’s correlation was used to analyze the relationship between the length of the oviduct and body weight, uterine weight, length of the uterine horns, length of other genital organs and number of ovulations. Length of the oviduct was compared between left and right sides by using paired t-test. The influence of reproductive cycle and body weight on the length of the oviduct was analyzed by using multiple ANOVA.

Results and discussion
On average, the gilts were culled at 300.9±49.3 days of age and the body weight at culling was 145.5±20.2 kg. The reason for culling included anestrus (154 gilts), abnormal vaginal discharge (n=62), repeat breeding (n=41), abortion (n=27), not pregnant (n=20), non-reproductive problems, e.g., lameness, illness, and poor conformation (n=21) and miscellaneous (n=8). Of these gilts, 294 gilts (88.0%) had normal oviducts, 29 gilts (8.7%) had moderate to severe congestion of the oviducts, 4 gilts (1.2%) had salpingitis, 3 gilts had pyosalpinx (0.9%), 3 gilts (0.9%) had congenital abnormalities, i.e., unilateral hypoplasia, oviductal diverticulum and a remaining of epididymis in a true hermapodite gilt, and 1 gilt had blood clot obstruction in the oviduct. Of the anestrus gilts, 134 had normal oviduct, 12 had oviduct congestion, 3 had congenital abnormalities, 2 had salpingitis and 1 had pyosalpinx. Of the gilts culled due to vaginal discharge, 54 had normal oviduct and 2 had pyosalpinx. Of the repeat breeding gilts, 33 had normal oviduct, 6 had oviduct congestion, 1 had salpingitis, and 1 had blood obstruction. Of the aborted gilts, 25 had normal oviduct and 2 had oviduct congestion. Of the non-pregnant gilts, 17 had normal oviduct, 2 had oviduct congestion and 1 had salpingitis. All of the gilts culled due to non-reproductive and miscellaneous causes had normal oviduct. Of the gilts with normal and congested oviducts (n=323), the length of the oviducts was 27.9±6.7 cm. on the left and 26.2±6.2 cm. on the right sides. The left oviduct was 1.7 cm longer than the right oviduct (P<0.001). The length of the oviducts during inactive phase was shorter than luteal and follicular phases (21.1 versus 28.7 and 31.3 cm, respectively (P<0.001). Gilts with a body weight of 92-130 kg had a significantly shorter oviduct than gilts with a body weight of above 150 kg (P<0.008). The length of the oviduct was significantly correlated with body weight (r=0.34, P<0.001), uterine weight (r=0.62, P<0.001), length of the uterine horns (r=0.54, P<0.001), length of the uterine body (r=0.44, P<0.001), length of the cervix (r=0.26, P<0.001), length of the vagina (r=0.31, P<0.001) and number of ovulation (r=0.21, P=0.003). The present study demonstrated some important gross morphology of the oviduct in slaughtered replacement gilts in Thailand.

Urinary tract infections in sow herds with and without frequent puerperal diseases

Michael Wendt1 Jutta Verspohl2

1. Clinic for Swine and Small Ruminants, Hannover, Germany; 2. Institute for Microbiology, Hannover, Germany

Introduction
Uncomplicated infection of the lower urinary tract frequently occurs in sow herds. Clinical symptoms in sows are very mild and include urinary anomalies and vulvar discharges. However, urinary tract infections (UTI) are often associated with the development of puerperal endometritis and reduced fertility accompanied by increased rates of regular returns to estrus and repeat-breeder sows (1).

The aim of this study was to investigate the prevalence of UTI in sow herds with or without frequent puerperal diseases.

Materials and Methods
During farm visits as many mid-stream urine samples as possible were collected from a total of 34 sow herds by spontaneous micturition of sows in dry sow, gestation and farrowing areas (herd size: group 1-50: n=3, group 51-100: n=8, group 101-250: n=16, group 250-500: n=7).

Urine samples were first investigated by macroscopic examination (turbidity, irregular contents). Visually altered samples were selected and further controlled by test strips (pH, nitrite, protein, blood) as well as by microscopic investigation (crystalluria). Aerobic bacterial counts were estimated by dip slides, 10^5 cfu/ml urine were taken as a threshold for a significant bacteriuria (=UTI). Specification of bacterial isolates was carried out by aerobic culture techniques in 129 samples (4 per farm on average).

Results
In total 1194 urine samples were collected; the mean percentage of sampled sows per farm was 20.3%, ranging from 8.2 to 64.8%. Macroscopic changes were detected in 500 samples (41.9%), on 8 farms <30% of samples were altered, on 21 farms 30-60% and on 5 farms >60%. 435 out of 500 visually altered urine samples were investigated using dip slides, revealing 213 samples with significant bacteriuria (49.0%). Severe crystalluria was a common finding in visually altered samples (37.7%; unspecific phosphates, triple phosphates, calcium oxalate), but only one third was accompanied by a bacteriuria.

The mean percentage of UTI for all herds was 20.9%; on farms without frequent puerperal problems UTI were detected, in 13.0 (+8.1)% of the herd, on farms with frequent MMA problems UTI were present in 25.3 (+12.6)% of the herd. However, sample size for a prevalence survey (with 90% confidence interval, 10% precision, estimated prevalence 20% >> sows per herd/sows to be sampled: 50/24, 100/31, 250/37, 500/40, >500/43) was fulfilled only in 15 herds. The mean percentage of UTI for these 15 farms was 18.0 (+9.6)%, 5 herds without MMA problems and 10 herds with frequent MMA problems revealing 10.6 (+6.0)% and 21.6 (+9.1)% UTI, respectively (p<0.05).

Results of test strips with regard to nitrite-contents were compared to results of bacterial counts (dip slides). Only 40.3% of urine samples showing significant bacteriuria were nitrite-positive.

Bacteriological investigation of 129 samples demonstrated in 110 cases only one species with a bacterial count >10^5 cfu/ml; in 19 cases two species with a high bacterial count were found. E. coli was isolated most frequently (n=96) followed by Enterococcus spp. (n= 14) and alpha-hemolytic streptococci (n=7).

Discussion
Intensive sampling is necessary to obtain a sufficient number of urine samples for a conclusive UTI prevalence survey. The mean UTI percentage seemed to be overestimated when sample size was too small. UTI has to be supposed as an important risk factor for frequent MMA problems, if the prevalence in a herd exceeds 20%. Ascending infection of the uterus follows uncomplicated UTI after farrowing (2). The bacterial flora found in the infected bladder in this study is often detected in puerperal endometritis of sows (3).

As significant bacteriuria rarely occurs in urine samples without visual changes, only visually altered samples were selected for dip slide investigation; for this reason the percentage of UTI may be slightly underestimated. However, severe crystalluria was also a common reason for turbidity.

Nitrite content alone was not a sufficient diagnostic parameter for UTI, because 60% of UTI cases were not detected by this test.

Introduction

The leukocytes presence analyze, in boar semen, as a routine technique for quality control of seminal doses is not commune, however, in human is performed with strict care, because of its association with low fertility patients. Ramírez et al. (1) and Solís et al. (2) have indicated that the porcine rubulavirus pig has affinity with epididymis and prostate declining the semen quality on boars, so a study was conducted to determine the relationship between leukocytes presence and ejaculate quality on boars.

Material and methods

Nine York-Landrace boars, aged 12 months, serologically free of reproductive diseases underwent two experimental phases: Phase I, before-infection, where 10 ejaculates per animal were obtained, and, Phase II, after-infection where boars were inoculated intranasally with 5 ml 10^5 TCID50/ml of strain PAC-3 Jalisco/1992, scoring 21 ejaculates per animal. The boars ejaculates were evaluated without fractions: Volume (ml), sperm concentration (spz ml^-1) motility progressive (% MTP), abnormalities, and live sperm (% SL) were recorder. The leucocytes count (L x 10^3 ml) was conducted in two phase, using a Neubauer counting camera (3), and stained slides with Wright solution. Statistical analysis was a repeated measure design with SAS Mixed Model.

Results

Table 1 shows the quality and production values of boar’s sperm obtained during the evaluated phases. There were significant difference (P<0.05) on abnormalities, spz ml^-1 and leukocytes count. The volume, motility and SL were not different (P>0.05).

</tr>
</tbody>
</table>

Least square means within a row with different subscript letter differ (P<0.05)

Discussion

The production and semen quality of boars during Phase I was similar to healthy boars and weekly work rhythm, reported for Kolenbrander et al. (4). However, during Phase II, sperm production (spz ml^-1) decreased 66%, abnormalities rose twice, and the leucocytes presence beginning at eight days after-infection (P<0.05). There was a significant increase on Leukocytes weekly, where its highest value occur at the eighth week, to gradually decline thereafter, reaching a level of 20 leukocyte x 10^3 ml, holding constant these values the last five weeks of the experimental work.

Conclusion

The inoculation of porcine rubulavirus had a negative effect on sperm concentration and abnormalities increase, but volume, live spermatozoa’s and motility remained without changes. In addition, leucospermia showed, which at least not disappear during the period under investigation and the semen quality never recovers.

Influence of maternal antibodies on PCV2 vaccine efficacy

Brad J. Thacker, Warren D. Wilson
Intervet/Schering-Plough Animal Health, Desoto, KS, USA

Introduction

Vaccine interference due to maternally-derived antibodies (MDA) has been shown to occur in a number of species and with a number of diseases. The data reported in this paper was derived from a previously reported study where Circumvent® PCV (Intervet Schering Plough Animal Health) was shown to be effective in controlling PCVD in a herd with a history of moderate PCVD. In this paper, we report the influence of MDA at weaning (time of first vaccination) on the growth performance and mortality of vaccinated and non-vaccinated pigs.

Materials and Methods

The study was conducted in a 1700 sow herd that had experienced a mild increase in mortality rates and a severe increase in cull rates due to PCVAD. This herd had not previously vaccinated for PCV2 so the dams of the pigs used for this study had never been vaccinated. Pigs were weighed, tagged and their gender was determined one day prior to weaning at approximately 23 days of age. The pigs were allocated to vaccinated or control groups with stratification by weight, gender and litter. The pigs were vaccinated per label directions at 3 and 6 weeks of age (VAC) or left as non-vaccinated controls (CON). The pigs were weighed at weaning with a final weight at 21 weeks of age.

One pig per litter (the largest pig) was bled at weaning and periodically thereafter. Antibody titers to PCV2 were measured using an indirect immunofluorescence assay (IFA). Titers are reported as the highest dilution that inhibited fluorescence. The IFA titer at weaning of the tested pig was used as a surrogate MDA titer for litter mates. Not all litters contained a pig that was bled and those litters were not included in the analysis. The growth rate and mortality from weaning to 21 weeks of age were evaluated by linear regression and Fisher’s exact test for each titer level, respectively. Previous studies indicated that an MDA titer of >=640 may interfere with vaccination based on post-vaccination serological responses so the data was grouped by MDA titers <=320 or >=640. These titer groupings were similarly evaluated by ANOVA and Chi Square.

Results

The number and percentage of pigs with each MDA titer is presented in Table 1. Table 2 presents growth and mortality data for vaccinates and controls overall and grouped by MDA titers <=320 or >=640. There was no influence of MDA titer on either growth or mortality rates. Overall, vaccination improved growth rate and decreased mortality.

Discussion

MDA titer at weaning (time of first vaccination) with Circumvent® PCV appeared to have no impact on the subsequent performance of the pigs. Growth rate and mortality in the pigs that were sampled was not impacted by MDA titer as well (data not shown). The dams of the pigs used in this study had never been vaccinated. Both dam titers and pig MDA titers have been shown to be increased by vaccination of the dams prior to farrowing. Vaccination of dams was not evaluated in this study. However, serological evaluations of young pigs from sows that were vaccinated as young pigs have yielded similar IFA titer patterns as reported in Table 1 of this study.

**Introduction**

Leptospirosis is considered an important zoonosis as well as an emerging infectious disease. Pigs are among those domestic animals mostly affected by clinical disease, resulting from infection with pathogenic leptospires. Clinical signs of leptospirosis in pigs mainly include unspecific symptoms related to reproductive disorders, such as abortion, stillbirth, mummification and birth of weak piglets [1]. Similar symptoms may also be caused by a variety of common infectious agents, making laboratory testing for leptospirosis essential for both clinical diagnosis as well as eradication of the agent from affected livestock. Importantly, *Leptospira*-infected animals may proceed to an asymptomatic carrier state, shedding infectious leptospires into the environment and thus providing a source of infection for humans [2]. In order to develop a rapid, simple and sensitive method for direct demonstration of leptospires in clinical materials, polymerase chain reaction (PCR) based methods have been propagated in recent years. Among these, real-time PCR methods are especially attractive for clinical applications, because they allow not only qualitative, but also (semi)-quantitative detection of leptospiral DNA. However, only a few published real-time PCR protocols have been validated using clinical material from humans or livestock [3-5]. Here, we describe the design and validation of a novel real-time PCR specific for the detection of DNA from pathogenic *Leptospira* spp. and our experience with testing a variety of porcine clinical samples.

**Materials and Methods**

The LipL32 coding region that is only present in pathogenic *Leptospira* spp. was chosen as target region for the design of primers and hydrolysis probe for real-time PCR. Special care was taken to minimize the number of mismatches between primers/probe and the available LipL32 target sequences. Real-time PCR kinetics and analytical sensitivity were evaluated by amplifying serially diluted DNA obtained from a culture of *L. interrogans*. Analytical specificity was determined by analyzing nucleic acid extracted from non-pathogenic leptospires and *Leptospira*-related bacteria as well as from a variety of viral, bacterial and protozoan infectious agents involved in clinical disorders of swine. Clinical material from pigs, such as EDTA-blood, serum and tissue samples was obtained in the course of routine testing, from private veterinary practitioners and from a private veterinary laboratory.

**Results**

Alignment of all *Leptospira* LipL32 sequences (n = 106), which were available from GenBank at the time of assay design revealed a maximum of 1 mismatch to the forward primer (13 sequences) and 4 mismatches to the reverse primer (1 sequence). Eight sequences showed a single mismatch to the hydrolysis probe and 2 mismatches to the probe were evident in 9 sequences, all of which belonged to *L. santarosai*. Real time PCR analysis of a serial dilution of leptospiral DNA showed high sensitivity, linear amplification within 5 orders of magnitude and acceptable real-time PCR kinetics (R2 > 0.99; PCR efficiency = 92-94%), independent whether leptospiral DNA was diluted in yeast tRNA or in pig genomic DNA. The assay was capable of detecting all serovars of pathogenic leptospires tested (n = 13), while no positive signal was observed with any non-pathogenic member of the *Leptospiraceae*, or with any of the other infectious agents tested. Leptospiral DNA was detected in several clinical samples obtained from pigs.

**Discussion**

The real-time PCR assay described here was shown to be specific for the detection of DNA from pathogenic leptospires. The presence of pig genomic DNA in serial dilutions of leptospiral DNA did not influence real-time PCR performance, suggesting that the test can also be used for demonstration of leptospires in tissues from infected pigs. This is further supported by detection of leptospiral DNA in porcine clinical samples. Straightforward detection and quantification of leptospiral DNA is necessary for clinical diagnosis and may also increase our understanding of the epidemiology of leptospirosis.

Diagnostic investigations on mycobacterial abortion in a sow herd

Benjamin Schade1 Britta Janowetz1 Heike Köhler2 Irmgard Moser2 Ulrike Mittermeier1 Reinhard Nothum3 Jens Böttcher1

1. Tiergesundheitsdienst Bayern e.V., Poing, Germany; 2. Friedrich-Loeffler Institute, Institute of Molecular Pathogenesis, Jena, Germany;
3. Veterinary Practice Dr. Reinhard Nothum, Haselbach, Germany

Introduction

Swine abortion associated with a mycobacterial infection is an uncommon finding (Ellsworth et al.). Since intradermal testing is time-consuming and therefore cost-intensive, alternative test systems are needed to get an economically justifiable overview of the situation in an affected sow herd.

Materials and Methods

Case history: In March 2009, three neonatal porcine fetuses were submitted for diagnostic investigations. The sow was necropsied one month later.

Histopathology: Samples were fixed in 10% buffered formalin. 4-μm-thick sections were cut and stained with haematoxylin and eosin, as well as Ziehl-Neelsen’s stain.

PCR: DNA was extracted from fetal and maternal tissue with the DNeasy Blood and Tissue Kit (Qiagen, Hilden, Germany) following the manufacturer’s instructions. Presence of mycobacteria of the Mycobacterium-tuberculosis-complex and Mycobacterium-avium-complex were examined using the primers according to Rodriguez et al., Guerrero et al. and Kunze et al..

Immunological tests: Blood samples were collected from 30 sows and 10 suckling, growing and fattening pigs, respectively. They were stimulated with phosphate-buffered saline (PBS), Avian PPD (Prionics) and poke-weed mitogen (Sigma), respectively. Thereafter plasma was analyzed for IFN-γ with Quantikine® Porcine IFN-γ Immunoassay (R&D Systems, Wiesbaden; Cut-off 40 pg/ml). Serum was tested for antibodies with two prototype ELISA ID-Screen® Paratuberculosis Indirect Multispecies (IDVet-MAHS) and Mycobacterium avium hominisuis (IDVet-MAP) ELISA (kindly provided by Philippe Pourquier, Montpellier).

Results

Necropsy and histopathology: The fetuses showed numerous, small (Ø 2-6 mm), white foci in the liver. Sow: Several white, small, firm nodules projected from the surface of the endometrium. Several lymph nodes were enlarged. Multifocal, small (Ø 2-4 mm), white, firm nodules were seen on the surface of the lungs and in the kidneys. Fetal livers and the affected organs of the sow showed a mild to severe, multifocal, granulomatous inflammation, multinucleated giant cells with single to numerous, intracytoplasmatic, acid-fast and rod-shaped bacteria.

PCR: M. avium ssp. hominisuis was detected in fetal liver and organs of the sow including endometrium, lung, kidney, tonsil and several lymph nodes. Mycobacteria of the Mycobacterium-tuberculosis-complex were not detectable.

Immunological tests: Eleven of 27 sows (3x >1000; 4x 100-1000 and 4x 40-100 pg/ml) and only one suckling piglet (104 pg/ml) responded to Avian PPD. Three sows had detectable antibodies (one positive in both ELISAs had to be excluded from IFN-γ-test; one positive in IDVet-MAHS and IFN-γ-test; one positive in IDVet-MAP and negative in IFN-γ-test). None of the other animals showed a serological reaction.

Discussion

Tuberculous lymphadenitis caused by M. avium ssp. hominisuis is common in swine but genital and/or systemic infections seem to be rare. Detection of subclinically infected animals is essential, as they could be a source of infection for others. Frequent infection of sows was demonstrated by IFN-γ-test (41%). In contrast, antibodies were detectable only in single cases. Preliminary data are promising, but further investigations are necessary to validate this new test system.

A case report of porcine circovirus type 2 (PCV2) infection with many mummified in a newly started sow herd

Jesper S. Olesen
Porcus Swinespecialists, Ringe, Denmark

Introduction
This case report fully proves that PCV2 infection can result in many mummified fetuses at farrowing and be a costly problem for the producer. The report describes in details a PCV2 outbreak in a newly started 550 head sow herd in Denmark autumn 2008. PCV2 is also described in the literature as the cause of return to estrus as well as mummified and stillborn (1).

Materials and Methods
Data material consists of the production results from the first 399 inseminated gilts in a newly started sow herd. The results for each animal includes: identification number, date of insemination, date of farrowing, liveborn, stillborn, and mummified. Thirty mummified fetuses from four different sows were sent to the Veterinary Institute, Copenhagen for proper pathological testing. The mummified fetuses were tested in the following ways: 1) bacteriological, 2) porcine parvovirus virus (PPV) by antigen-ELISA, 3) PPV antibodies by immunofluorescence, 4) amount of IgG by ELISA, and 5) PCV2 by immunohistochemistry. Three out of the four sows with mummified fetuses sent to the laboratory were also blood tested. The blood was analyzed for: 1) PCV2 antibodies by ELISA, 2) PPV antibodies by ELISA, and 3) PCV2 by PCR.

Results
Out of the 399 inseminated gilts 356 farrowed (farrowing rate of 89.2 %). The number of total born was 14.5 piglets, live born was 12.8 (88.5 %), stillborn was 1.0 (6.8 %), and mummified was 0.7 (4.7 %).

The average duration of gestation was 117 (± 1.7 days). There were mummified fetuses in 86 (24.2 %) of the litters. The number of mummified fetuses ranged from 1 to 15. More than 75 % of the sows had 1 to 3 mummified fetuses. The number of mummified fetuses per litter was observed to be highest in a period of 4 – 6 weeks. There were stillborn in 182 (51.1 %) of the litters ranging from 1 to 10 piglets. More than 75 % of the sows had 1 to 2 stillborn. Out of the 30 mummified fetuses was: 3 examined bacteriological all negative for pathogene bacteria, 6 examined for PPV virus all negative, 8 examined for PPV antibodies all negative, 3 examined for the amount of IgG all normal, 9 examined for PCV2 in the heart muscle all 9 was positive. The 3 blood tested sows had low antibody titers for PCV2 and PPV infections. In the PCV2 PCR test two sows were negative and one sow had a low reaction.

Discussion
The case report shows PCV2 can cause many mummified fetuses in a newly started sow herd. The diagnosis is best in the heart muscle on the mummified fetuses using immunohistochemistry. A differential diagnosis that should be taken into account in Denmark typically includes PPV. Blood testing of the sow with many mummified fetuses is not a good choice if you suspect PCV2. With the production losses described in this abstract caused by a PCV2 infection, vaccinating gilts for PCV2 before mating must be seriously considered when initially populating a newly started sow herd.

Introduction

Mummified fetus is one problem that affects number of piglets born alive. Uterine space has been reported to be a factor increasing in percentage of mummified fetuses (1, 2). Diseases could associate with mummy's appearance in lower litter size sows (2). Several diseases cause fetal death including Porcine reproductive and respiratory syndrome virus (PRRSv), Porcine parvovirus (PPV), Porcine circovirus type 2 (PCV-2) and Japanese encephalitis virus (JEV). These viruses could be detected in mummified fetuses by molecular biology methods such as polymerase chain reaction (PCR) and reverse transcription PCR (RT-PCR) (3). The objectives of this study were to investigate the presence of viruses in mummified fetuses collected from sows using appropriated molecular biology methods and to study an association of the viruses found in sample with reproductive performance of those sows.

Materials and Methods

A total of 66 mummified fetuses were collected from 5 commercial pig farms, with percentage of mummies greater than 3. The mummified fetuses then were necropsied and collected tissue sample from lung, liver, spleen, kidney and brain. Lysate of collected tissue were extracted for RNA for PRRSv and DNA for PPV, PCV-2 and JEV. Specific primers were used in each reaction as follow; for PRRSv: W7PRRS-1 (ATGGCCAGCCAGTCAATCAGC), W7PRRS-2 (TCGCCCTAATTGAATAGGTGAC), W7USA (TG-GAGGATTTAGTTTGCCKACGCA) and W7EU (AAAACTGACCTTCCC-GCTGGA), for PCV-2: PCV-2F (TAGGTTAGGGCTGTGGCCTT) and PCV-2R (CCGCACCTTCGGATATACTG), for PPV: NS1-142F (AGCACAAAATGCAAACCCCAATA) and NS1-142R (CTCCACGGCTCCCAAGGCTAAAAG), for JEV: PWN - JE1 (GTGAAYATGACCAGCCAGGT) and PWN - JE2 (CATGAACCARATGGCCYCTGC). All samples were required to run for beta-actin primer specific to nuclear receptor co-repressor 1 (NCOR 1) and mito-primer specific to cytochrome B (CB) to proof the presence of RNA and DNA, respectively. Sample products that had negative results for each primer were excluded from corresponded test.

The reproductive performance parameters, including total born/litter, born alive/litter, % stillbirth, average daily litter weight gain, wean to first service interval and number of pig wean/litter, of sows that mummified fetuses were collected from were recorded and analyzed for association with viral antigens found in those mummified fetuses.

Results

The results showed that 80\% (4/5) of farm was positive to PRRSv and 60\% (3/5) was positive to PPV. There were only 2 farms found both viruses. The results from PCR and RT-PCR showed that 17.95\% (7/39) of the samples were positive to PRRSV and 7.69\% (3/65) were positive to PPV. All fetuses had negative results for PCV-2 and JEV.

Statistical analysis revealed only an association between litter sizes at 13 or lower and the positive samples (p = 0.033). Moreover, sows with litter size of 13 or lower had an odd ratio=2.4 to have positive results comparing to sows with bigger litter size.

Discussion

The results showed that PRRSv and PPV antigen were able to be detected in mummified fetal organ. There was no evidence of PCV-2 and JEV in the participated farms. Meanwhile, there was no association of viral antigen found with sow's breeding performances. However, mummified fetuses in lower litter size (≤ 13) sows associated with number of positive samples (odd ratio=2.4). Virus infection might play a role in being an additional cause of fetal death during gestation in low litter size sows.

College of Agronomy and Veterinary Medicine – University of Passo Fundo, Passo Fundo, RS, Brazil

Clinical manifestation of reproductive failures is highly variable and may be presented by either a subclinical infection or by the termination of pregnancy. The etiology of abortions is usually diffi cult and a conclusive diagnostic occurs in only 30-40% of cases (1). Several infectious agents are associated with abortion and reproductive failures in swine production. In Brazil the porcine circovirus 2 (PCV2) associated diseases (PCVAD) are the most economically important viral disease for swine production and it is associated with reproductive losses. The objective of this study was to perform diff erential serology for pathogens that cause reproductive failure in sows from farms with a history of severe PCVAD in the last 12 months before the sampling.

Material and Methods

Blood samples were collected from 120 sows which presented reproductive problems (mummifi ed, stillborn or unviable piglets). Samples were collected from 27 swine farms and up to 15 days following the farrowing or abortion. Analyzes were performed by routinely standardized laboratory tests and / or recommended by veterinarian surveillance authorities and OIE. Tests were performed at CEDISA, Embrapa Swine and Poultry Research Center or Veterinary Hospital from University of Passo Fundo, RS, Brazil. Serological tests used in this work included in house tests like immunocytochemistry or ICC for PCV2, Haemagglutination inhibition (HI) test for porcine parvovirus or PPV; Rose Bengal test (RBT) and the buffered plate agglutination test (BPAT) to identify antibodies against Brucella suis; Microscopic agglutination test (MAT) for diagnostic of leptospirosis (antigens selected for use in the MAT included representative strains of the serogroups known to exist in the region) and commercially available tests such as the Elisa screening for Pseudorabies virus (IDEXX HerdChek® PRV gB Antibody Test Kit), followed by serum neutralization test; IDEXX HerdChek® Porcine Reproductive and Respiratory Syndrome Antibody Test Kit and for classical swine fever virus the IDEXX HerdChek® CSFV Antibody Test. For Toxoplasma gondii antibody detection the indirect hemagglutination commercial kit Imuno-Hai from the Wama-Diagnostica Laboratories (SP, Brazil) was used (2).

Results and Discussion

Antibodies against viruses (PCV2, PRRSV, PPV, PRV, CSFV); specific bacterial agents (Leptospira sp., Brucella suis) and protozoa (Toxoplasma gondii) from selected sows with reproductive problems were investigated. All sows tested for PCV2 presented a positive reaction at ICC, but with diff erent titers (Table 1). Titers varied between 1:20 - 1:160 (+), 1:320 - 1:2560 (++) and above or greater than 1:5120 (+++). PPV antibodies were also very frequent whereas most of the sows (113 or 94.2%) were positive. High positive titers for PPV varied from 1:128 to 1:1024 (++) and 1:2048 to > 1:8192 (++) (Table 1). In contrast, 117 (97.5%) of sows presented no titer to leptospirosis, and 3 were reagent to serovar L. Bratislava with diff erent titers, one sample 1:100 and two samples at 1:400. All sows were negative for brucellosis, PRRSV, PRV and CSFV, confi rming the control and surveillance programs enforced in the country. No T. gondii antibodies were detected in the tested samples.

This study analyzed antibody response of individual sows with reproductive problems in order to investigate the possible infectious cause. Results indicate indicated a low frequency of antibodies for bacterial agents and a high frequency of antibodies for endemic viral agents such as PCV2 and PPV.

Reproductive disorders in Iberian sows in extensive farms caused by Chlamydophila abortus
Carmen Borjé1 Nieves Ortega2 María José Rangel1 Alfonso Carbonero1 Jesús Salinas2 Anselmo Perea1 María Rosa Caro2
1. Department Animal Health, Veterinary Faculty, Córdoba, Spain; 2. Animal Health Department, Veterinary Faculty, Murcia, Spain

Introduction
Members of Chlamydiaceae family are obligate intracellular pathogens with a broad host spectrum. They have been associated with a wide range of diseases, including enteritis, pneumonia, conjunctivitis, pericarditis, perinatal mortality, and reproductive disorders, particularly abortion and endometritis. Chlamydial species detected in natural infections in swine include Chlamydophila (Cp.) abortus, Cp. pecorum and a recently proposed species, Chlamydia (C.) suis, strains phylogenetically related to human C. trachomatis (Everett K.D. et al., 1999). The present study describes an outbreak of reproductive disorders associated to Chlamydophila abortus in a farm of Iberian pigs in Southwest Spain.

Materials and Methods
Farm characteristics.- The outbreak was conducted on a multi-site farrow-to-finish farm with 2060 Iberian sows (nulliparous) introduced from a free disease’s farm in 2008. Animals were distributed weekly in 22 flocks. Natural mating is used and pregnancy is confirmed by ultrasound between 21 and 24 days post-insemination. The pigs were reared in semi-extensive systems.

Outbreak description.- Disorders were initially detected from flock 10 onwards in October 2009. They consisted of a decreased in farrowing rates (from 92% to 54%); decrease in piglets born alive/litter (from 7.03 to 5.69), increase in piglets born dead/litter and with low viability (from 14.05% to 25.05%) and decrease in the weaned piglets per sow (from 6.62 to 5.62). The last 3 flocks showed a higher rate in the return to oestrus, cyclic and acyclic (from 19.1% to 60.6%).

Bacteriology and viriological examination.- Six fetuses were examined for bacteriological and virological pathogens by standard methods. When the other aetiological agents were discarded, a screening for chlamydiae by PCR was performed, follow by the typing of chlamydial DNA. To get the DNA, a DNAeasy tissue kit (QIAGEN. Berlin. Germany) was used. DNA was amplified with different protocols and primers. Firstly, a family-specific PCR were carried out using CHYF and CHYR primers which target 16S rRNA gene of the Chlamydiaceae family, following the protocol described in Condon and Oakey (2007). After that, a specific PCR Chlamydophila abortus using primers pmp-F and pmp-R821 which target pmp 90/91 gene were used following the protocol described by Berri et al., (2009).

Serological examination: A total of 53 sera from aborted sows with reproductive disorders were tested by an ELISA- rPOMP specific to Cp. abortus using the ELISA kit commercialized by IDDEX Laboratories. An anti-Pig IgG- Peroxidase conjugated was used (Sigma). The results were expressed as optical densities (DO). In addition, 13 sera were tested a second time 17 days after abortion looking for sero-conversions.

Results
All six abortion cases tested were positive in stain. The PCR showed 3/6 positive samples (samples a, b, c) and 3/6 doubtful samples (samples d, e, f) when DNA was amplified with a family-specific PCR for the gene of the Chlamydiaceae family. However, when these samples were tested with a specific PCR Cp. abortus we only detected 2/6 positive results (samples e, f). Fifty nine per cent of the sera were positive for specific antibodies against Cp. abortus. Seroconversions 17 days post-abortion were detected in 83% of the cases.

Discussion
The results suggest that Cp. abortus may be a possible cause of returns to oestrus, abortion and increase of incidence of litters with stillborn piglets and piglets with low viability in Iberian sows (Camenisch et al., 2004). However, the positive samples amplified with a family-specific PCR for the gene of the Chlamydiaceae family (samples a, b, c) and negative when were tested with a specific PCR Cp. abortus (samples a, b, c, d) suggest the involvement of other species included in the family Chlamydiaceae (C. suis, Cp. pecorum) as pathogen in porcine reproductive disorders.

The role of domestic or wild ruminants like sources of infection and their importance for transmission must be also studied.

PCV2 subtype and co-agents involved in reproductive failure occurring in PCV2-positive swine farms in São Paulo state, Brazil

Alessandra M. Castro¹ Tatiana M. Kanashiro¹ Vanessa R. Salgado¹ Sheila O. Souza¹ Tais F. Cruz²

Introduction
Porcine circovirus type 2 (PCV2) is widespread and has been associated with several disease complexes (3). Naturally occurring reproductive diseases related to PCV2 infection have been reported and intra-fetal inoculation of PCV2 at various stages of gestation showed that virus replicates highly in fetal tissue eventually leading to fetal death (1, 2). The aim of this study was to identify the subtype of PCV2 and the co-agents involved in the reproductive failure in São Paulo state, Brazil.

Materials and Methods
One hundred sixty-eight samples from reproductive failure (44 aborted and 124 stillborns) collected in positive PCV2 swine farms were examined between 2007 and 2009. The homogenized pools of tissue were analyzed for PCV2 by PCR and the positive samples tested for PPV, Leptospira spp and Brucella spp by PCR to verify the presence of co-infection. To determine the extent of genetic diversity among PCV2 detected, a target segment encompassing the open reading frame 2 (ORF2) of the PCV2 genome was sequenced from nine samples.

Results
PCV2 was detected in 18 (10.7 %) out of the 168 samples examined. Among the 18 PCV2-positive samples, 14 were aborted fetuses and 4 stillborn piglets. The others agents detected were PPV (2/18) and Brucella spp (10/18). The Brucella spp (3/10) and PPV (2/2) positive samples were sequenced and compared with sequences contained at the GenBank database demonstrating a nucleotide identity of ≥ 95 %. The phylogenetic relationship of nine PCV2 positive samples showed nucleotide and amino acid identity values of 92.2 to 99.8 % and 91.3 to 99.5 %, respectively. A Neighbour-Joining tree was assembled and showed that six samples had been classified in subgroup PCV2-1(A and B) and one in the PCV2-2E. Considering the phylogenetic analysis of representative sequences from the three Swedish genogroups (SG1-3), all samples were grouped in genogroup 3 (SG-3) (Fig. 1).

Discussion
The surprised results are that Brucella spp. is the main co-agent present in co-infection, since the São Paulo state participates of the national controlling program for Brucellosis. Therefore the positive farms are being oriented about this zoonosis with the objective to negative them. However PPV, the main virus involved in PCV2-associated disease since PRRVS is absent in Brazil, was detected in only two of 12 co-infected animals which demonstrates that the farms follow active vaccination program for the control of these viral infections. The almost PCV2-positive samples involved in reproductive disorders of sows in São Paulo state, Brazil are grouped in PCV2-1 subtype and SG-3.

Figure 1: Neighbour-Joining tree of the PCV2 ORF2 for genogroup (A) and subgroup (B) classifications with PCV1 as outgroup. Numbers indicates values calculated on 1000 repeats of the alignment with the heuristic method. Strains are indicated by their GenBank access number and subgroup or genogroup identification between parentheses.

Effect of vaccination against Swine Erysipelas in % of piglets born dead on a farm in Guanajuato State in Mexico

Oscar Huerta Alva; A. Ayllón
Laboratorios Sanfer SA de CV, Mexico, DF, Mexico

Introduction
The improved production is a constant that requires us competitive in any market, the pig is no exception and towards more pigs sent per female in a year, directly depends on the number of piglets born alive per litter and these is reduced by the % of stillborn piglets and mummies, the latter two are caused by a myriad of causes and in the specific case of stillborn piglets may be involved the Swine Erysipelas (personal communication from Drs C. Sanchez [2005] and R. Treviso [2007]).

The Swine Erysipelas is an actual disease, as reported Schwartz (2002), Sierra (2006), Perea (2006) and Hopkins (2006-2008), is a systemic disease and has a direct effect on blood vessels, causing more fragile cord cord, same as the time of delivery breaks more easily.

Materials and Methods
By delivering a live vaccine against swine erysipelas 2 or 3 weeks before delivery reduced the number of piglets born dead (personal communication of Dr. C. Sanchez [2005], R. Treviso [2007], in Monterrey 2007 staff report) on this basis, the aim of this study is to confirm the personal experiences of Sanchez and Huerta Treviso applying erysipelas live vaccine strain in two groups, one 2 weeks before delivery and another 3 weeks before delivery, on a farm of 650 stomachs located in the State of Guanajuato, as main problem is the number of piglets stillborn birth. The groups 16 and 17 were interviewed with the swine erysipelas live vaccine and compared against two previous groups (14 and 15) and two subsequent groups (18 and 19). The farm was an outbreak of Swine Erysipelas 5 months ago.

Discussion
In the weeks 16 and 17 where sows were vaccinated with a live vaccine strain vs. rhusiopathiae Erisipelothrix Koganei 65-0.15, females at birth had about 50% less stillborn piglets, compared with the two previous groups (14 and 15) and 36% less than groups 18 and 19. Consequently increased the number of piglets born alive.

Conclusion
According to these results I conclude that vaccinating pregnant sows 2 to 3 weeks before delivery with a live vaccine against Erisipelothrix rhusiopathiae strain Koganei 65-0.15, declined by 50% the number of piglets born dead.

We must remember that the swine erysipelas is a systemic disease with high affinity to blood vessels (become friable) and at delivery, the umbilical cord to get power out piglets and is likely to be broken by the stress of labor.

Induction of ovulation in weaned sows: how much Buserelin is needed to get a normal LH surge and normal embryonic development in primiparous or multiparous females?

H.M.J.M. Swarts3 N.M. Soede1 J. van der Lelij1 M.A. Driancourt2
1. Dept. Animal Science Wageningen University, Wageningen, Netherlands; 2. ISPAH R&D Pharmaceuticals, Beaucouze, France; 3. ISPAH, Global Marketing Swine, Boxmeer, Netherlands

Introduction:
While the ability of 10μg Buserelin to induce ovulation in gilts has already been demonstrated, the dose of Buserelin needed to induce ovulation in weaned sows has not been established. The aim of this experiment was to assess the ability of different amounts of Buserelin to induce a normal LH surge, ovulation and early embryo development and monitor whether parity or genetic line were modulating the response to Buserelin.

Materials & methods
On 77 hours after weaning, 64 sows received an intra-muscular injection of either 0 μg, or 6 μg, or 10 μg, or 16 μg of Buserelin. Sows were equally allocated to treatments based on parity (primiparous: parity 1 and multiparous: parity 3 to 6) and breed (TOPIGS20 and TOPIGS40, both from Topigs, Netherlands). Subgroups [dose of Buserelin * breed * parity] were therefore set to include four animals.

The end points used were (1) the detection of ovulation by ultrasoundography at a specific time window (32-44h) after treatment, (2) the detection of an LH surge (and its magnitude) in blood samples collected 1, 2.5, 4, 12 and 24h following treatment, (3) the number of corpora lutea and viable embryos at slaughter 5 days after the expected ovulation and (4) the progesterone secretion by the corpora lutea at slaughter.

Results
As 2 sows had already ovulated within 85h after weaning and as 5 others ovulated within 32h of injection, data from 15 control sows as well as 15, 11 and 12 sows treated with 6, 10 or 16μg Buserelin were used for statistical analyses.

* = Hrs after weaning

Of the Buserelin treated sows 76% were synchronized to ovulate between 32-44h after treatment. The proportion of sows successfully induced to ovulate was unrelated to the dose of Buserelin applied (73, 73 and 83% in sows receiving 6, 10 or 16μg Buserelin). Parity however had a clear effect on treatment’s efficacy as 100% multiparous sows ovulated during this time window, while only 50, 50 and 67% of the primiparous gilts ovulated following injection of 6, 10 or 16μg Buserelin.

In all sows that ovulated during the 32-44h time window, a clear increase in LH concentrations was observed. Its magnitude (2.4ng/ml) was similar to that observed in the control group (2.8 ng/ml) and unaffected by the amounts of Buserelin injected. In control and treated sows that ovulated at the expected time, neither parity nor breed affected the features of ovulatory LH surge. In contrast, sows that ovulated late had a blunted increase in LH concentrations.

The number of corpora lutea (23.5 on average) was unaffected by treatment (control vs treated) and by the amounts of Buserelin injected. Cyst formation was more common in primiparous gilts (4/8 and 5/7) injected with 6 and 16μg compared to those receiving 10μg Buserelin (1/6). Cyst number reached 7.3 ± 8.5 in the 6μg Buserelin group.

In contrast, the average number of good embryos (18.7) was unaffected by treatment and by the dose of Buserelin applied.

No interaction between breed or parity and treatment was detected for progesterone concentrations on day 5 post ovulation.

Discussion and conclusion
It is concluded that:
(1) In all multiparous sows of either breed, administration of Buserelin at 77h after weaning successfully triggered a full ovulatory process generating a normal number of good embryos.
(2) In primiparous sows, injection of Buserelin may have to be delayed past 77h after weaning.
(3) 10μg Buserelin appeared the optimal dosage based on the occurrence and number of cystic follicles.
Urinary tract infections (UTI) are a major health concern in breeding herds and one of the major causes of death or culling of female breeding pigs. Infections may be caused by ascending bacterial pathogens from the external genitalia to the bladder and kidneys as a consequence of coitus and parturition, and incomplete closure of the vulva and/or damaged urethra. Intensive housing conditions where vulvas get in direct contact with faeces may lead to the infection with faecal flora. Several farms in Germany, the Netherlands and Slovenia, known to have a history of urinary tract infections in sows were included in the study. Housing and management conditions were maintained stable during the clinical trial.

Sows (sows and gilts) showing urinary tract infections associated with Escherichia (E.) coli were treated with Baytril® (enrofloxacin) in a dosage of 5.0 mg/kg body weight. One group (T1) was treated for three consecutive days, 24hrs apart, and one group (T2) was treated twice, 48hrs apart. Both groups were compared to a control group (T3), dosed with 15.0 mg/kg bodyweight amoxicillin (Duphamox® LA) twice, 48hrs apart.

Sows were included in the clinical trial if at least 105 colony forming units (cfu) were detected per mL mid-stream urine, and at least one criterion related to macroscopic appearance of the urine was abnormal (pH≥8.0 or smell or cloudiness). The minimum bacterial count had to be fulfilled in one of two systems: either in urine analysis of a native urine sample or in the Uricult® dip stick agar system. In addition, the general health was observed and bacterial isolation and identification was performed to identify the associated pathogen. E. coli (including haemolytic and mucoid growth) was identified in 76.8% of the positive animals. Other bacterial species identified were Enterobacter spp., Enterococcus spp., Klebsiella spp., Staphylococcus spp. and Streptococcus spp.

Pre-treatment clinical signs (general health) and urine assessment were compared to post-treatment assessment of the same criteria three and 14 days after the start of treatment. The success criterion was the bacteriological cure rate on day 14 of animals bacteriologically positive for E. coli on Day 0, but negative on day 14 (animals with a bacteriological result of less than 105 cfu/mL in both, Uricult® dip stick agar system and urinary analysis).

E. coli was eradicated in 46.4% of the animals in treatment group T1, in 53.1% of the animals in treatment group T2 and in 44.8% of the animals of the control group (T3). For the subgroup where mucoid growth of E. coli was identified, the rate of eradication was 80.0% in T1 and 100.0% in T2 compared to 42.9% in the control group. Similar results were observed using the Uricult® dip stick agar system: E. coli was eradicated in 45.5% of the animals in the T1 group, in 36.8% of the animals in the T2 group and in 43.2% of the animals in the control group. For the subgroup where mucoid growth of E. coli was identified, the rate of eradication was 83.3% in T1 and 100.0% in T2 compared to 33.3% in the control group.

Assessing the urine pre (Day 0) and post treatment (Day 3 to day 14) using the Macroscopic Urine Score (MUS), calculated as sum of scores of the cloudiness (score 0 to 3) and foul smelling (score 0 to 2) of the urine, a significant reduction was observed (p<0.05). On day 3 and day 14 the MUS was reduced significantly within each treatment group as compared to day 0. General health was good at pre-treatment and was kept at this stage during the study.

Based on the results observed Baytril® 10% used as an antimicrobial therapy for sows showing clinical signs of E. coli urinary tract infection, was shown to reduce the infection pressure on animal and farm level and can help to interrupt infection cycles. Therefore, it should be part of an eradication program including improvement of housing conditions, herd management and gestation programs in farrowing and nursing pig farms.
Introduction
The vaccine against boar taint – Improvac® - was approved through central registration in the European Union in May 2009. The European licensing procedure includes a full assessment of food safety and the product is considered safe for consumers of pork. In many countries, however, including Denmark, informed consumers develop their own opinions about the use of new technical approaches in food production, taking into account both the possible effect on food and the impact on areas of ethical concern, such as animal welfare. To investigate consumer attitudes market research has earlier been carried out in other countries 1, 2. The aim of this investigation was to learn the reaction of Danish consumers to different ways of controlling boar taint: castration without anesthesia, castration with pain relief (NSAID), castration with local anesthesia, and vaccination against boar taint.

Material and Methods
Capacent, the leading Nordic business consultancy company was in charge of collecting, analyzing and reporting the results of computer assisted telephone interviews of 1012 persons with an age of 18 years or older. A random sample of consumers was secured and only one person per household could be interviewed. A short factual description of each method was developed in collaboration with industry stakeholders and presented to the interviewed persons. Interviews took place between August 3rd and 16th 2009

Results
Asked how acceptable do you find:
1. Castration of piglets without anesthesia or pain relief (named castration in the chart), the answers were 65% unacceptable, 12 % neutral, 23% acceptable and don’t know 1 %.
2. Castration of piglets with pain relief (named NSAID in the chart), the answers were 44 % unacceptable, 16 % neutral, 39% acceptable and don’t know 2 %.
3. Castration of piglets with local anesthetics (named Lidocaine in the chart), the answers were 43 % unacceptable, 18 % neutral, 37% acceptable and don’t know 2 %.
4. Vaccination instead of castration, the answers were 16 % unacceptable, 9 % neutral, 73 % acceptable and don’t know 3 %.

Discussion
Modern, educated consumers may question the use of new products in food production. However, there is also growing consumer concern about the pain and stress suffered by piglets during and after physical castration. As in other consumer acceptance investigations 1, 2 the results here confirm that when fully informed consumers prefer vaccination as the way of controlling boar taint, with their concerns about pork quality and animal welfare outweighing their caution about the use of a new technology.

Introduction

Surgical castration of male piglets is still a common procedure worldwide and is primarily done to prevent entire boars from developing an unpleasant taste and flavour of meat. For animal welfare reasons, several countries are enacting new laws to ban surgical castration without anaesthesia (2). Immunisation with two doses of a gonadotrophin releasing factor (GnRF) vaccine against boar taint, the second dose given 4 to 5 weeks prior to slaughter, suppresses testicular function through the induction of antibodies against GnRF (1). The timing of vaccination makes it possible to maintain the economic advantages of boars for most of the fattening period, while also avoiding the presence of boar taint at slaughter. The objective of this study was to determine the effect of using a GnRF vaccine on growth performance of male pigs. Vaccinated pigs were compared with surgically castrated pigs and entire males under conventionally managed farm conditions.

Materials and Methods

Male pigs were randomly assigned to three treatment groups: pigs surgically castrated during the first week of life (group „C“, n=274), pigs immunised twice during the fattening period with a GnRF vaccine (Improvac, Pfizer Animal Health), the first time when 13–14 weeks of age and the second time when 20–21 weeks of age (group „V“ , n=280) and entire males (group „E“ , n=56). Average daily weight gain (ADG), mortality and medical treatment were measured during the study. Additionally, feed conversion ratio (FCR) was assessed during the fattening period.

Results

No difference in the ADG during the fattening period could be determined between „C“ and „V“ (Tab. 1). From the start of the study until slaughter at study day 160/173 the ADG in group „E“ was lower (625 g/day; P < 0.001) and group „V“ (675 g/day; P < 0.001) and group „V“ (675 g/day; P < 0.001) and group „V“ (675 g/day; P < 0.001). The FCR during the fattening period until study day 160, three days before the first batch of pigs were slaughtered at 24–25 weeks of age, was higher in group „C“ (2.72 kg feed intake/kg weight gain) compared with group „V“ (2.44 kg feed intake/kg weight gain; P < 0.001) and group „E“ (2.44 kg feed intake/kg weight gain; P < 0.001). Pigs in group „V“ performed similarly to those in group „E“ until the second vaccination (day 135) after which time they showed a substantial increase in feed intake and ADG, while retaining an FCR advantage over group „C“ (Tab. 2). The mortality from the start to the end was 10.6%, 11.8% and 8.9% in groups „C“„V“ and „E“, respectively. During the same time period, pigs in groups „C“„V“ and „E“ were medically treated 0.51, 0.63 and 0.29 times per animal.

Discussion

The present study supports in part earlier findings that, by replacing surgical castration early in life with vaccination of pigs against GnRF during the fattening period, the feed conversion advantages of boars could be retained for pig production (1). Higher ADG of vaccinated animals compared with castrated animals could only be detected after the second vaccination. No effects of vaccination could be observed on the mortality or need for medical treatment over the whole lifetime. To take greater benefit from the effect of vaccination on ADG, the second vaccination could be brought forward to the earliest possible point of time, although this study did not examine the possible negative effects of doing this, such as increased carcass fatness.

Influence of Improvac on FSH and LH concentrations and on the development of testicles and the expression of boar taint in male pigs

Thilo Fuchs1 Rico Thun2 Nahid Parviz6 Heiko Nathues1 Annika Koehrmann2 Stuart Andrews3 Fiona Brock3 Guenter Klein4 Nadine Sudhaus4 Elisabeth Grosse Beilage1

Introduction

Surgical castration of male pigs is frequently performed due to the fact that entire male pigs have the potential to develop an unpleasant taste and flavour of the meat. Vaccination with Improvac (Pfizer Animal Health) suppresses testicular function through the induction of antibodies against gonadotropin-releasing factor (GnRF). GnRF is released from the hypothalamus and stimulates the pituitary gland to release luteinising hormone (LH) and follicle stimulating hormone (FSH) which controls the production and release of testicular steroids, including androstenone. Antibodies against GnRF disrupt this hypothalamic-pituitary-gonad axis and thereby reduce the production of testicular steroids (2). The objective of this study was to evaluate the effect of Improvac vaccination on the concentrations of LH and FSH in blood, the development of the testicles, and the suppression of boar taint (3).

Material and Methods

A total of 610 males were randomly assigned to three treatment groups (T). 274 were surgically castrated in the first week of life (T1), 258 (number then remaining) were vaccinated twice with Improvac during the fattening period, at 13–14 and at 20–21 weeks of age, respectively (T2) and 56 were left entire (T3). From a subgroup of both T1 and T2 and from all pigs of T3, blood samples were collected immediately before second vaccination (T2) and again before slaughter at either 24–25 or 26–27 weeks of life to determine the serum concentrations of LH and FSH. Meat and fat samples were examined with the cold cooking and the melting tests. Length, width, weight and volume of testicles were determined after slaughter.

Results

Immediately before the second vaccination (T2 only) LH and FSH concentrations were not significantly different between T2 and T3 (Tab. 1). However, LH and FSH concentrations were significantly higher in T1 compared with T2 and T3 at this time as well as before both slaughter dates. Before the first slaughter date LH and FSH concentrations were significantly lower in group T2 compared to T3 (Tab. 2). In the cold cooking test as well as in the fat melting test 100% (25% of total T1) of the samples of T1 were rated negative for boar taint. In T2, 98% were rated negative for boar taint, whereas in T3 94% were rated positive. In the fat melting test 97% of T2 were rated negative and 3% were rated positive, including the pigs testing positive in the cold cooking test. In T3 94% were rated positive. All pigs in T2 which were positive for boar taint in the cooking or melting test and that were tested had androstenone and skatole concentrations in backfat below threshold levels of 1 μg/g and 0.2 μg/g, respectively.

Discussion

After vaccination with Improvac levels of LH and FSH in blood as well as testes size were significantly reduced, consistent with mode of action. Of the vaccinated pigs, 98% (235/239) were rated negative for boar taint in the cold cooking test and 97% (232/239) in the fat melting test. The androstenone and skatole levels of the pigs testing positive for boar taint (7/239, 3%) were below the commonly accepted threshold levels for these substances (1).

References

Introduction

Boar taint is related to sexual maturity and male hormones and is usually controlled by surgical castration. With growing focus on animal welfare, surgical castration without anesthesia has become controversial. Alternative approaches include immunization against gonadotropin releasing factor (GnRF), which disrupts the hypothalamic-pituitary-gonad axis, thereby temporarily suppressing testicular function and steroid synthesis. Our aim was to compare productivity, carcass quality and meat quality of pigs vaccinated against GnRF using Improvac against those of surgically castrated pigs under field conditions.

Materials and Methods

The trial was conducted in a commercial farm in Lithuania. 402 cross-bred pigs were split into two groups. Pigs in group 1 (204) were castrated at 3 days of age. Pigs in group 2 (198) were vaccinated with Improvac at day 95 and day 140 of life. All pigs were fed the same farm-made diet depending on the growth phase. Animals were weighed in groups of 20-30 at weaning (d.28) entry to the fattening stage (d.60); first vaccination (d.95), second vaccination (d.140) and on the day of slaughter (d.180) and daily weight gain (DWG) was calculated. Mortality was recorded and necropsies performed. Fat was measured using a Fat-o-Meater according to the routine slaughterhouse procedures. Samples of longissimus dorsi were tested to assess meat quality.

Means, standard deviations and coefficients of variation were calculated for the variables assessed. The unpaired t-test (MS Excel 2003) was used to test differences between the mean values of groups. P<0.05 was used as the significance level.

Results

Castrates were significantly heavier (74.1kg v 66.5 kg, P<0.05) at day 140 but other differences were not significant. Overall mortality rates from farrowing (Gp 1, 14.7%, Gp 2, 14.41%) were not significantly different. Lifetime DWG in vaccinated pigs was 629.1g compared with 631 g in controls, with the differences being +69.73g, -40.56g, -143.85 and +125.07g for the four periods (Fig 1).

Vaccinated animals had reduced carcass fat thickness (P<0.001) as measured on 2 points of the carcass (22.79±3.93 and 17.17±2.78 v. 26.2±5.2 and 19.2±3.7 mm). Lean meat in vaccinated animals was greater by 1.9 percentage points (56.7±2.4% v 54.8±3.1%, P<0.001). Meat quality parameters did not differ between the two groups (Table 1).

Discussion

Compared to boars, castrates are known to be fatter and less efficient. Feed conversion was not assessed in this study but DWG showed distinct differences between the groups. It was initially lower in vaccinated pigs compared to castrates, but after second vaccination weight gain was superior and at slaughter pigs were heavier (not significant). Other studies have reported a higher final live weight in vaccinated pigs. The higher growth rate following second vaccination was probably due to higher feed intake reflecting reduced sexual and aggressive activity. Use of vaccination reduced fat thickness and had a positive effect on muscling. Vaccination did not affect objective meat quality parameters.

Under the conditions of this study, Improvac appears to offer an alternative to physical castration that reduces back-fat and increases lean meat percent, while having no impact on meat quality. Further work may allow the differences in growth patterns to be exploited to improve overall performance.

**Introduction**

Entire male pigs are known to be superior to physical castrates with regards to lean meat production and growth performance, which could lead to more profitable pig production (1, 2). Nevertheless, physical castration of male pigs is still a common procedure in many countries in order to prevent an unpleasant taste and flavour of the meat of sexually mature boars. The main objective of this comparative study was to investigate the carcase characteristics of physically castrated pigs and pigs immunized with a gonadotrophin-releasing factor (GnRF) vaccine, which acts via the hypothalamic-pituitary-gonad axis and suppresses testicular function through the induction of antibodies against GnRF. Pigs were raised under field conditions in a conventionally managed farm in Germany.

**Materials and Methods**

Male pigs were randomly assigned to three treatment groups: pigs surgically castrated during the first week of life (group T1, n=274), pigs immunised twice during the fattening period with a GnRF vaccine (Improvac, Pfizer Animal Health), the first time when 13–14 weeks of age and the second time when 20–21 weeks of age (group T2, n=280) and entire males (group T3, n=56). All pigs were weighed individually three days before slaughter in either the 24th or 26th week of life. Pigs of groups T1 and T2 that weighed 110 kg or more on day 160 were slaughtered in the first batch. Overall, 242 pigs met these criteria. The remaining 241 pigs were slaughtered in the 26th week. At slaughter, testes were removed and hot carcase weight determined. Lean meat percentage, thickness of backfat and backmuscle was measured. The boned ham, boned shoulder, loin and belly weights alongside the lean meat percentage of belly were measured with the AutoFOM ultrasound system. Carcases were categorised, using the EUROP grading system.

**Results**

There was neither significant difference between the groups in terms of average liveweight nor in the hot carcase weight (Tab. 1). The mean dressing percentage was 1.5% higher for T1 than for T2 (P<0.0001). The lean meat percentage was significantly higher in T2 (P<0.0001). Backfat and backmuscle thickness were significantly higher in T1 (P<0.0001 and P=0.0099, respectively). The weight of the belly was significantly higher (P=0.0042) in T1 while the lean meat percentage of belly was significantly higher (P<0.0001) in T2.

**Discussion**

In this study differences in carcase characteristics between physically castrated pigs and vaccinated pigs were evaluated. There were no statistically significant differences between the physically castrated pigs and those immunized with a GnRF vaccine in terms of the average live bodyweight of pigs before slaughter. The immunization with a GnRF vaccine improves lean meat content, EUROP grading score and reduces backfat thickness. Despite a lower dressing percentage, no adverse effects on the weights of valuable parts of the carcase such as ham, loin and shoulder could be detected with the exception of a lower belly weight and a lower back muscle thickness. In conclusion, the use of a GnRF vaccine to control boar taint could contribute to producing pigs with leaner and more muscular carcasses.

**Welfare consequences of slaughter strategy in entire male pig production**

**Bente Fredriksen; Cathrine Hexeberg; Ola Nafstad**

*Animalia, Oslo, Norway*

**Introduction**

Aggressive and sexual behaviour is more frequent in entire male pigs than in castrates, and might represent an animal welfare problem (EFSA 2004). While the incidence of unwanted behaviour might be kept on an acceptable level by measures in the herd, like sibling groups, the conditions during transport and lairage might be harder to control. In Norway, and probably also in other countries, a common practice is that the animals are sent to slaughter as they reach a certain weight. Consequently, not all animals from a pen are delivered to slaughter at the same time (split marketing). This practice causes a considerable mixing of unfamiliar animals during transport and lairage. The aim of the study was to investigate the practical and animal welfare consequences of different slaughter strategies in entire male pig production.

**Materials and Methods**

The study was performed as a field study with two replicates in one herd in the period June 2008 – January 2009. A total of 134 entire male pigs and 139 castrates, all Noroc hybrids (LYxLD) were included. The animals were regrouped by sex into pens of 9 animals when transferred to the growing/fattening unit. In half of the pens within each sex, the animals were slaughtered by traditional split marketing while the other half were slaughtered pen-wise, without mixing with unfamiliar pigs during transport and lairage. Skin lesions were recorded regularly for all animals in the herd and also at the slaughter house. A four point scale was used for front, middle and back on both sides of the animals. Both total score and max-score were used for the statistical analyses. Behaviour was also recorded both in the herd and at the slaughter house. A sexual index (S-Index) and an aggression index (A-Index) per pen were calculated in the following way:

Sexual index = (((number of flank pushes + 2x number of attempts to mount + 3x number of mountings)/number of males in the pen)/number of minutes recorded) x 60.

Aggression index = (((number of head knocks + 2x number of bites + 3x number of fightings)/number of pigs in the pen)/number of minutes recorded) x 60.**image1**

**Discussion**

Even though higher skin lesion scores as well as higher A- and S-indexes were recorded for entire males than for castrates, the effect of sex on parameters recorded in the herd was moderate. At the slaughter house, the effects of both sex and slaughter strategy were pronounced (Figure 2). Split marketing seems to have a negative effect on animal welfare, especially for entire male pigs. In addition, the fighting might affect meat quality and result in downgrading of carcasses because of skin lesions. When the animals were kept penwise during transport and lairage in the same units as in the herd, aggressive and sexual behaviour in entire males were reduced significantly.

Impact of vaccination against boar taint on production variables in Poland, Czech Republic and Hungary

Zygmunt Pejsak1 Jacek Zmudzki1 Marian Porowski2 Marek Lesiak3 Marek Zizlavsky4 Robert Travnicek5 Tamas Abonyi6

Introduction
The meat industry is highly competitive and is subject to two major drivers of change: new legislation and technological innovations. For meat processors, immunological castration provides better quality carcasses, with less fat, less wastage and thus higher value (1). The objective of this study was to evaluate the efficacy and production benefits of vaccination with Improvac for the control of boar taint under field conditions in Poland, Czech Republic and Hungary.

Materials and Methods
The study was performed at 4 commercial pig farms located in Poland (PL) (2 farms: PL-L and PL-S), Czech Republic (CZ) and Hungary (H). Male piglets (PL-L, 108; PL-S, 60; CZ, 119; and H, 83) were surgically castrated (T01). On each farm, the same number of piglets were vaccinated with Improvac subcutaneously twice: initially at ages 9–10 weeks (PL), 11–13 (CZ), 20–23 (H) then again at ages: 20 (PL), 22–24 (CZ), and 24–27 (H) weeks (T02). Pigs were slaughtered at ages 24–26 (PL), 27–29 (CZ) and 28–31 (H) weeks. Average body weight (ABW) at castration, 1st and 2nd vaccination, and slaughter was determined and average daily body weight gain (ADG) was determined for the periods: castration to 1st vaccination, castration to slaughter, 1st vaccination to slaughter and 2nd vaccination to slaughter. Lean meat percentage was estimated at slaughter.

Results
Compared with barrows (T01), ABW of pigs vaccinated with Improvac (T02) was comparable at castration, and 1st and 2nd vaccination, but 7% higher at slaughter on farm PL-L On farms PL-S, CZ and H, ABW was similar at castration, 1st and 2nd vaccination and slaughter (Table 1a). From castration to 1st vaccination, ADG of barrows (T01) and vaccinated pigs (T02) was comparable on all farms. From castration to slaughter, 1st vaccination to slaughter, and 2nd vaccination to slaughter, ADG was 7%, 9% and 32% higher respectively in vaccinated pigs than barrows on farm PL-S, and 5%, 9% and 7% higher respectively in vaccinated pigs than barrows on farm H. On farm PL-L, ADG was marginally lower in vaccinated pigs compared with barrows from castration to slaughter and 1st vaccination to slaughter, but 5% higher in vaccinated pigs than barrows from 2nd vaccination to slaughter (Table 1b). Compared with barrows (T01), lean meat percentage of vaccinated pigs (T02) was 3% higher on farm CZ and 5% higher on farm H (Table 1c).

Discussion
ADBWG was higher in pigs vaccinated with Improvac compared with barrows, especially following the 2nd vaccination. Vaccination resulted in a significant increase in lean meat percentage.

Introduction

Hematological reference values for slaughter age boars are rare and none are published for boars vaccinated with Improvac® (GnRH-analogue vaccine against boar taint (1)). The objective of the study was to determine and compare mean hematological values at slaughter in boars vaccinated with Improvac and controls among two crossbreeds.

Materials and Methods

A total of 549 blood samples were collected by exsanguination from 410 Piétrain cross (96 entire boars and 314 boars vaccinated with Improvac (1)) and 139 Duroc cross (42 entire boars and 97 Improvac) boars. Mean body weights at slaughter were between 118.6 kg (Piétrain) and 119.9 kg (Duroc). Blood cells were counted using an ADVIA120 hematological counter (Bayer). Differential white blood cell counts were estimated by microscopy.

Results

Piétrain crosses had lower hemoglobin, MCV, MCH and MCHC than Duroc crosses. In Piétrain crosses, leucocyte count was higher in entire boars compared with boars vaccinated with Improvac driven by a higher lymphocyte, monocyte and eosinophil count in this group. The platelet count in Piétrain crosses was higher in entire boars than vaccinated pigs (table 1).

Discussion

Mean values for all groups were within existing physio-logical ranges of swine (2) except raised leucocytes in entire boars of both breeds. Further examination is needed to determine if this effect is boar specific.

The vaccination of boars with Improvac had no impact on haematology results.

Clinical chemistry in entire boars and boars vaccinated with Improvac®

Tatjana Sattler1 Ruth Wipf1 Franziska Sauer1 Kerstin Lösel1 Friedrich Schmoll1, 3

Introduction
Blood markers of protein and mineral metabolism in swine are likely to be different between breeds and gender (1). Reference values for slaughter age boars are rarely described and none are published for boars vaccinated with Improvac® (GnRH-analogue vaccine against boar taint). The objective of the study was to determine and compare mean values of blood markers for protein and mineral metabolism at slaughter in boars vaccinated with Improvac and controls among two crossbreeds.

Materials and Methods
A total of 569 blood samples were collected by exsanguination of 425 Piétrain cross (96 entire boars and 329 Improvac) and 144 Duroc cross (44 entire boars and 100 Improvac) male pigs. Boars had a mean body weight of 118.9 kg and a mean age of 180 days at slaughter. The analysis of alkaline phosphatase (AP), measured at 37°C, urea, creatinine, inorganic phosphate (P) and calcium (Ca) were determined with an analysis automate Hitachi 704 (Boehringer Mannheim).

Results
Boars from both breeds had higher serum AP concentrations as well as lower serum creatinine and serum urea concentrations than boars vaccinated with Improvac.

Improvac vaccinated Duroc boars showed higher AP activities and lower Ca and P concentrations than the vaccinated Piétrain boars. The creatinine concentration was over all higher in Duroc boars than in the Piétrain boars (table 1).

Discussion
Mean values for all groups were within previously reported physiological ranges of swine (2, 3) and were consistent with published reference intervals for boars from different German boar studs and breeds (1). Pigs in this study were fed a standard diet (optimised for barrows and females and not for boars) but there was no evidence of an undersupply of nutrients. There was no evidence that vaccination with Improvac affected the variables measured.

Introduction

Typically, male pigs are physically castrated in Europe to control boar taint. Use of Improvac allows male pigs to grow as efficiently as boars until the time of second vaccination. This study examined the impact of feeding low and high density diets to entire boars, barrows, vaccinates and gilts after the second administration of Improvac to vaccinates.

Materials and Methods

A total of 179 F2 crossbred pigs aged 66 days from Yorkshire x Dutch Landrace sows sired by Piétrain boars were enrolled: 48 gilts, 47 barrows, 42 entire boars and 42 boars vaccinated with Improvac at enrolment (day 0, 66 days of age) and day 84, which was approximately 6 weeks before slaughter (day 123). Pigs were grouped by weight within sex, and groups randomly allocated to pens so that there were 6 pens per sex fed a low energy (9.04 MJ) and 6 pens fed the high energy (10.01 MJ) finishing diet. These diets were fed from day 84, after being fed the same boar ration. Pigs were weighed on days 0, 12, 34, 62, 84 and 123. Feed intake was monitored using a computerised feeding system and residual feed was weighed when pigs were weighed.

Results

Before the second injection of Improvac vaccinated pigs performed similarly to boars: they were significantly lighter than castrates, but also had significantly lower feed intake and feed conversion. After administration of the second dose of Improvac and partitioning of sex groups into low and high density diets, feed intake and average daily gain (ADG) of vaccinates increased markedly and their performance diverged from entire boars. Thus, final bodyweights and overall study ADG values for barrows (874 g/d) and vaccinates (875 g/d) were similar. Overall, feed conversion ratio (FCR) was significantly different (p<0.05) between vaccinates (2.34) and barrows (2.66). Boars had the lowest overall FCR (2.26). From day 84 to 123, there was a significant effect of sex (P<0.001) but not diet on ADG which was highest in vaccinated pigs. From day 84 to 123, the difference in ADG and feed intake between vaccinates on the LE and HE diets was not significant but there was a significant effect of sex (p<0.001) and diet (p<0.0001) on FCR. From day 84 to 123, barrows had the best feed conversion and barrows the worst, with FCR in vaccinated boars being 17% lower than barrows on the LE or HE diets. In vaccinates and barrows, the HE diet resulted in a significantly lower FCR. In barrows this was associated with a significantly increased ADG, but in vaccinates it reflected a small increase in ADG and a reduction in FI.

Discussion and Conclusion

After the 2nd Improvac vaccination feed intake increased tremendously, even exceeding that of castrates. This was associated with a high ADG and favourable FCR, particularly when fed the high energy diet.

A comparison of carcass characteristics of entire boars, boars vaccinated with Improvac™, barrows and gilts fattened on low and high energy diets

Herman G. Prust1 Evelien Hangoor2 Fiona Brock3 Michael Pearce3 David Lamot2

Introduction

Typically, male pigs are physically castrated in Europe to control boar taint1. However, entire male pigs have better feed conversion and produce a leaner carcass than physically castrated pigs and gilts2. Use of Improvac allows male pigs to grow as efficiently as entire males until the time of second vaccination. This study examined the impact of feeding low and high energy diets to entire boars, barrows, vaccinates and gilts after the time of the second administration of Improvac to vaccinates.

Materials and Methods

A total of 179 F2 crossbred pigs aged 66 days from Yorkshire x Dutch Landrace sows sired by Piétrain boars were enrolled: 48 gilts, 47 barrows, 42 entire boars and 42 boars vaccinated with Improvac at enrolment and again 6 weeks before slaughter. Pigs were grouped by weight within sex, and groups randomly allocated to pens so that there were 6 pens per sex fed the low energy (9.04 MJ) and 6 pens fed the high energy (10.01 MJ) finishing diet. Pigs were fed the same diet until administration of the second dose of Improvac. Pre-slaughter live weight was taken before transport after 8 hours of fasting. Slaughter was at a commercial abattoir. Carcass lean meat and back fat were measured using a Hennessy Grading Probe. Lean meat % was calculated using a formula in EU Directive 2005/627/EG.

Results

Overall, liveweight and hot carcass weights were highest in barrows and vaccinated pigs (P≤0.0041); killing out percentages were highest in barrows and gilts (P<0.0001); and meat percentage was highest in boars and gilts, and lowest in barrows (P=0.0024). In both the latter cases, Improvac vaccinated pigs were significantly different from other groups.

In gilts, lean meat percentage was 1.5 percentage points higher in those fed the low energy diet (P=0.018) and backfat was 14% thicker in those fed the high energy diet (P=0.0348) There was a significant difference (P=0.033) in the killing out percentage between vaccinated pigs fed the low energy diet (79.5%) and those fed the high energy diet (80.5%) and in the carcass lean meat percentage (55.4% compared with 56.7% respectively).

Discussion and Conclusion

Differences between sex groups are consistent with published literature. The high energy diet was predicted to result in increased fatness in the Improvac pigs but this did not occur. In fact fat was numerically less and lean meat % significantly increased. Dressing percentage was also improved, perhaps associated with the increased loin thickness.

A comparison of mortality (animal withdrawal) rates in male fattening pigs reared using either physical castration or vaccination with Improvac® as the method to reduce boar taint

James R. Allison¹ Michael Pearce¹ Fiona Brock¹ John Crane²
¹. Pfizer Animal Health, New York, NY, USA; ². Pfizer Animal Health, Sandwich, UK

Introduction
In most of Europe, male piglets are physically castrated early in life. The procedure is traumatic and leaves an open wound, creating opportunities for bacterial infection and other complications. Improvac is a vaccine alternative where male piglets are left entire but are administered two doses of vaccine later in life, the second 4 to 6 weeks before slaughter. The second dose results in a temporary suppression of testicular function and a reduction in boar taint. At this time pig behaviour also changes to become similar to that of physical castrates. The objective of this analysis was to compare the impact of these two approaches on pig mortality at various stages of the production cycle.

Materials and Methods
A meta-analysis was conducted on data from 15 European field studies comparing physically castrated and Improvac vaccinated pigs. The studies were primarily conducted to compare efficacy in the reduction of boar taint or to look at the impact of the two approaches on growth performance. In all cases piglets were selected and randomly allocated to treatment groups at the time of physical castration. As part of normal procedure, records were kept of all animals that died or were withdrawn from the studies until the trials closed at slaughter, resulting in a database of 4393 animal records, well balanced between physically castrated and vaccinated pigs. In general, study withdrawals were of animals considered too sick to continue or in such poor condition that a producer would not normally retain them, so would equate to mortality in commercial practice. To avoid introducing subjective judgment all withdrawals were included in the analysis except those due to over-recruitment or logistical reasons.

Data on mortalities-cum-withdrawals were analysed for four time periods: castration to weaning (C-W), weaning to 1st vaccination (W-V1), 1st vaccination to 2nd vaccination (V1-V2), and second vaccination to slaughter (V2-S). The number and percentage of withdrawals were summarised by study and overall. Only those pigs present at the start of a period were eligible for withdrawal within that period.

Until first vaccination the experimental unit was the pig and withdrawals were analysed in two pooled analyses within PROC GLIMMIX (SAS v9.1.3), with treatment as a fixed effect, and study and study by treatment interaction as random effects. A binomial distribution and a logit link were used to force logistic regression for the model due to the dichotomous response for completion of a period. The ilink option was used to transform the LS mean model estimates into the estimated percentage removed for each treatment group during each time period.

From first vaccination onwards, the experimental unit was the fattening pen and the percentage removals within each fattening pen were analysed with linear mixed models (PROC MIXED, SAS v9.1.3) for each study with treatment as a fixed effect and random effects for fattening pen and where appropriate study site and fattening pen within study site, where the study was conducted in multiple locations. The LS means from each of these models were then used in meta-analyses to estimate the percentage removals from each treatment group. Three studies were not appropriate for these analyses due to the study design and data limitations.

Results
Records were available for 2196 physical castrates and 2197 vaccinated pigs. Comparative mortality-cum-withdrawal rates for the four periods are shown below, as percentages of the number of pigs entering that phase. The mortality-cum-withdrawal rate pre-weaning was significantly higher in the castrate group. Differences in other periods were not significantly different.

Discussion and Conclusion
The design of Improvac field studies and the large number of studies undertaken provide a unique database of pigs monitored from a few days of age until slaughter. This analysis confirms anecdotal reports that physical castration increases pre-weaning mortality in male pigs.
Impact of surgical castration of piglets on growth performance, feed efficiency and health parameters

Djane Dallanora¹ Karine G. Pasinato² Roniê Pinheiro¹ Glauber Machado¹ Cleber Henn³

1. Integrall Soluções em Produção Animal Ltda, Patos de Minas, MG, Brazil; 2. Universidade do Oeste de Santa Catarina, Xanxerê, Brazil; 3. Pfizer Animal Health, São Paulo, Brazil

Introduction

During the pre-weaning period, piglets are exposed to several challenges which can limit weight gain and also increase wasting and mortality indexes. Surgical castration is a traumatic procedure that has been associated with inflammatory conditions and impact on immune system development (1,2). Behavioral and physiological responses of castrates indicate that suffering and pain are not limited to the few hours after castration and are still present up to 4 days after the surgical procedure (3). The goal of this study was to evaluate the impact of surgical castration on the growth performance of young pigs from pre-weaning till the end of the nursery period.

Materials and Methods

The experiment was carried out in a commercial farm with 3400 sows, in Santa Catarina state, Brazil. A total of 1024 four-day old piglets were individually weighed and randomly allocated into 2 treatment groups: T1 (entire males) and T2 (surgically castrated males, castrated at 4 days of age). Weaning took place at 21 days of age, and the end of nursery was on day 63 of age. After weaning, piglets were distributed into 16 pens (experimental units) within each treatment, being five pens with 20 piglets and 11 pens with 34 piglets each. During pre-weaning and nursery phases, the main parameters evaluated were piglet body weight at 4th, 21st, 35th, 49th and 63rd days of age, daily weight gain (DWG), mortality rate, incidence of wasting (runts), incidence of arthritis and diarrhea, mortality rate and number of piglets receiving additional injections treatment. For all these parameters the experimental unit was the individual pig. Also during the nursery phase feed consumption and feed conversion (experimental unit was the pen). Analysis of Variance was performed for comparison between treatment means. For non-parametric data, Chi-square test and Kruskall-Wallis were used.

Results and Discussion

Table 1 – Mortality, additional injectable medication and weight at weaning for both treatments.

<table>
<thead>

<td>5.42b</td>
</tr>
</tbody>
</table>

Different superscripts in the same column mean significantly different values (p<0.10).

There was no effect of treatments on the incidence of diarrhea and arthritis before weaning. During the nursery phase, there was also no effect of treatments on the occurrence of arthritis, but the incidence of diarrhea was significantly higher for surgically castrated pigs (p=0.002). No statistical differences between treatments were detected for weight at 35th, 49th and 63rd days of age, daily gain, feed intake and feed efficiency. A higher frequency of light-weight pigs was found among castrated pigs, both at weaning (p=0.017) and at the end of nursery period (p=0.052), as seen on table 2.

Table 1. Incidence of light-weight pigs at weaning (D-21) and at the end of nursery period (D-63)

<td>8.7%b</td>
<td>22.2%b</td>
</tr>
</tbody>
</table>

Different superscripts in the same column mean significantly different values (p<0.10).

Under the conditions of this study, surgical castration had a negative impact on weaning weight, mortality rate and incidence of light weight pigs. Surgical castration at day 4 also increased the need for additional injectable medication before and after weaning, as well as the occurrence of diarrhea during the nursery phase.

Continuous throughput compared with ‘all in-all out’ in the management of a farrowing unit in Thailand

Alexander A. Eggen¹ Suraphan Boonyawatan²

¹. Intervet/Schering-Plough, Boxmeer, Netherlands; ². Intervet/Schering-Plough, Bangkok, Thailand

Introduction

An all in-all out production system minimizes the transmission of infection between different age groups and batches of pigs. For a farm operating a continuous flow production system it is normally difficult to change to and manage an all in-all out system, but the economic benefits can be significant. Regumate® can be used to synchronize insemination and farrowing as a major step towards establishing an all in-all out system.

The aim of this study was to compare the production performance of a farrowing unit managed by continuous flow and by an all in-all-out system.

Materials and Methods

This study was performed on a 400-sow farm arranged as follows. There were two farrowing houses each with 65 farrowing pens, and a dry sow house with 520 pens. Sows were served by AI (19-26 sows per week), and between 12 and 24 sows farrowed per week. The farm manager realized that this system did not allow for the proper cleaning and disinfection of the farrowing accommodation.

A batch farrowing system was instituted in January 2008 with estrus synchronized on a 3-week cycle using Regumate®. Thereafter 68-72 sows were inseminated every 3 weeks, and 55-65 sows farrowed in the same period. So the first batch of sows and gilts that was inseminated farrowed in March 2008 and their piglets were weaned in April 2008.

It is possible therefore to compare the performance of the farrowing unit between April 2007 and April 2008 (continuous production) and April 2008-April 2009 (All in-all out management) (Fig 1).

Results

Twenty-one weeks after the change to batch farrowing, the farm could be divided into seven batches of 55-65 sows per batch. All the sows had been through the system, so the farrowing accommodation could be emptied, cleaned and disinfected. Many performance indicators improved in 2008 even though Thailand experienced a PED outbreak.

The performance in the farrowing unit is shown in Table 1.

Discussion

After implementing all in-all out management a lot of improvements were seen on this farm.

In spite of 1% fewer sow inseminations, 18% more pigs were weaned. The farm was easier to manage. Inseminations were better planned and more controlled, and the labor force involved were more focused and less stressed.

The farrowing house could be properly cleaned and disinfected, and one of most important improvements was that the farm manager could organize and plan all aspects of production according to a reliable timetable.

Pig Flow - Managing the health of the business

John Carr
Portec Australia, Belmont, WA, Australia

Setting formal pig flow targets through batching allows a unique opportunity for veterinarians to help manage the health of their client’s pig and keep their own businesses healthy.

Batch farming sets targets, minimises variation and reduces under and overstocking – a major cause of disease, reduced performance and increase in costs.

A key control of the expression of the clinical signs of disease is through vaccination and prophylactic medication.

But – on many farms while a highly efficient preventative medicine programme is designed by the veterinarian, it is on trust that this programme is used and implemented by the farm staff.

Setting pig flow targets allow at least purchases of health items to be monitored within pre-agreed parameters by the whole health team.

To set a pig flow model, the easiest initial point of reference is in the organisation of the farrowing house – the number of farrowing places per batch.

Example of a pig flow medicine monitoring system using an Excel spreadsheet:

Discussion

The records clearly show that:
1. Medicine compliance. The farm is PRRSv and PMWS free and vaccines are not used.
2. There was a period of non-compliance in quarter 1 and 2 which was associated with a particular stockperson and this was resolved with a training opportunity.
3. The non compliance was associated with a reduction in health and performance.
4. The Improvac errors are serious as they impact slaughter value (boar taint) and sales.
5. There was a overuse of Lepto/ery vaccine in quarter 3 – farm playing catch up.
6. Veterinary sales were lost due to poor compliance and this was rectified. 17 HSP vaccine and 4 Improvac. This was a loss of $4000 Aus sales.
7. The client’s satisfaction was ensured because of the proactive health management and attention to details provided.
8. The system is easy to run and modify to other health product sales such as injection, water, feed medications or disinfectants.

Hygiene and the relevance of Endotoxins on swine producing farms

Simone Schaumberger¹ Christine Ratzinger¹ Lukas Krüger¹ Sabine Masching² Gerd M. Schatzmayr¹
1. Biomin Research Center, Tulln, Austria; 2. Biomin Holding GmbH, Herzogenburg, Austria

Introduction
Endotoxin associated diseases are a result of permanent existing endotoxin values in the gut and through outside influences like dust, feces, food and other organic materials. Small amounts stimulate the immune-system in a positive way but excess amounts lead to influenza like symptoms, shock and death.

As endotoxins are known to play a significant role in different pig associated diseases, especially in MMA in sows and the post-weaning syndrome in piglets, a screening on piglet producing farms was performed to find out if there is any correlation between detected endotoxin levels and the incidence of illnesses in the animals.

Material and methods
16 farms with documented MMA problems were chosen. 32 mother sows (2 sows/farm) were sampled between the first and third lactating week. One sow was without medical treatment and the other sow of the same farm was on treatment (antibiotic) against MMA. Samples taken of the sow were milk, feces and urine. Environmental samples were taken from water, feed and air. Additionally temperature and humidity (EL USB-2 Data logger, RS Components) were measured. For air collection a WISA suction pump with pyrogen free glass fiber filters (Whatman) was used. All samples of the sows and environmental samples were tested with the kinetic chromogen Limulus-Amoebacryl Lysat test (Charles River Laboratories). Feces, air and feed were extracted with Tween20 for 1 hour and dilution rows of all the samples were prepared within 12 hours after sampling. Dilution of the samples tested was chosen depending on the sample matrix, for example water samples were tested in a 1:10 dilution and feces samples in 1:10,000. All used material was proved pyrogen free. Performance Standards were valid with $r^2 > 0.97$ and the recovery of all samples ranged between 50 – 200%. Statistical analysis was done with SPSS 17.0 (Box plots, p-value, Regression).

Results
Levels of endotoxin in the air revealed significant differences (p=0.003) between farms with dry and wet feeding systems. Airborne endotoxin concentrations of farms washing their sows before moving them to the weaning boxes were lower compared to those not washing their sows. Disinfection of the stables before moving the sows seemed to reduce air endotoxin values as well, but there was no significant difference compared to farms without disinfection. No positive correlations of endotoxin air levels and levels in feces (p=0.052) or urine (p=0.124) could be observed. No correlation between stable temperature and air endotoxin values (p=0.641) nor humidity and air endotoxin values (p=0.617) could be found. Although water samples of one farm widely varied in their endotoxin values (SD=14.39), the design of the drinking troughs did not reveal any correlation (p=0.342) with detected endotoxins.

Discussion
Management and hygiene have an impact on endotoxin air values and further consequences on humans and animals. Especially endotoxin levels in the air are an important issue not only for the animals, but also for the farmers because they spend a lot of time in the stable.

In this study some interesting approaches for measuring possible risk factors could be observed. Dust seems to be a major source of endotoxin in the air according to the results of farms with different feeding systems. Dry feeding produces more dust than wet feeding. Besides feeding, hygiene of the sows plays a major role as well. Disinfection of the stable does not seem to be as important as washing the sows before moving them into the weaning boxes.

This study could not prove the coherence of endotoxin values and the incidence of illness but showed clear trends concerning hygiene and endotoxin values. Results of this study will be verified in follow up studies on different farms.

Application of mineral sorbents for reduction of odorous volatile compounds emitted from pig manure

Roman Kolacz; Mariusz Korczyński; Sebastian Opalinski; Zbigniew Dobrzanski
Wroclaw University of Environmental and Life Sciences, Department of Environmental Hygiene and Animal Welfare,
Chelmonskiego 38C, 51-630 Wroclaw, Wroclaw, Poland

Introduction
Odors are specific air pollutants, since human nose is able to detect and differentiate odorous compounds even when their concentrations are below the threshold detectable by technical facilities, e.g. gas chromatography. It has been estimated that odor detection threshold by the human nose is as low as \(10^{-9}\) molecules, while 1 g of ethyl mercaptan in the air contains \(10^{16}\) molecules of this gas, which is \(10^{15}\) higher than the detection threshold \([4, 5]\). Major odors emitted from animal breeding include ammonia and its derivatives, sulfur compounds (hydrogen sulfide, mercaptans), volatile fatty acids and phenolic compounds, adversely affecting human and animal health \([1, 2]\).

Many efforts have been made to reduce the emission of odors from animal manure. One of the potential means of limiting odors in the air of livestock buildings is the application of aluminosilicate sorbents.

The aim of the investigation was to study under laboratory conditions the influence of bentonite and halloysite, added to pig manure, on the reduction of odorous volatile compounds emission.

Materials and Methods
The samples of fresh pig manure (50g) were placed in 9 cone-flasks (500 ml). The flasks were divided into 3 groups and the sorbents were added as follows: group I – control - no sorbents, group II – raw bentonite (20 % of the manure mass), group III – raw halloysite (20 % of the manure mass). The odorous compounds were extracted (sampling time = 30 min.) from the headspace of each flask at 30 °C after d 1, 4 and 8. The extraction of the substances was carried out using a manual SPME holder with StableFlex 50/30μm divinylbenzene/ carboxen/polydimethylosiloxan. DVB/CAR/PDMS fibers were used (Supelco, USA). The analysis of air samples was performed using a GC/MS method (Thermo Electron, Finnigan Focus Polaris Q type). Identification of volatile odor substances was based on comparative analysis of mass spectra and NIST spectra database.

Results and Discussion
40 volatile odor compounds (VOCs) were identified in the samples collected from the air immediately above the manure. They included 4 sulfur organic compounds and alcohols, ketones and other derivatives, e.g. benzene and xylene. The identified substances contained 7 compounds very poisonous to humans \([3]\), i.e. trimethyloamine, cyclohexanone, toluene, methylpentanol, 2-heptanone, chlorobenzene and 1,4-dichlorobenzene.

The sorbents used in the study, especially halloysite, markedly reduced the emission of odorants from pig manure (Table 1). The greatest efficiency of the sorbents was observed on d 8. Reductions of volatile odor compounds accounted for 65.62% (bentonite) and 83.14% (halloysite). On d 1 and 4 of the experiment, halloysite was the only sorbent that reduced the emission of odorants from the manure. In contrast, bentonite, applied at the same time, increased the quantity of VOCs. Significant reductions were also observed by Turan et al. \([4]\) who added 10% of aluminosilicate and vermiculite to poultry slurry. The reduction reported by them was comparable to the results observed in our study with the use of bentonite (61.53%). Summing up, it can be concluded that the greatest efficiency in reducing VOC emissions from pig manure was achieved with the use of halloysite (from 5% after d 1 to 83% after d 8).

Table 1. The effects of bentonite and halloysite on reductions (-) and increases (+) (%) in VOC’s concentrations.

Impacts of technological level on production efficiency and economic variables in pork farms in the States of Guanajuato, Jalisco, Sonora and Yucatán, México

Juan Nava; Rafael Trueta
Universidad Nacional Autonoma De Mexico, Mexico, DF, Mexico

Introduction
The objective of the present study was technological level grading (high, intermediate and low) and its impact on production efficiency, defined as the number of animals sent to market per sow per year and on the main economic indicators, of a random sample of complete cycle pork farms in the four states of Mexico showing greater production. 31.1% of farms use high technology, 39.9 % use low technology and the remaining 29.5 % can be described as semi-technified. The Kruskall-Wallis non parametric statistical analysis provides conclusive evidence that high level yields a lower cost, MXP 9.45 vs 11.20 and 11.84 for the intermediate and low technology levels, respectively (P<0.01).

Materials and Methods
Data on technical, animal health, production and economic variables was obtained through surveys performed in a random sample of complete cycle swine farms. Farms were graded in accordance with their technological level taking into account the following parameters: a) biosafety, b) reproduction parameters, c) production parameters.

Results
Production efficiency
When farms were grouped by technological level, the number of animals sent to market yearly per sow was 18.60, 15.97 and 11.67 (P<0.01) for high, intermediate and low technological levels, respectively.

Economic production variables
Production cost
Average cost of production per kg live weight when farms were grouped by technological level, those in the high technology bracket showed a lower Ckg, MXP 9.45, while those in the intermediate and low levels, showed MXP 11.20 and 11.84, respectively.

Revenue
Profit per average kg live weight sold for the 61 farms was MXP 4.93. At the high technology level Pkg was MXP 5.52, MXP 4.77 for intermediate and MXP 4.59 for low technology.

Profitability
Average profitability per kg sold (Rkg), the high technology level showed the higher Rkg, 64.9 %, well above the 49.1 % and 49.9 % found for the intermediate and low technology levels, respectively.

Discussion
Obtaining profits (income – costs) is the most important goal of commercial farmers. One of the determining factors for improving economic efficiency is technology that manifests through multiple expressions. Results obtained in the present study confirm this notion, because production costs of swine show an inverse relationship to the technological level of the farm. In the interest to share this experience with other producers, we list the deficiencies found in low technology farms studied: 100 % did not have perimeter wall, 83.3 % did not have a sanitary moat; 66.6 % does not compel workers to bathe; 83.3 % allows animals to enter the premises; 66.7 % did not use AI and 66.7 % do not use balanced feed. Besides, none of them have systematic parasite and vaccination programs. Low technology farms acquire more competitive advantages when introducing technology than those of a higher level.

The effect of standard deviation reduction on optimal average slaughter weight

Dennis DiPietre1 Eric Lewandowski2 Remy Jagu2 Matthias J. Adam1
1. Boehringer Ingelheim Animal Health, Ingelheim am Rhein, Germany; 2. Boehringer Ingelheim Vetmedica, Pace, France; 3. KnowledgeVentures, LLC, Columbia, MO, USA

Introduction
In a previous paper(1) we show the economic impact of reducing the standard deviation of slaughter weights on overall farm profitability as measured by return over feed costs. In that paper we present a side-by-side trial, where pigs were randomly assigned at weaning to two treatment groups, Circovac® (CV) or Ingelvac CircoFLEX® (FLEX). Pigs of both groups were kept in separate pens, but in the same rooms(2). The producer was blind to the treatments and employed his standard selection and marketing procedures to both groups. Though market weights for the two groups were almost identical, the standard deviation of market weights was 16.7% less for the FLEX pigs. This was estimated to produce a €1.85/head advantage for the FLEX group. The amount of the increase in profitability depends on the market price, cost of feed, and the particular buying matrix used. In this paper, we extend the analysis by examining how changes in standard deviation of marketing weights also change the optimal average weight of the distribution of pigs marketed.

Materials and Methods
A stochastic simulation method was used to estimate the average carcass weight which maximizes expected return over feed costs for each group based on its distribution of slaughter weight at the time of marketing. Distributions were fitted to the actual observations for carcass weight and lean percent in each group. These distributions were correlated to match the correlation between weight and lean in the actual data. 10,000 pair of observations on carcass weight and correlated lean percent were then randomly drawn from each group’s estimated distribution and used in the analysis. The optimal average weight for each group of 10,000 observations was determined through the use of a detailed simulation model employing growth and average daily feed intake functions matched to the farm and utilizing the actual pricing matrix in which the pigs were originally sold. The average feed cost per Mton wean-to-finish was $200 and the base carcass price was $1.30 per kg. The estimated optimal average weight was compared to the marketing weight chosen by the producer. In the original case, the producer was blind to the treatments and chose to market the pigs in both groups at essentially the same average weight.

The model employed can be represented as follows:
Find mean average carcass weight \( Q^* \) of the distribution of weights marketed which maximizes return over feed cost:
\[
\text{Max } P_j=\sum_i P_{Q_i, L_i} N_j(Q_i, L_i) - TFC_{Q_i, L_i}
\]
Where:
- \( J = \) the treatment group
- \( P_{Q_i, L_i} = \) Grid determined price/kg (a function of current base carcass price and premium or discount associated with carcass weight and lean percent)
- \( N(.) = \) Correlated distributions of carcass weights (kg) and associated lean percents estimated from the sales data for each of the treatment groups
- \( TFC_{Q_i, L_i} = \) Estimated total feed cost to produce carcass \( Q_i, L_i \)

Results
Table 1: Economic returns over feed/hd for both groups

<table>
<thead>

<td>€71.98</td>
<td>€70.23</td>
<td>1.75</td>
</tr>
</tbody>
</table>

Discussion
Profit optimizing average weight results in an improvement in return over feed costs for each group. In this case, \( Q^*_{\text{FLEX}} = 96.4\text{kg} \) with average return over feed costs per head of €71.98/ hd and \( Q^*_{\text{CV}} = 95.0\text{kg} \) with return over feed costs equal to €70.23/hd. This is an improvement from “as marketed” of €1.58/ hd and €1.68/hd respectively. In conclusion optimized carcass weights would generate substantial additional returns irrespective of treatment groups.

The analysis of farm management factors affecting the MSY in Korea's hog industry

Hwa soon Kang
Cargill Agri Purina, Inc., Seongnam-si, Korea

The purpose of the hog farm operation is to maximize a profit. But, compared to the advanced countries for pork production, Korean hog industry has faced the challenge to be sustainable and to be developed due to lower productivity. In addition, as the trade barrier between countries has been gradually lowered, Korean hog industry has been challenged seriously. Under the existing circumstances, to accomplish the objective of the hog farm operation and to grow sustainably, it is necessary to analyze the performance, to operate efficiently and to maximize the productivity level in each production stage. Therefore, it is necessary to analyze the factors affecting the farm productivity to improve farm productivity, to grow sustainably, and to increase the competitiveness of the industry.

Previous studies on the farm productivity and the competitiveness of the industry were conducted to measure the productivity level and recommend the ways for improvement by analyzing farm facility, farm management, disease control, management capability, each component adoption, profit, and so on. However, in this study, it is assumed that all the factors affecting farm productivity level are compounded, as the hog industry has been integrated and been complex, and they are interconnected with one another. Additionally, biological indicators, such as PSY and quantitative indicators, such as income and spending are limited to measure farm performance level and to represent financial performance, respectively. And, there is a tendency that qualitative factors, i.e., technology adaptability and management capability, are individually analyzed to be indicated in a quantitative manner.

In this study, a diverse array of factors, such as facility, technology, workforce, and management, are analyzed by considering effect of each factor on the farm productivity and qualitative feature. An indicator for farm productivity is determined to be an MSY, because there is no one solid standard to determine farm productivity, because it has not been feasible to collect realistic data for profitability and to use factors such as income and spending for evaluating productivity under the circumstance that every farm's management type and financial status are different. Moreover, considering the accessibility and objectivity to the information, MSY, the number of pigs alive from birth to market per sow per year, is determined the most suitable indicator for productivity effectiveness. The data used for analysis were gathered through a set of in-depth interviews with hog industry expert and farm owner while visiting on-site. The data collected were specifically on farm productivity level, farm workforce status, farm owner's characteristics, facility and disease status.

Through the Decision Tree used for the analysis, broad impacts of the factors mentioned above on productivity and interactions between factors were identified. And, using the result from the Decision Tree analysis, variables for CARTEG using optimal scaling were selected and using the optimal scaling while considering that the data from the interviews are three different types, i.e. category, sequence, numeric value are blended, the conclusion for CARTEG was drawn.

Based on the this result, after setting average MSY as a primary basis to categorize the data set into two groups, the higher and the lower, respectively, the factors to influence on hog farm productivity were identified. In addition, while the higher and the lower groups were divided by MSY value, the variables affecting hog farm productivity for each group were figured out and the strategies to increase MSY value for each group were provided.

For those farms on the bottom, they need to establish business plans while focusing more on avoiding exclusive management dependent on experience, systematic and regular participation in training, farm consulting, workforce management by capability, implementation of incentive program to promote longer years of service and high performance, broadening workforce benefits program, facility management, such as specialized access control system, all-in all-out system as well as site management, regular service call by specialized veterinarians, and prevention of antibiotics’ abuse. And then, to be more competitively in the future, farm owners or farmers' group have to set business plans and implement them while especially bearing in mind following areas: self-designed training program, customized training, business direction setting with farm consultants, farm analysis and record maintenance, long-term strategy for sustainable growth including operating principles and succession plans, as well as modernized and environmentally-friendly farm.

These kinds of strategies for higher MSY are useful not only to increase competitiveness of individual farms or farmers’ groups, but also to establish the foundation of Korean hog industry to compete against the imports in the era of FTAs. Accordingly, primary purpose of this study is to enable individual farms to choose necessary strategies to manage farms effectively, leading to more income. And, the ultimate purpose of this study is to propose strategies for securitizing competitiveness of overall hog industry and for further development of the industry.

Measuring full value pigs

Paul D. Matzat1 Dennis DiPietre2

1. Elanco Animal Health, Greenfield, IN, USA; 2. Knowledge Ventures, LLC, Columbia, MO, USA

Introduction
The concept of capturing maximum profit or full value from every pig that comes into a producer’s care has been discussed and developed over the last few years by Elanco Animal Health. All production outcomes less than full value are defined as lost opportunity, deviation from optimal or as attrition for a contemporary group. Optimizing profitability for a group of pigs means identifying the point at which the group’s marginal input cost equals marginal revenue. This requires knowledge of the production function to estimate the cohort’s marginal cost of gain and jointly determined market value. Although the underlying determination of profit maximization is the same, the process for estimating it for a group is much more complex than for a single pig.

Materials and Methods
The slaughterhouse is the only place in the current swine production chain where every animal is individually weighed and assessed for quality. Information is often reported to producers in summary form, such as total animals sold, average weight, average price, average discount or premium and other assessments. Generally there is little or no reporting of group outcomes and the impact of variation on lost opportunity. The premium and discount schedules that buying programs provide vary across geographies and between pork processing companies and thus must be clearly understood prior to developing a marketing strategy or standard marketing procedure. Figure 1 is an example of actual market weight and selling price outcomes.

Results
The marketing decision for a single animal can be easily calculated and demonstrated by determining if adding another kilo of weight prior to marketing will add profit margin. However, making the marketing decision for a truck load, building or entire site can be difficult due to discounts imposed on pigs in the tails of the target weight distribution. Producers can accurately identify weights of pigs to initiate the marketing process. This may be done by scaling pigs, visual appraisal or use of calendars and growth curves to trigger marketing of animals within a group or barn. Accuracy of selection, both from an optimal weight perspective and minimizing variation within the group of pigs can be metrics used to score how effectively marketing decisions were implemented for each load and for the entire population of pigs evaluated.

Discussion
Developing targets or report cards for the team responsible for executing the marketing plan is critical for continuous process improvement and capturing opportunity costs. First, those who physically identify or mark pigs must have rapid and accurate feedback reporting achievement. Second, the load out crew must receive reports demonstrating how effective they are at placing the correct pigs on the transport vehicle. Third, the transportation team must have an understanding of transport losses that could impact financial outcomes. And finally, farm managers responsible for marketing activities and financial results must have reports indicating profits and identifying value opportunities.

Creating a grade, metric or score that allows various levels of the farm organization to quickly and easily see how well the marketing activity is being executed is important to drive continuous improvement. We propose the metric, Full Value Pigs, to mean all animals marketed within a contemporary group which achieve at least 90% of the single pig optimal margin over feed cost. Establishing a score or rating allows a better understanding of system achievement and helps the entire team responsible for the marketing activities target and capture opportunities for continuous improvement.

Description of the economic impact of the political crisis on small-scale pig farmers and butchers in Western Kenya

Cate E. Dewey¹ Jared Wohlgemut¹ Florence Mutua² Mike Levy¹

1. University of Guelph, Guelph, ON, Canada; 2. International Livestock Research Institute, Nairobi, Kenya

Introduction

Politically based violence followed the 2007 federal election in Kenya. This crisis caused the Nairobi Stock Exchange to drop by $600 million USD. In the first week, the crisis caused the Nairobi Stock exchange to drop $600 million USD and costs due to crisis-related damage was $1 billion US. Tourism was severely affected. Hotel occupancy rates dropped from above 80% to under 20% and 120,000 tourism-related jobs were lost. The purpose of this research was to describe the economic impact of this crisis on the smallholder pig farmers and pig butchers in Western Kenya.

Materials and Methods

In June 2008, face-to-face interviews were used to collect information from 100 farmers, 38 pig butchers, and 17 government staff in Busia and Kakamega Districts of Western Kenya. Farmers were randomly selected but butchers and government staff represented a census. Farmers were asked what livestock they owned in June 2007 and June 2008 and the price they paid for raw meat before and after the crisis. Everyone was asked to describe the effect of the crisis on their businesses. The 2007 and 2008 livestock numbers were compared with a paired t-test.

The cost of meat before and after the crisis and from Busia to Kakamega was compared using Student’s t-tests.

Results

Food became more expensive, additional family members moved in with the farmers to escape violence in the city, farm inputs became expensive and scarce, it was impossible to travel outside the village and off-farm jobs were lost. Farmers sold livestock to feed their families and because they had no food for the pigs. In Busia, ownership of sows, boars, growing pigs and piglets decreased by 41%, 32%, 42%, and 40% respectively. In Kakamega, sows and boars decreased by 27% and 46%; growing pigs and piglets decreased by 55% and 70% respectively.

Many butchers (52%) had less business due to the crisis. More butchers in Kakamega (42%) closed for longer periods of time (40 +/- 19 d) than in Busia where 18% of butchers closed for 18 +/- 19 d (P<0.001). Pork price increased from 105 to 119ksh/kg in Busia and from 116 to 146ksh/kg in Kakamega after the crisis (P<0.0001). The live pig price did not increase.

Extension workers were unable to travel to farms. Pig mortality increased to due malnutrition and untreated diseases.

Discussion

The pig industry in this area of Western Kenya relies on trade within and between villages. The transport of pigs is done either on foot or using bicycles. Therefore, this drastic decrease in the numbers of pigs in the region will have a large impact on the industry. Sows are 12-14 months old when they wean their first litter and pigs are 8 – 12 months old when they reach market weight. It will take more than a year to replace the pig herd to return to the previous population.

The closure of butcher businesses has left the butchers with little to no financial reserve. There will be few pigs for the butchers to buy, which will put pressure on them to purchase smaller weight market pigs. With less pork to sell, the fixed costs of slaughter will result in low to no profit.

The crisis had a severe impact on the pig industry’s sustainability, shocking market equilibriums. The farmers needed to sell pigs to support their families when food prices were high. The current low breeding population has reduced the supply of pigs, forcing upward pressure on prices and jeopardizing long term sustainability. Improved breeding efficiency is now essential to ensure a renewed availability of pigs. The political crisis has negatively affected all of the industry’s stakeholders.

Economic income of small pig production systems in Mexico.
Enriquez Celestino; Giovanna Penuelas; Francisco E. Martinez Castañeda
Universidad Autonoma del Estado de Mexico, Toluca, MEX, Mexico

Introduction
53% of Mexican population lives with some level of poverty and hungry. Backyard breeding animals is a central element of strategic and improving diversifying economies all around the world. The aim of this study was to evaluate the economic performance of small pig production systems in Texcoco Mexico.

Materials and Methods
With participative techniques we analyzed 53 small pig producers in Texcoco, Central Valley of Mexico. Three Strata were defined according the number of sow and with a proportional allocation model: Strata 1: from 1 to 4 sow; Strata 2: from 5 to 10 sow; Strata 3: from 11 to 16.

Results
Strata 1 had 80% of small production units with an economic income of 16% of total family income. Strata 2 got 12% of all producers and the economic income was 17%. Finally, Strata 3 represent 8% only and 28% of economic income (Fig 1).

The animal inventory was 173 sow and 23 boars. 90% of producers live in a nuclear family and only 10% were singles. Age average was 51 years old and we detected producers with more than 70 years old.
33% of all population analyzed produce complete cycle, 33% sell piglets, 14% finished piglets to market and less than 3% transform pigmeat.

Discussion
The best economic performance and income was for the bigger Strata 3. It is known as big is the enterprise more possibilities and access to resources can get. It is difficult to establish scale economies in this kind of production systems, but it is also true that more animals in market, represents less variables costs.

One amazing data is the average of producers, because it seems that in general this economies strategies represents an important diversification of incomes due to this producers are at the end of this working age. That way, small pig production systems can be not only an economic way of life.

Several authors mentioned the importance of this systems. We want to add the fact that the historical way of production is very important in the occupational health of families.
**Introduction**

Since January 2010 surgical castration of male piglets without anesthesia is forbidden by federal law for the protection of animals in Switzerland.

Due to ignorance to alternative methods avoiding surgical castration by the swiss meat industry, pig breeders are forced to perform surgical castration under general anesthesia. Pig producers can choose between using an inhalation device with isoflurane or anesthesia by intramuscular injection performed by the veterinarian.

Azaperon and Ketamin is the only registered drug combination to anesthetize pigs in Switzerland. The surgical tolerance of this combination is considered to be not sufficient for painful procedures. Our own experiences confirm this estimation, especially if these drugs are given intramuscularly. We observed also adverse reactions like excitement, hyperesthesia and convulsions.

Consideration concerning improvement of this combination to a more balanced anesthetic protocol with better analgetic action led to a triple combination where a potent analgetic drug (e.g. opioid) by off-label use was added.

Because of good experiences with this drug, butorphanole was chosen. In a field trial the security and efficacy of a combination of azaperone, butorphanole and ketamine for general anesthesia by intramuscular injection to allow castration of piglets was tested.

**Materials and Methods**

Out of another study the optimal doses for the combination were found: 5 mg per kg bodyweight of azaperone, 0.2 mg per kg bodyweight of butorphanole and 15 mg per kg bodyweight of ketamine.

From three different pig breeding units 140 male pigs (suckling piglets and weaners) received an intramuscular injection of the combination mentioned above, mixed in the same syringe and performed by the veterinarian. After reaching an adequate depth of anesthesia they were castrated by the farmer in the habitual manner.

For piglets older than 3 weeks of age an emasculator was used. Before administration of the drugs the pigs were shortly clinically examined and alterations in health status were recorded.

**Results**

Out of 140, 138 pigs reached within 5 to 10 minutes an adequate depth of anesthesia. Two pigs received an additional dose of 2/3 of the original dose.

Eighteen, especially piglets weighing between 2.5 and 3 kg showed moderate struggling during tension on the funiculus. After a maximum of two hours all pigs recovered uneventful. There were no losses with coherence to the anesthesia.

The older the pig was, it was more likely to be judged by score A. None of the pigs were judged by score C.

**Discussion**

This anesthesia protocol showed to be valuable for use in practice to provide general anesthesia allowing surgical castration of piglets. The experiences made showed relevant advantages in comparison of experiences made with azaperone/ketamine alone.

The ideal point in time to perform this procedure showed to be after a piglet’s age of three weeks.

Clinical effects of NSAID treatment in piglets with arthritis

Helena Frohm1 Magdalena Jacobson1 Mate Zoric2
1. Dept. of Clinical Sciences, SLU, Uppsala, Sweden; 2. National Veterinary Institute, Uppsala, Sweden

Introduction
In Sweden, approximately 10% of all piglets are treated against arthritis. The disease is mainly caused by hemolytic streptococci and Staphylococcus spp (1, 4) and the piglets are usually treated with intramuscular injections of penicillin once daily for five days. The disease causes suffering to the affected piglets and it has become increasingly common to also include NSAIDs in the treatment. This regimen has however not been evaluated. The purpose of this study was to investigate the clinical effects of combining treatment of lame piglets with NSAID-drugs and penicillin and compare it to treatment with penicillin only.

Materials and Methods
In this study 40 piglets (Group 1) with arthritis from four different herds in Sweden were treated with benzylpenicillinprokain (20 mg/kg bw) i.m. once daily for five days. 43 piglets (Group 2) were treated similarly but with the addition of a subcutaneous injection of meloxicam (0.4 mg/kg bw) the first day of treatment. The piglets included were below three weeks of age with evident lameness. The rectal temperature, weight, degree of lameness and degree of joint swelling were recorded day 1, 2 and 6 (the day after the final treatment). The degree of lameness and joint swelling were scored none (0), mild (1), moderate (2) or severe (3) by a person blinded for treatments. In each pen, a matched, apparently healthy piglet was included as weight gain control. The results were analyzed by MannWhitney Rank Sum test (rectal temperature and weight), and Fischer’s exact test (lameness and joint swelling). Comparisons were made between the two treatment groups, between piglets included day 1-2 (i.e. pigs that might have been lame before the start of the study; n = 48; 58%) and those included day 3-7 (i.e. pigs that developed arthritis during the study), as well as between piglets with joint swelling in the claws and those with swelling of other joints.

Results
In both groups, a decrease in rectal temperature was noted between day 1 and 2 (Group 1; P<0.01, Group 2; P<0.001) and day 1 and 6 (Group 1; P<0.05, Group 2; P<0.001). The differences between the groups were not significant. Further, there was no difference between the groups in the decrease of swelling of the joints (Table 1). In both groups, the swelling persisted to a larger degree on day 6 among piglets included day 1-2 (P < 0.01) than among those included later. Within groups, the swelling was more pronounced day 6 among the piglets in group 1, included day 1-2 (P = 0.05). Swelling of the claw joints were more severe day 6 as compared to other joints (P < 0.001). There were no differences with respect to weight gain or lameness between the groups (Table 1).

Group 1 = piglets treated with penicillin only for 5 days, Group 2 = piglets treated with penicillin for 5 days + metacam the first day of treatment. Group 3 = healthy weight gain control. Day 1 = median values measured before the first treatment, Day 6= median values measured the day after the last treatment

Discussion
Initiating treatment early in the course of disease is important to avoid persistent infection, haematogenous spread and further damage to the joints (3). This was also emphasized in the present study by the persistent swelling of the joints among piglets included early in the study, as these piglets may have suffered from a more progressed infection. The results also indicate that the use of meloxicam may reduce joint swelling in these progressed infections. The significance of persistent joint swelling needs further investigation but the degree of synovitis and amount of exudates may influence the ability to eliminate the infection with antibiotics (2). Further studies are also needed to investigate the poor response to therapy of piglets with claw joint swelling. No clinical signs of adverse effects were noted and in conclusion usage of meloxicam in piglets with arthritis can neither be supported nor rejected based on this study.

Efficacy of NSAIDs in treatments of lame piglets

Mate Zoric¹ Eva Norling² Ulla Schmidt² Per Wallgren¹

¹. National Veterinary Institute, Uppsala, Sweden; ². Swedish University of Agricultural Sciences, Uppsala, Sweden

Introduction

Joint swelling and lameness are the most obvious and persistent clinical signs of infectious arthritis in piglets (1). Prompt treatment with antibiotics is required to achieve a positive treatment effect in lame piglets that limp due to pain (2). Hitherto pain-reducing drugs have rarely been used within veterinary medicine, but the potential of recently introduced non-steroidal anti-inflammatory drugs (NSAID) is apparent from welfare aspects. However, pain prevents activity and pain-reducing may lead to over-activities with chronic injuries of affected joints as a consequence. Therefore, the aim of this study was to validate the clinical effects of concurrent treatment of lame piglets with NSAID-drugs and antibiotics to that of using antibiotics solely.

Materials & Methods

The study was carried out at the research station at Funbo-Lövsta, Swedish University of Agricultural Sciences. The farrow-to-finish herd comprised 110 sows and piglets were given individual identities at birth. The piglets were weighed at birth and at five (weaning) and nine weeks of age. Records of disease and treatments were kept for each pig.

All piglets born alive during six months were included in the study. Piglets attended with lameness were randomly allotted into one of two groups. Piglets in group I were injected intramuscularly with 20 mg benzyl penicillin (Penovet® vet., Boehringer IngelheimVetmedica) per kg bodyweight once a day for five days. Piglets in group II were additionally injected with 3 mg ketoprofen (Romefen vet., Merial) per kg bodyweight once a day for three days.

The occurrence of lameness was registered until the age of 5 weeks and the clinical efficacies of treatment were assessed daily. Lameness and/or visibly swollen joints, as well as general condition were scored as 0 (good), 1 (almost good), 2 (not good), 3 (not good at all). Groups were compared by Chi²-tests using two-by-two frequency tables.

Results

In total 93 out of 1572 liveborn piglets were diagnosed with lameness (5.9%). Around 85% of these diagnoses took place during the first 3 weeks of life. As shown in Figure 1, the clinical response differed significantly (p<0.05) between the two treatment groups. The clinical status of penicillin and ketoprofen treated piglets (n=49) was improved daily during the first four treatment days (p<0.05 to 0.01), whereas a significant (p<0.01) improvement only was recorded between days 2 and 3 of piglets solely treated with penicillin (n=44).

Discussion & Conclusions

Like other diseases (3), lameness reduced the growth rate of the piglets. Despite the low number of pigs in this study, our results clearly indicated an earlier recovery among lame piglets treated with both antimicrobials and NSAIDs. Use of NSAIDs in combination with antibiotics as treatment for lameness in piglets ought therefore be considered for animal welfare issues.

No difference in weight gain between the treated groups were recorded, but the earlier recovery of piglets given NSAIDs may contribute to higher activity including suckling which could improve the general condition of affected piglets. This will be scrutinised in enlarged studies. However, it should be emphasized that pharmacological treatment of pain in sick piglets not can replace the management routines, floor quality and good care.

Effect of ibuprofen on pigs during routine vaccination and willingness to approach behavior

Peggy Anne Hawkins; Michael Strobel; Leah M. Erickson
Veterinary Provisions, Inc., Northfield, MN, USA

Introduction
Vaccinations are a necessary part of producing healthy pigs. Today, nearly all pigs receive some vaccinations during the nursery and/or grower phases of production. The objective of this study was to determine if ibuprofen administered in the water could reduce fever associated with vaccination of pigs as measured by rectal temperature. Additionally, a pilot study on the behavior known as willingness to approach was evaluated in pigs with and without ibuprofen at the time of vaccination. The ibuprofen group had significantly lower rectal temperatures as compared to the non-medicated group.

Materials and Methods
One of two rooms was randomly assigned to receive the ibuprofen medication. And, fifty (50) pigs within one randomly chosen pen in each of the two rooms were selected. Pigs were tagged for identification 5 days prior to vaccination day. At ~3:00p.m. the day prior to vaccination, a stock solution of ibuprofen (VetRx®) was prepared according to label directions: 16oz (473ml) q.s. with water to 1 gallon and metered to the pigs at 1:128. Ibuprofen remained available to the pigs for 24 hours post-vaccination. The next morning at ~9:00a.m., pigs were vaccinated, booster dose, per veterinary recommendation (M+Pac® and Circumvent® PCV2; Intervet/Schering). Pigs were crowded in the pen and injected in the neck muscle. Immediately following vaccination individual rectal temperatures (RT) were measured. About 5 hours after vaccination, the pigs were crowded in the pen again and RT were taken again. Pigs in the remaining pens of the room were used to evaluate willingness to approach as described by Baumert et al. (1). The baseline or pre-vaccination evaluation for the approach study was done the afternoon before vaccination. The post-vaccination evaluation was done the following afternoon about 5 hours post-vaccination.

Results
The non-medicated control pigs had an average RT 105.7°F and the ibuprofen group was 105.6°F immediately following vaccination. At 5 hours post-vaccination, non-medicated control pigs had an average RT 105.5°F and the ibuprofen group was significantly lower at 104.8°F. Additionally, there was no difference between the immediate RT of either group and the RT of the control group after 5 hours (Fig. 1). Plots with different letters are different (P<0.05).

Discussion
Vaccines stimulate and activate the immune system of pigs (2). The inflammatory response is an important part of this development (3). A febrile response is expected when a vaccine has done a good job of stimulating immunity. However, a very high fever response (>105.0°F) may do more harm than good for the animal. Ibuprofen is used effectively in human medicine to control vaccine induced fever. In this study, the increase in RT due to the stress of the vaccination process (crowding and injection) was not affected by having ibuprofen in the drinking water. But, at 5 hours after vaccination, the non-medicated animals continued to have an increasing RT with some as high at 108.0°F. Pigs with a high fever were less likely to exhibit willingness to approach behavior than pigs with RTs controlled by ibuprofen. Further work will be presented at the meeting.

Introduction

In many European countries, the search for a reasonable alternative to piglet castration without analgesic treatment is ongoing. In Austria a new method was developed in 2008. It combines the application of topical cryogen spray on the scrotal area before skin incision and spraying local anesthetics (LA) on the fixed spermatic cord after removal of the testes. Therefore the spermatic cord is fixed with a clamp (1). The intent of the present study was to evaluate the impact of cryogen spray application, intraoperative fixation of the spermatic cord and intraoperative application of local anesthetics on castration induced stress and pain. Similar to other studies, the dimension of stress was evaluated by cortisol measurements (2,3).

Materials and Methods

A total of 221 clinically healthy male suckling piglets were randomly assigned to eight different treatments and groups (Table 1).

</table>

The cryogen spray (ethyl chloride) was applied on the scrotal skin from a distance of 10 cm until a skin temperature up to -12°C was achieved. The temperature of the scrotal skin was measured by a pyrometer. The local anesthetics (40 mg procaine-hydrochloride with 0.05 mg epinephrine) were either dropped into the wound after removal of the testes (Group 5 and 6), injected into the testes 10 minutes prior to castration (Group 7) or dropped on the fixed spermatic cord after removal of the testes (Group 8). Blood samples taken from the cranial vena cava were collected from each piglet half an hour before and half an hour, one hour, four hours and one day after treatment. Based on cortisol measurements, the impact of the various treatments on pain and stress was examined.

Results

The average values of cortisol concentration of all groups are shown in Figure 1.

Figure 1: Average values of cortisol concentration before and 1/2 h, 1 h, 4 h, 24 h after treatment

Fixation and application of cryogen spray (group 2) caused half an hour after treatment significantly higher average cortisol concentrations than fixation alone (group 1) (p ≤ 0.05). A minimizing effect on castration induced stress using a cryogen spray prior to castration was not evident (group 3 vs. group 4, p > 0.05).

Four hours after castration, the average cortisol concentration of Group 5, 6 and 7 were significantly higher than that of Group 3 (p ≤ 0.05). The application of cryogen spray combined with the use of a clamp to fix the spermatic cord (Group 8) lead to a significant increase in serum cortisol concentration one hour after castration compared with serum cortisol concentration of Group 3 (p ≤ 0.05).

The results of the cortisol measurements indicated that none of the examined castration methods (Groups 4-8) induced a significant minor stress reaction than the conventional method of castration (Group 3).

Discussion

Results indicate that neither cryogen spray nor local anesthetics as applied in this study cause an appropriate analgesia for piglet castration. Therefore, those techniques are not feasible as alternative to conventional piglet castration.

Evaluation of different topical anaesthetics for pain reduction during surgical castration of male piglets

Karl-Heinz Waldmann¹ Dina Rittershaus¹ Manfred Kietzmann² Birger Puppe³
1. Clinic for Swine and Small Ruminants, Hannover, Germany; 2. Department of Pharmacology, Toxicology and Pharmacy, University for Veterinary Medicine , Hannover, Germany; 3. Research Institute for the Biology of Farm Animals, Dummerstorf, Germany

Introduction
80 % of the male piglets in the EU and almost all male piglets in Germany are castrated to avoid unpleasant odour and taste of the meat of entire male pigs [1]. According to European law, castration can be performed without anaesthesia during the first 7 days of the piglets’ lives. Various studies however documented painfullness of this procedure. Therefore different research projects were started to find an alternative to conventional castration of piglets. However, general anaesthesia showed some disadvantages [2] and for antiphlogistics, positive effects could be found merely on postoperative pain [3]. This study intended to test the ability of different topical anaesthetic techniques for pain reduction during castration of male suckling piglets.

Material and Methods
193 male piglets at 6 or 7 days of age were included in the study and divided into 8 different groups. There were 5 castration groups, in which the piglets were castrated conventionally or after use of chloroethyl spray, a combination of chloroethyl and lidocaine spray or EMLA-cream, which is an euthectic mixture of lidocaine and prilocaine. One group of piglets, which were castrated after intratesticular application of local anaesthesia in combination with an NSAID served as positive control. Additionally, piglets of three control groups were either not medicated or treated with chloroethyl spray or EMLA-cream and fixed but not castrated. For measurement of the impact of castration on the piglets, blood samples were taken pre OP and 1 and 24 hours after castration or fixation with cortisol levels being measured afterwards. Vocalizations of the piglets were recorded and analyzed to detect pain during castration/fixation. The piglets were followed up (wound control/weighing) for three weeks.

Results
In piglets castrated without anaesthesia, a significant rise of cortisol levels from the basal value to the value 1h after castration could be registered (p<0.05). Piglets which underwent topical anaesthesia had almost equally high cortisol levels (p>0.05). In contrast, piglets which received local anaesthesia before castration and uncastrated piglets had almost no increase of plasma cortisol levels. Animals of the castration groups showed distinct changes of vocalisation during the possibly painful surgery stages, which could not be found before or after castration. Although sound analysis indicated pain reduction during surgery by use of chloroethyl spray, it also showed that application of chloroethyl spray itself is painful. Regarding EMLA-cream, sound analysis was suggestive of some anaesthetic effects on the skin, but not on the spermatic cord. On the contrary, in piglets, which were castrated under local anaesthesia, almost no changes of vocalization were detected. Wound healing showed no difference between the control group and the treatment groups (p>0.05) except for piglets, which had received an injection of a local anaesthetic prior to castration, which had significantly (p<0.05) increased wound healing disorders.

Discussion
On the basis of increase of plasma cortisol levels, no stress reduction by the use of chloroethyl spray and just a small but not significant improvement by using a combination of chloroethyl and lidocaine spray or EMLA-cream were discovered. Although analysis of the piglets’ vocalisations indicated some pain reduction during the skin incision and the emasculation by use of chloroethyl spray, it also showed that application of chloroethyl spray itself is painful. Regarding the usage of EMLA-cream, sound analysis was suggestive of some anaesthetic effects on the skin but not on the spermatic cord.

Altogether the results of this study show that none of the topical anaesthetic techniques is as effective for pain reduction as an intratesticularly applied local anaesthetic. Since local anaesthesia prior to castration produced increased wound healing disorders, further research is required to find a practical and efficient alternative to conventional castration of piglets.

Possibilities of pain reduction in tail docking in piglets
Tim Kilchling; Daniela Schiele; Susanne Zöls; Andreas Palzer; Matthias Eddicks; Karl Heinritzi
Clinic for Swine, LMU Munich, Oberschleißheim, Germany

Introduction
Tail docking is performed as a precautionary move to prevent tail biting in pigs (1). According to the German Animal Rights Law, tail docking is only allowed without anaesthesia and pain medication until the fourth day of life. However, this procedure appears to be painful for piglets.

The aim of this present study was to identify the pain caused by tail docking and the possibility of reducing this neuroendocrine stress reaction by administering a nonsteroidal anti-inflammatory drug (NSAID) before tail docking. A further study evaluated the pain caused by tail docking based on cortisol values (2).

The evaluation of cortisol permits the measurement of the neuroendocrine stress reaction in animals (3).

Materials and Methods
A total of 219 one-day old clinically healthy piglets were randomly assigned to seven different groups. A general overview of the seven different groups, number of piglets per group, the tail docking method and the drug administered is depicted in Table 1. Piglets from Group 1 served as controls and were manually restrained in the same position used for tail docking without having their tails removed.

</table>

The tail docking was always performed on the third day of life. On that day, approximately 2-3 ml of blood was collected from each piglet via the vena cava cranialis thirty minutes before tail docking. The cortisol concentration, determined from the serum samples taken 30 minutes before tail docking served as the base value. Following blood collection, piglets from Groups 3, 4, 6 and 7 were administered their respective NSAIDs. After drug administration, the tails from piglets of all groups, with the exception of Group 1, were removed using the corresponding instrument. Thereafter, blood was collected from all piglets 30 minutes, 60 minutes, four and 24 hours for cortisol measurement.

Results and Discussion
The average values of the serum cortisol concentration of all groups is shown in Figure 1.

No difference could be found in the basal value (p>0.05) of each group. The cortisol concentration of Group 2 and Group 5 was significantly (p<0.05) increased 30 and 60 minutes after tail docking when compared to the control Group 1. The cortisol concentration, measured 30 minutes after tail docking, was significantly (p<0.05) lower in all groups that received NSAID prior to tail docking when compared to Groups 2 and 5. 60 minutes after tail docking, the cortisol concentration of Group 3, which received Meloxicam, was significantly lower than that of Group 2. Additionally, the cortisol concentration of Group 6 was also significantly lower when compared to Group 5. After Flunixin administration, the cortisol concentration of Group 7 was significantly reduced in comparison to Group 5.

Significant differences between the both tail docking methods were not observed at any of the examined times. The serum cortisol concentration of Group 5 tends to be higher than that of Group 2.

Conclusion
The results of the study infer that the cortisol concentration caused by the neuroendocrine stress reaction is not influenced by handling or blood-sampling, but significantly raised due to pain and distress like tail docking without any treatment. It can be reduced by the prior administration of an analgesic such as Meloxicam or Flunixin.

A non-penetrating captive bolt (modified Zephyr) is effective for euthanasia of neonatal piglets

Teresa M. Casey-Trott1 Suzanne T. Millman2 Penny Lawlis3 Tina M. Widowski1
1. University of Guelph, Guelph, ON, Canada; 2. Iowa State University, Ames, IA, USA; 3. Ontario Ministry of Agriculture, Food and Rural Affairs, Guelph, ON, Canada

Introduction
On-farm euthanasia of low viability piglets is an inevitable task for producers, and it is essential that a humane and cost-effective method be established. Any euthanasia method must ensure minimal pain, fear and distress as well as include considerations for the overall aesthetic acceptance of the procedure (AVMA, 2007). Currently acceptable methods for piglets up to 12 lbs include carbon dioxide, anesthetic overdose, non-penetrating captive bolt, and the most common method, blunt force trauma (NPB-04259-01/09; AVMA, 2007). To be considered effective without a secondary step, the non-penetrating captive bolt must cause sufficient depression of the central nervous system and destruction of brain tissue to cause both immediate insensibility and rapid death (AVMA, 2007). Recent work comparing a non-penetrating captive bolt (Zephyr, round head, 120 PSI) to blunt force trauma found that both methods rendered piglets immediately insensible, but some piglets showed signs of returning to consciousness when the Zephyr was used (Widowski et al, 2008). Variation in depth of depression resulting from different guns used in that study may have contributed to this finding. For the current study, the design of the nylon bolt head attachment for the Zephyr gun was modified to a convex shape to increase the depth of depression when used at 120 PSI without causing penetration.

Methods
All procedures were approved by the Animal Care Committee at the University of Guelph. Ten experienced stock people were trained to use the Zephyr, and each stock person euthanized 10 low-viability or compromised piglets < 72h of age. Each stock person manually restrained the piglet on its sternum on a hard, flat surface. Two shots were administered rapid fire on the frontal bone (NPB-04259-01/09), followed immediately by one shot delivered to the back of the skull behind one ear. Piglets were assessed for signs of consciousness using brainstem and spinal reflexes: presence or absence of corneal reflex, pupillary light response, jaw tone, and response to nose prick. Reflexes were repeatedly checked in that order every 15 seconds for at least 4 minutes. Clonic and tonic neuromuscular spasms (convulsions) were monitored along with the presence of breathing and heartbeat. Termination of tonic convulsions was used to estimate time of death (ETOD). Macroscopic scoring was used to assess skull fracture and hemorrhage at necropsy. Skull fractures (SK) were recorded on a 5 point scale; 1 (no fracture) - 5 (fully fragmented). Subcutaneous (SC), Subdural Dorsal (SD-D) and Subdural Ventral (SD-V) scores used a 6 point scale; 1 (no hemorrhage) - 6 (complete coverage). A brief questionnaire was provided to each stock person to assess individual experience and rate the method on a 10 point scale; 1 (completely ineffective) - 10 (highly effective).

Results
Data from 98 piglets showed that 100% were insensible immediately, and no piglets showed signs of regaining consciousness. ETOD averaged 225.9 ± 88.6 s (±S.D). Five of the 98 piglets required a secondary step (exsanguination) for cessation of movement and were not included in the ETOD average. Macroscopic scores averaged 3.3 ± 0.5 (SK); 4.5 ± 1.1 (SC); 4.2 ± 0.9 (SD-D); and 4.4 ± 0.8 (SD-V). Stock personnel rated the effectiveness of the Zephyr at 8.7 ± 1.6.

Discussion
The modified Zephyr used in this trial was a highly effective method of euthanasia for neonatal piglets less than 72 hours of age. The Zephyr caused immediate insensibility without return to consciousness in all 98 piglets and led to death without a secondary step in 95% of piglets. Macroscopic scoring indicated that moderate to severe damage was inflicted to the skull and brain tissue of all piglets. The potential of the Zephyr for on-farm euthanasia was supported by a reasonable average ETOD (3m45s) and high stock personnel ratings. With additional modifications for safety and portability, the Zephyr has potential to be an effective and practical method of on-farm euthanasia within the swine industry.

**Reduction of the discomfort at castration of piglets with azaperone**

Bert Driessens 2 Jan Jourquin 1 Sanne Van Beirendonck 2 Rony Geers 3 Lieve Goossens 1

**Introduction**
Castration of piglets is widely practiced throughout the world to avoid boar taint. Castration is performed at very young age and is recognized to be a painful experience for the piglets. To improve welfare, castration has been banned (UK) or is only allowed when the piglets receive an analgesic (EU) or under local (Norway) or complete (The Netherlands) anesthesia. Today, there is also the option of immunocastration.

A distinction is made between the direct pain during the act of castration and the pain after the procedure. Farmers are not allowed to use anesthetics which raises the need for an alternative to reduce the discomfort at castration.

The aim of this study was to investigate if the use of azaperone (Stresnil®), a sedative registered for pigs and allowed to be used by farmers, could be a valid alternative to anesthesia of the piglets.

**Materials and Methods**
In the experimental farm of Lovenjoel, 392 piglets were included in the trial. As a reference group, 258 piglets were sham castrated (REF). The negative control group consisted of 71 piglets castrated without any treatment (NC) and 63 piglets were injected with 2 mg/kg azaperone IM 15 minutes before castration (AZA). Castration was performed during the first week of life. Weight gain was measured at 23 and 63 days post castration. In 21 NC and 16 AZA piglets, vocalization at handling, injection and castration was measured with a decibel meter. The behavior of the piglets was recorded every minute during 10 minutes after castration. Walking, sitting, standing, huddled up position, isolated position, trembling and udder massage were categorized as negative behavior, while suckling, sleeping, lateral and ventral lying was categorized as positive behavior.

The generalized linear model approach was performed in SAS® 9.1 for the statistical analysis.

**Results**
There was no difference in weight gain 23 and 63 days post castration between the three groups. The vocalization results are shown in Table 1. Injection caused a significant increase of screaming intensity compared to only handling, but the screaming intensity was lower compared to screaming at castration. The screaming intensity at castration was significantly reduced in the AZA compared to NC.

**Discussion**
An injection of azaperone 15 minutes before castration diminishes the screaming intensity at castration. The behavior of the piglet immediately after castration resembles that of a sham castrated piglet and is significantly better than conventionally castrated piglets.

Azaperone (Stresnil®) is a registered product for pigs and can be applied by the farmer. With a cost of less than 3 Eurocent per piglet, there is no economical constraint.

In conclusion, the use of azaperone prior to castration could be taken into account as an alternative to anesthesia.
Biopsies for grading of shoulder ulcerations in sows
Henrik E. Jensen; Kirstin Dahl-Pedersen
University of Copenhagen, Frederiksberg, Denmark

Introduction
The presence of shoulder ulcerations in sows commonly develop and signal poor animal welfare (1). Presence of shoulder ulcerations is due to pressure and is significantly related to the laying bout duration (2, 3). Clinically, it may be difficult to state the presence of an ulceration. Moreover, it is not always straightforward to deduce the progression of shoulder ulcerations (4). With reference to national strategies initiated towards limiting the presence of shoulder ulcerations, an intervention must be initiated when the ulceration has penetrated into the subcutaneous tissue. Therefore, different para-clinical techniques should be evaluated for the characterization of ulcerations. Such techniques should enable one to state the presence or absence of an ulceration and preferably aid for grading the ulceration.

Based on pathology, shoulder ulcerations are graded 1-4 according to the progression into the different anatomical structures of the shoulder region with the following characteristics (1,3):
Stage 1) the ulceration is limited to the epidermis (necrotic or sloughed off), and may be covered with a scab. Stage 2) the dermis is ulcerated and may be covered with a scab. Usually a small amount of granulation tissue or fibrosis is bordering the ulcer. Stage 3) the subcutaneous tissue is ulcerating and may be covered with a scab. It is accomplished by heavy formation of granulation tissue or fibrosis towards the surroundings. Stage 4) an ulceration with exposed bone (tuber spina scapula). Stage 4 ulcerations are always accompanied by a heavy proliferation of new osseous tissue. Shoulders free of ulcerations are scored as stage 0 (3).

In the present study, the diagnosis of shoulder ulcerations based on the examination of a single biopsy taken from the skin overlaying tuber spina scapula, i.e. centrally from the ulcer when present, was compared with the classical method implying examination of cross-sectioned shoulder areas during necropsy.

Materials and Methods
Shoulder regions from 33 sows admitted to the department for necropsy were evaluated. Before cross-sectioning and grading the shoulder ulcerations, a punch biopsy (8 mm in diameter, KRUUSE, Denmark) was taken from the skin overlaying tuber spina scapula from animals without ulcerations, and centrally from the ulcer when present. Tissue specimens were fixed in 10% neutral buffered formalin for 7 days, processed through graded concentrations of ethanol and xylene and embedded in paraffin wax. Tissue sections were cut at 4-5 μm and stained with haematoxylin and eosin (HE). The grading of ulceration stages from the biopsies was compared with the grading based on the cross-section method (3).

Results
The cross-section method revealed the following pattern of shoulder ulcerations: stage 0 = 16; stage 1 = 0; stage 2 = 4; stage 3 = 13; and stage 4 = 0. In five cases, the stage of ulceration was based on gross examination because the sections taken for histology were all bordered by granulation tissue, i.e. the involved tissues of the skin could not be judged histologically. Presence (n=17) or absence (n=16) of an ulceration, as assessed by cross-sectioning the shoulders, was in all cases verified in the biopsies. In the biopsies, four cases of both stage 2 and stage 3 ulcerations were confirmed, too. However, in four and five cases of stage 3 ulcerations the biopsies deducted the ulcerations being stage 2 or at least stage 2 ulcerations, respectively.

Discussion
Examination of a single biopsy taken from the skin overlaying tuber spina scapula in all cases enabled one to settle whether an ulceration was present or not. Moreover, in eight sows with ulcerations a correct stage was documented in the biopsies.

In four out of nine stage 3 ulcerations, however, the biopsies showed a stage 2 ulceration, and in five out of nine stage 3 ulcerations the biopsies revealed stage 2 ulceration at least. Due to the limited tissue sampled by a punch biopsy, however, some ulcerations are difficult to grade because the material is mainly made up by granulation tissue.

In conclusion, a single biopsy is sufficient for stating the presence of an ulceration and when a stage 3 ulceration is documented in a single biopsy it is in accordance with the cross-section method. Moreover, a major advantage of punch biopsies is that they can be sampled from living animals.

Clinical assessment of shoulder lesions in Danish sows

Helle Stege1 Jens Strathe2 Anders R. Kristensen1 Jens P. Nielsen1
1. KU-Life, Copenhagen, Denmark; 2. Hyovet, Bigum, Denmark

Introduction

Decubital shoulder lesions in lactating sows may compromise animal welfare. Lesions with adherent crust/scar to the tuber spina scapula (TSS) and lesions penetrating to exposed bone are notifiable in Denmark and are here defined as pathological lesions. The severity of shoulder lesions may be difficult to determine by clinical inspection and palpation ante mortem because the wound can be undermined and be more extensive than the mere penetration of the skin shows. The aim of this study was to identify combinations of simple clinical signs as markers of pathological shoulder lesions for veterinarians in an advisory situation.

Materials and Methods

The study was observational and included 363 Danish culled sows sent to an abattoir during a two week period. Each sow was registered by sow- and herd-number and date of registration. All sows were examined ante mortem, a visual body condition score (1-5) was assigned and the following clinical signs were recorded: Skin-covered shoulder, i.e. “Normal” (no sign of epithelial deficit); Skin alterations (Erythema; redness in the skin overlaying the TSS or peripheral to a crust/swelling and Crust; dried exudate overlying an epithelial deficit); Swelling (soft or firm elevation of the skin); Adherence to the TSS (scar/crust or swelling adherent to the underlying bony foundations by palpation); Scar (intact skin with scar tissue apparent at the site). Diameters of swellings and diameters of crust/scar (the largest width) were measured with callipers, using a hierarchy of swellings rather than crust/scar when both signs were apparent. After slaughter, the following pathological signs were recorded by post mortem examination: No lesions of the skin; lesions limited to the epidermis with or without a moderate crust; lesions involving the dermis with or without extensive crusting and with little fibrosis and/or granulation tissue; lesions penetrating to the subcutis with intense formation of granulation tissue; ulcer penetration to the bone or ulcer development with periosteal bony proliferation. A Bayesian network (1) modelling the causal relations between pathological shoulder lesions and ante mortem clinical signs was constructed. Furthermore, the body condition score (normal-to-fat vs. thin) was included as a risk factor.

Results

According to the post mortem examinations, 83 sows (22.9%) had shoulder lesions. Hereof 76 sows (20.9%) had mild lesions and 7 sows (1.9%) had pathological lesions. Among the 76 sows with milder lesions, 39 sows (51.3%) had no ante mortem findings, 26 (34.2%) had skin alterations, 7 (9.2%) had skin alterations and firm swelling, 2 (2.6%) had skin alterations and adherence and 1 (1.3%) had firm swelling and adherence. Among the 7 sows with pathological lesions, 6 (85.7%) had skin alterations, firm swelling and adherence. The probability of having a pathological lesion (as determined by post mortem examination) was calculated in the Bayesian model for all clinical signs, recorded ante mortem: Skin alteration = 11.7%; firm swelling = 21.8%; skin alteration + firm swelling = 71.1%. The probability of a shoulder lesion being pathological increased from 35.5% to 81.7% when increasing the width of the swelling from 30-35 mm to 60-65 mm. Including Adherence resulted in a very high probability of the shoulder lesion being pathological (96.7%). Finally, when known state of the body condition was added to the evidence of a severe shoulder lesion the probability of having a pathological lesion by post mortem examination increased from 96.5% (normal-to-fat) to 98.4% (thin).

Discussion

Based on calculations in the Bayesian network, the best predictor of pathological shoulder lesions were; Firm swellings with a fair extent (>50 mm in width) and adherence of lesions to the underlying bony foundation. In summary, the condition of the skin (crust/scar) in itself was of little value if not compared with the palpable findings in the tissue underneath, where especially firm larger swellings and adherence to the underlying bony foundation (TSS) were the most useful markers of pathological lesions. All the milder shoulder lesions were considerably smaller in extent than the pathological lesions, suggesting that pathological shoulder lesions may be differentiated from milder shoulder lesions by the size of the swelling involved.

Rubber mats in farrowing pens as prevention of sow shoulder lesions

Lisbeth B. Petersen; Mai Britt F. Nielsen
Pig Research Centre, Danish Agricultural and Food Council, Copenhagen, Denmark

Introduction

Shoulder lesions in sows are a common disorder in most countries with intensive pig production. It has been shown that rubber mats have a positive therapeutic effect compared with fully slatted floors in farrowing pens (1) (2). It has therefore been assumed that mats also are a way of preventing shoulder lesions from developing. The objective of this trial was to determine if rubber mats under the sow in farrowing pens were better than solid concrete floor in terms of prevention of shoulder lesions.

Material and methods

The trial was carried out in two herds with crossbred sows (LY): herd A with 1700 sows and herd B with 800 sows. The farrowing pens had crates, liquid feed and partly slatted floor. The floor in the main part of the pen was made of solid concrete. The back of the pen had slatted floor (cast iron). The sows were placed in the pens app. one week prior to farrowing and remained there until weaning of the piglets 4-5 weeks after farrowing. Three groups were compared: Group 1: solid concrete floor (control). Group 2: rubber mat, solid, thickness: 17 mm. Group 3: rubber mat with a core of foam, thickness: 45 mm (centre), 17 mm (edges).

Mats in groups 2 and 3 were placed on the solid floor under the sow during her entire stay in the farrowing pen. The effects of the flooring systems were compared with respect to shoulder lesions at weaning, body condition score (BCS) and scar tissue on the sow’s shoulder when entering the farrowing compartment.

Results

A total of 888 sows were included in the trial. The over-all prevalence of shoulder lesions was 16.3 percent in herd A and 15.2 percent in herd B. Sows with poor BCS had a higher prevalence of shoulder lesions compared with sows in good body condition (p=0.07 in herd A and p=0.02 in herd B). Sows with scar tissue had a higher prevalence of shoulder lesions than sows without scar tissue (p<0.0001 in herd A and p=0.002 in herd B). Overall, 681 sows were regarded as ‘sows not at risk’, i.e. good BCS and no scar tissue. On average, only 10% of these sows developed shoulder lesions. The combination of low BCS and scar tissue (207 sows) resulted in a prevalence of 35%. The effect of soft floor on the prevalence of shoulder lesions was significant in herd B, but not in A. However, the effect in herd B was primarily related to sows at risk (table 2).

Discussion

Rubber mats in farrowing pens was effective in one of two trial herds in respect to prevention of shoulder lesions. Only a minority of sows that are not at risk of developing a shoulder lesion, do in fact develop a lesion. In contrast, app. one third of sows at risk develop a lesion. Therefore, rubber mats are primarily relevant for sows at risk.

Pathological and haematological findings in tail biters, bitten finishing pigs and their controls

Camilla Munsterhjelm2, 3 Päivi Palander3 Hanna-Kaisa Sihvo3 Anna Valros3 Linda Keeling2 Mari Heinonen1
1. University of Helsinki, Faculty of Veterinary Medicine, Saarentaus, Finland; 2. Swedish University of Agricultural Sciences, Uppsala, Sweden; 3. University of Helsinki, Faculty of Veterinary Medicine, Helsinki, Finland

Introduction
Tail biting continues to be a well-known and important problem in pig production. It is associated with considerable economic losses to the whole industry and decreased animal welfare. It has been found to be associated with carcass condemnations due to abscesses. Tail biting leads to the spread of infection and activation of the acute phase response (1). This study was carried out in order to describe pathological and haematological findings in tail biters, victims and control pigs.

Materials and Methods
Tail biting and control pens were identified with direct observation in a finishing herd with an ongoing problem with tail biting. Quartets of age and gender matched individuals were chosen: tail biter (TB, n=16), victim (V, n=16), a control pig in the pen with tail biting (Ctb, N=9) or control pig in pen without tail biting (C, n=14). Pigs were injected intramuscularly with midazolam, ketamine and butorphanol, after which a blood sample was collected from the vena cava cranialis while the animal was in dorsal recumbency. Immediately afterwards pigs were euthanized with an intracardial injection of pentobarbital and taken to autopsy, which was performed the next day. The pathological findings were analysed pair-wise using McNemar’s test for binomial and Wilcoxon rank sum test for continuous variables. Haematological values were analysed using a mixed model.

Results
The general trend seemed to be that pigs in all groups, except the controls in pens with no tail biting, had several pathological findings. The haematological values did not differ between groups (Table 1).

TB tended to be heavier than Ctb (43.7±3.6 vs 42.4±4.9 kg, p=0.09). More V tended to have changes in the stomach wall (ulcers or mild lesions) than TB (38 vs 6% of the animals, p=0.06). A score classifying the severity of joint lesions (cartilage and joint capsule) tended to be greater in both TB (0.5±0.3) and V (0.3±0.2) pigs compared to C (0.0±0.0; p=0.1) pigs. The Ctb (0.4±0.3) pigs had a high level of joint lesions even if this difference was not significant. Infections in respiratory organs were more frequent in V than Ctb (63 vs 13% of individuals, p=0.03). Although scores of acute tail lesions (0=healthy to 3=severe) were significantly worse in V (median (range) 3(1-3)) than TB (1(1-3), p=0.01) these scores were not significantly lower in Ctb than V despite the fact that Ctb received significantly fewer bites to the tail during the behavioural observations than V (bites received Ctb=0(0-1) vs V=11(1-31), p<0.01).

Discussion
The pathological findings were more frequent than anticipated, even considering that this farm had ongoing problem with tail biting. The pigs in tail biting pens seemed to suffer not only from tail biting but also from other health problems (stomach ulcers, joint lesions). However, cause and effect were not separated in this study.

Haematology did not reveal problems in the organs. The variation in haematological values was large and the lack of a difference here may reflect the relatively small sample size in the study. In contrast to our findings, differences in blood values have been found (2), mostly in clinical chemistry. However, the same parameters were not investigated in our study.

**Effect of zinc organic supplementation on feet lameness of sows**

Annop Suriyasomboon1 Nualprae Seanbungkhor2 Sutep Luengyotuechakul3 Supunnee Jiarakhun3

1. Chulalongkorn University, Bangkok, Thailand; 2. Laemthong Hybrid Co., Ltd., Bangkok, Thailand; 3. Zincpro Co., LTD., Bangkok, Thailand

**Introduction**

Feet and leg problems of sows were the major economic losses in pig industry. Many lameness sows usually were not seen in herds and underestimated. These lameness sows were affecting on the herd productivity [1, 2, 3]. There were several factors contribute to lameness such as bacterial infections, genetics, management, and nutrition [1, 2, 3, 4]. Nutritional factors may contribute to lameness. The aim of this study was to investigate the effect of zinc supplementation on feet lesions of sows.

**Materials and Methods**

Sixty crossbred (LR x LW) sows were divided into two groups, 20 sows in control group (C) and 40 sows in treatment group (T). Sows in C and T group were accordingly classified to parity number and location. Group C was gilt (P0) and sow in parity 1, and located in unit B. Group T was sow in parity 2 or more, and located in unit E. All sows were directly examined for the feet performances during the lactating or gestating periods. The feet lesions were classified into three groups: heel over-growth and erosion (HOE), heel-sole crack (HSC), and white line (WL). The level of lesion scores were classified into three levels: no lesion (0), mild (1), moderate (2), and severe (3). Sows had feet lesions were identified and randomly selected for testing the feed additive supplement, Avila-Zn 120. The selected sows were taken pictures of the feet lesions and examined the lesion scores before giving feed additive. Sows in group C were received conventional diets, and sows in group T were received daily of 40 ppm of Avila-Zn 120 by mixing in the conventional diets for 90 days. Feet performances and feet lesion scores were monitored at 1, 2, and 3 months after Avila-Zn 120 supplementation. The repeated sows and/or culled sows will be examined and taken pictures for checking the feet lesion improvement. Chi-square analysis (PROC FREQ) was used to analyze the frequency distribution of feet lesion scores.

**Results and Discussion**

This study was investigated the effect of zinc supplementation on feet lesions of sows. At least one feet lesion was found in sows in both groups. Some sows had more than one feet lesions. In general, gilts and sows in parity 1 had lower feet lesions than sows in parity 2 or more. There was a trend (P=0.09) for higher proportion number of sows with more feet lesions in the C group (i.e. HOE). Moreover, there were lower proportion of sows with HSC in the T group (P<0.001). This improvement might be explained by the higher bioavailability of zinc in the feed. This is in agreement with a study performed in Danish sows herd [5]. In conclusion, the supplement of zinc organic might be an alternative choice to improve the feet quality of sows.

Use of a subjective scoring system to describe leg and claw conformation and gait in gilts and sows

Elisabeth O. Nielsen; Flemming Thorup; Hansen U. Lisbeth
Pig Research Centre, Danish Agricultural & Food Council, Copenhagen, Denmark

Introduction
Lameness and claw lesions are frequent causes of discomfort or pain in gilts and sows (1-3). Lameness in sows reduces productivity levels and the longevity. Describing leg conformation and gait is necessary when selecting gilts to achieve strong breeding animals. Furthermore, descriptions of gait and leg lesions are important to identify individuals in pain or discomfort, indicating a need for treatment and movement to a hospital pen. Despite the inclusion of leg soundness in the Danish breeding index, the producers need an individual evaluation of each gilt to know which gilt to breed and which one to cull. The farmer must also evaluate the leg soundness of the sows before the next breeding cycle.

The purpose of this study was to design a subjective scoring system to describe leg and claw conformation and gait in gilts and sows

Materials and Methods
The subjective scoring system was based on previous descriptions (4-6) of leg conformation and gait. The scoring system is used in ongoing studies. A training day for standardization is planned every six months throughout the studies. This paper presents scoring results for gilts and sows. A total of 255 gilts aged 9 months and 219 loose-housed gestating sows of different parities were scored. One technician scored gilts in one herd, and another technician scored gestating sows in another herd. Both herds had problems with lameness. All scorings was performed inside the pen. Scoring of one animal was completed in two to four minutes. The animal was evaluated both standing and moving slowly. Animals were not scored moving at high speed, because mild cases of lameness would not be easily seen. The pen floor was non-slip slats or solid floor. The animals’ feet were not cleaned before scoring the claws.

Results
The subjective scoring system includes 12 categories (Table 1). The categories describe different features in claw and leg conformation. Length of claws and dewclaws are described as normal, long and very long. The movement categories (swaggering gait, stride length and lameness) describe increasing abnormality. Lameness ranged from normal= 0 to "not able to rise"= 3. The scoring results of 255 gilts and 219 sows are presented in Table 1. A total of 18% of the gilts were lame to some degree, and 15% of the sows were lame to some degree. If the animal was lame, it was noted which limb(s) was affected, and acute lesions of the limbs were also noted (data not shown).

Discussion
A subjective scoring system was chosen, because it is easy to use and no instruments are needed. Although subjective scoring has inherent problems with repeatability (5,6), these problems can be overcome through repeated training of the observers. The scoring system must be simple, with clear definitions and good illustrations. Video sequences of the animals’ gait are useful. We plan to correlate the leg, claw and gait scores with the longevity of the gilts and sows. The scoring will then be refined and simplified for practical use in herds.

Three-year study of lameness in piglets and piglets mortality at a herd following repairation of floors

Mate Zoric1 Sigbrit Mattsson1 Cecilia Kellerman2 Petter Kjellerby2 Per Wallgren1
1. National Veterinary Institute, Uppsala, Sweden; 2. Vissgärde Farming, Uppsala, Sweden

Introduction
Many piglets die or are medically treated before they are weaned. The main causes of mortality are emaciation or crushing by the sow when lying down (1). Lameness in suckling piglets is another welfare issue in farrowing enterprises contributing to ill-thrift, piglet mortality, decreased growth and increased antimicrobial use (2). Environment can improve piglet survival (1), and the present study compared the prevalence of lameness and mortality in piglets during three years in farrowing units with different floor surfaces.

Materials & Methods
The study was carried out at a herd with four identical farrowing units with solid concrete floor, embedded with 1kg chopped straw per sow and 1 hg per piglet and day. Two units were dedicated as controls (●; ▲). In the third and fourth farrowing units, the floor surfaces were repaired with two-component materials; ◆ = Thorocrete SL® (Växa Halland, Sweden), a powder with cement, graded sand and additives and an acryl polymer emulsion, and; ● = Piglet Floor® (Flowcrete Sweden AB, Sweden), an epoxy free two-component solvent solution with natural quartz.

All of the 17,474 piglets born alive during three years were studied (● = 338 litters & 4425 piglets; ▲ = 341 & 4333; ◆ = 343 & 4525; ■ = 323 & 4191). Twenty-three farrowing batches were studied in each unit. Records of mortality and medical treatments for lameness were kept for each piglet until the age of 4 weeks.

Results
The mortality was defined as crushing and other causes of death. Up to 85% of the piglet losses occurred during the first week of life and the majority of the deaths were attributed to crushing. There were large differences in the prevalence of piglets found dead on the different types of floor (Fig. 1). Piglet born on the repaired floors had the lowest prevalence of mortality during the three-year study (◆ p<0.05; ● p<0.01).

The mortality during the first three days of life was high, but not correlated to lameness. In total, 971 piglets were treated for lameness, corresponding to 5.5% of the live born piglets. Approximately 85% of these diagnoses were made during the first three weeks of life. As seen in Fig. 2, the prevalence of lameness was lower in the units with repaired floor (◆ p<0.05; ● p<0.01) than in the control units (● and ▲).

Discussion & Conclusions
The mortality was highest during the first week, and to be crushed under the sow when lying down was the most common source of death. Also the frequency of skin lesions was highest during the first week. Lameness is associated to many factors out of which the floor is one (3). Maintaining the surface of concrete floors with these two commercially available solutions decreased the mortality and the incidence of lameness in piglets. Thus, a proper maintenance of the floor will improve roughness and abrasiveness of the floor which in turn can contribute significantly to prevention of lameness and mortality in suckling piglets. The floor can also affect lying down behaviour of the sow (4), and this study revealed that the piglets mortality was lower in the pens with repaired floors. The results suggest that reparations of the floor and sustainability in three years will pay off for both piglets and pig farmers.

Introduction
Claw lesions are reported to be an important underlying cause for lameness in pigs in breeding herds. However, not all claw lesions cause lameness in pigs. The area affected and the severity of lesion may determine the progression towards lameness. Previous studies have indicated the positive relationship of side wall and white line lesions with lameness in pigs1,2. Housing and nutritional factors are associated with the development of claw lesions in pigs. Trace minerals such as Cu, Zn and Mn are important in the keratinization process3. The bioavailability of trace minerals depends on the quantity and the form (organic or inorganic) of these minerals. Despite the high prevalence of claw lesions in pigs, attempts to minimize the incidence of claw lesions or to reduce the severity of lesions are not implemented widely in swine herds. The objective of the present study was to understand the effect of feeding complexed trace minerals (CTM; Cu, Zn and Mn) in decreasing the severity of claw lesions in breeding female pigs housed in group pens with ESF in comparison to those fed with trace minerals in inorganic form (ITM).

Material and Methods
This study included 104 sows of mixed parities (ITM diet, n=59 and CTM diet, n=45). Trace minerals supplemented in the ITM diet were Zn, 125 ppm, Mn, 40 ppm and Cu, 15 ppm, while CTM was a partial substitution of the inorganic minerals with complexed minerals (Zn, 50 ppm, Mn, 20 ppm and Cu, 10 ppm) with isovels of total trace mineral supplementation. The sows were fed the respective diets for a period of 3 parities. The first claw observation was performed at mid-gestation in the first parity. The claws of these sows were re-examined by the same person at mid-gestation in the subsequent third parity during the study period. Claw examination was facilitated by a mechanical restraint designed for the purpose. Different claw areas (side wall, heel, white line, sole, heel-sole junction and overgrown toes and dew claws) were examined for lesions on a severity scale of 0 (no lesions noted) to 3 (severe) following the Zinpro FeetFirst claw lesion scoring system. The total score for each area was obtained by adding the scores for that area in different claws of front and hind limbs. The proportions of sows showing either no change in lesion scores or a reduction in lesion scores in different claw areas in the CTM and ITM groups were compared using 2-sample proportion test (SAS v 9.1).

Results
The results indicated a higher proportion (P<0.05) of sows fed CTM (91%) had either a reduction or similar lesion score for vertical side wall cracks in the second claw examination compared to sows fed ITM (73%). The proportions of sows with similar or lower scores for total medial claw lesions, heel lesions and total side wall lesions were also higher in the sows fed CTM, though not statistically significant.

Discussion
The present results are similar to a previous trial which indicated a negative relationship between complexed trace mineral supplementation and number of lesions in different claw areas4. However, this study had not considered the severity of lesions. The previous study showed that sows receiving inorganic trace minerals had more lesions on the hind limbs than the sows receiving complexed trace minerals4. The same study also showed that sows consuming inorganic trace minerals had more lesions on the sole than sows fed with complexed trace minerals. The results of this study indicated a beneficial effect of feeding complexed trace minerals in reducing the severity or preventing the worsening of vertical side wall cracks in breeding female pigs.

Introduction
The beneficial role of trace minerals in improving the performance of breeding females has previously been described1,2,3. The bioavailability of trace minerals depends on both the quantity and form (organic or inorganic). Though the mechanism is not well understood, it has been reported that organic minerals are more soluble and may cross the intestinal wall more easily4. The objective of the present study was to compare the production performance of stall-housed sows receiving a supplementation of complexed trace minerals (CTM) with those receiving trace minerals in inorganic form (ITM).

Material and Methods
This study conducted at the Southern Research and Outreach Center of the University of Minnesota at Waseca involved 229 sows (ITM n= 113, CTM n= 116) housed in conventional gestation stalls. The sows were allocated randomly to two groups and fed either ITM (inorganic sulphate minerals, Zn, 125 ppm, Mn, 40 ppm and Cu, 15 ppm) or CTM (containing complexed trace minerals as a partial substitution of inorganic minerals: Zn, 50 ppm, Mn, 20 ppm and Cu, 10 ppm fed at isolevels of total trace mineral supplementation) diet. The analysis involved 399 parity records (ITM n=199, CTM n= 200) of these sows pertaining to 1 or 2 farrowings during the study period. Information on farrowing and weaning performances and lactation feed intake were collected from the PigCHAMP database of the research unit and sow cards and compared using 2 sample t-test (SAS V. 9.1).

Results
Sows fed CTM had more piglets born alive (P<0.05) compared to sows fed ITM (11.07 and 10.44 piglets per litter, respectively). However, the number of stillborn piglets per litter was higher in the sows fed CTM (1.0 + 0.12 vs. 0.70 + 0.09). Litter birth weight tended (P<0.07) to be higher in the sows fed CTM (37.45 + 0.68 vs. 35.64+ 0.72 lbs). Other parameters such as average mummies per litter, wean litter weight, weight of the sow at weaning and average lactation feed intake were similar, regardless of trace mineral form.

Discussion
A previous study involving supplementation with complexed trace minerals indicated higher litter birth weights in supplemented sows3 though the number of live born piglets was not different (P=0.2) in control (12.89) and treatment (13.37) groups. A higher number of stillborn piglets per litter in the sows fed CTM observed in the present study could be related to the higher number live born piglets per litter. Similarly, the higher litter birth weight in the sows fed CTM could also be related to higher number of live born piglets.

Conclusion
This study indicated a beneficial effect of feeding complexed trace minerals in terms of higher number of piglets born alive per litter.

Effect of the supplementation of complexed trace minerals on the healing of claw lesions in two sow herds

A. Da Silva; S.S. Anil; J. Deen; R.B. Morrison
University of Minnesota, Saint Paul, MN, USA

Introduction
Claw lesions are very common in sows. Claw lesions are reported to be associated with lameness (1), an important reason for premature removal of sows in swine breeding herds. Nutrition may play an important role in the development of claw lesions, since the quality of the claw depends on its physical structure and this is controlled by cellular processes affected by nutritional status (2). The importance of trace minerals in the keratinization process has been reported previously (3). Both the quantity and the form (organic or inorganic) of these minerals are crucial (4). However, the effect of these trace minerals in ameliorating claw lesions in pigs has not been well demonstrated. The objective of this study was to understand the effect of feeding complexed trace minerals (Cu, Zn and Mn) in reducing the severity of claw lesions in breeding female pigs.

Materials and Methods
Data for this study were collected from a convenience sample of 43 stall-housed sows (parities 1 to 6) belonging to two sow herds (Herd A, n=28 and Herd B, n=15) which had high prevalence of claw lesions. These sows were scored for lesions in different claw areas (side wall, heel, including overgrown heels, white line, heel-sole junction and overgrown toes and dew claws) twice. The first observation was done in May 2009 while the sows were in the farrowing crates, prior to the start of feeding complexed trace minerals (Zn, 50 ppm, Mn, 20 ppm and Cu at 10 ppm). The second one was done when these sows were in farrowing crates in their subsequent parity (approximately after 140 days). The claws were examined while the sows were in a recumbent position as there was no mechanical restraint to facilitate lesion scoring. The proportions of sows showing either no change in lesion scores or a reduction in lesion scores in different claw areas were analyzed using one sample proportion test (SAS v 9.1).

Results
In herd A, the proportions of sows with either similar or reduced severity of lesion scores in all claw areas were higher (Table 1) at the second claw examination (P< 0.05 for all). However, in herd B, similar results were shown only in the case of overgrown toes, heel-sole junction lesions and vertical and horizontal side wall cracks (P< 0.05).

Discussion
The present results are similar to a previous trial which indicated that sows receiving inorganic trace minerals had more lesions on the hind limbs than the sows receiving complexed trace minerals (5). However, that study did not assess the effect on severity of lesions. The same study also showed that sows consuming inorganic trace minerals had more lesions on the sole than sows fed with complexed trace minerals. The non-significant effects in herd B could be related to the small sample size. All the sows with baseline data could not be evaluated a second time in both farms as there was no mechanical device to facilitate lesion scoring in live animals. The results of this study are indicative of a preventive effect of feeding complexed trace minerals on claw lesions in breeding female pigs.

Melatonin release patterns in pigs kept under different light regimens

Arie van Nes1 Maaike Pannekoek2, 1 Inge van Geijlswijk2
1. Department of Farm Animal Health, Utrecht, Netherlands; 2. Veterinary Pharmacy Division, Utrecht, Netherlands

Introduction

Melatonin is a hormone controlling the biorhythm of mammals, birds and fish and might be an indicator for harmony between individuals and their environment. The major ‘zeitgeber’ for the release of melatonin is environmental light. It synchronizes the melatonin secretion with the 24-hour day/night cycle. Normally, melatonin levels are high in the night and low during the day.

Melatonin is not only synthesized in the pineal gland, it’s also synthesized in the gastrointestinal tract, retina, skin, lymphocytes, platelets and bone marrow. Despite this, the level of circulating melatonin is almost totally derived from the pineal gland. Melatonin is not stored in the pineal gland and the liver metabolizes the circulating melatonin rapidly. So levels of melatonin and its metabolite 6-sulfatoxymelatonin in blood plasma and saliva are representative for pineal biosynthetic activity (1).

In Dutch pig husbandry, it is obligatory to have minimally eight hours light per day. Some pig owners have these lighthours divided in several periods per day (multiphase lightregime).

The goal of this study is: Do pigs in multiple phase light regimes have other melatonin release patterns compared to single phase lightregimes? Therefore, we measured the melatonin release pattern in pigs kept under a single phase light regime to the melatonin release pattern in pigs kept under a multiple phase light regime.

Material and methods

The pigs kept under a single phase light regime had twelve hours of natural light per day. The other group is kept under a multiple phased light regimen, three periods of three hours of light spread over 24 hours.

Each group of pigs were sampled during a 24 hour period, by a saliva sample taken every hour. Saliva samples are taken because levels of melatonin or its metabolite 6-sulfatoxymelatonin in saliva (or blood plasma) are reflective of pineal biosynthetic activity, since there is no storage of melatonin in the pineal gland and circulating melatonin is rapidly metabolised in the liver.

Before the 24 hour sampling period, the pigs were trained for 3 days by test sampling and animal handling, to prevent stress in the pigs during the experiment.

In the experiment we used animals of about five months old. The animals were kept from the age of about two months under the multiple phase light regime. The pigs kept under the single phase light regimen, were at the time of sampling housed from birth under this light regimen.

Piglets at an age of ten weeks already show a normal regular melatonin release pattern (1).

The samples were collected by having the pigs chew on salivettes® for 30 seconds. A salivette® is a roll-shaped saliva collector made by Sarstedt by Etten Leur. The samples were stored at a temperature of 4°C and centrifuged within 24 hours and then stored at a temperature of -18°C. The samples were analyzed by Radio Immuno Assay (RIA) at hospital “Gelderse vallei” in Ede.

Results

There was no difference in the mean melatonin concentrations of the two different light regimens. The mean melatonin concentration in the single phase group was 12.34 ± 3.51 pg/ml, the mean melatonin concentration in the multiple phase group was 12.95 ± 2.48 pg/ml. Mean concentration of melatonin during the light hours in the single phase group was 13.75 ± 11.08 ng/ml, versus 15.01 ± 9.95 ng/ml in the multiple phase group. During the dark phases the mean melatonin level was 11.15 ± 6.08 ng/ml versus 11.07 ± 5.36 ng/ml. All concentrations were not significantly different.

There was no difference in melatonin concentrations during the light hours compared to the dark hours in both groups.

Discussion

Unfortunately, there was no nocturnal rise of melatonin like we expected to find in the control group, based on found literature (1,2). The curves were not flat but all pigs had a different moment of rise in melatonin concentration. Most peaks were found during daytime, when lights were on, which makes the melatonin concentration significant higher during daytime than during the night. These results are in contrast to melatonin curves found in other studies in pigs (1,2) and found in other animals (3,4) and in humans (5). But other studies found melatonin curves in pigs like we found in our experiment.

The influence of close confinement of pregnant sows on cortisol and acute phase protein concentrations

Roman Kolacz; Michal Kulok; Zbigniew Dobrzanski
Wroclaw University of Environmental and Life Sciences, Department of Environmental Hygiene and Animal Welfare, Wroclaw, Poland

Introduction
Confinement of pregnant sows to individual gestation stalls can be a major factor inducing stress responses, consequently affecting animal health and causing disorders in reproduction (1). The results of extensive studies carried out on acute phase protein (APP) show a lot of discrepancies. Changes in APP concentrations have been reported as a response to close confinement or hierarchizing within a group (3, 4), commonly known to be stressful for animals (5, 6), or a reaction to transport stress (2, 5).
The purpose of the present investigation was to study the impact of immobilization of sows during gestation on their condition, measured by cortisol concentrations and APP profile of the animals’ blood.

Materials and Methods
The experiment was carried out on two farms with varied housing systems with respect to animal mobility.
Experimental group (EG). The sows in this group were kept in unbedded individual stalls, with a pen floor area of 1.3 m², from d 1 to d 100 of gestation. On d 100, the sows were moved to a farrowing stall and kept there for the next 28 days. Getting up and lying down were the only movements possible for the animals.
Control group (CG). The sows in this group were also kept in unbedded pens, from d 1 to d 100 of gestation, but in groups of 10, with a pen floor area of 2.25 m² per animal. On d 100 the sows were also moved to a farrowing stall, where they had comparatively reasonable space for exercising. Blood samples were collected 4 times in each group: 1) on d 30 of gestation, 2) on d 98 (36 h before moving the animals to the farrowing stalls and 3) on d 100 after mating (12 h after moving the animals to the farrowing stalls).
The laboratory measurements included:
a) cortisol in the serum determined using ELISA kits (Diagnostic Systems Laboratories, Inc. USA),
b) acute phase protein profile; haptoglobin, amyloid A and C-reactive protein, determined using ELISA kits (Tridelta Ltd. Ireland).
Both the cortisol concentrations and APP profile were determined using a Bio Tek, Power Wave analyzer.

Results and Discussion
The results obtained in the study showed that keeping the sows in individual pens resulted in stress responses manifested by increased cortisol concentrations only in the first month of gestation. In the next months, the cortisol concentrations were higher in the sows kept in groups, which was likely due to more frequent hierarchy conflicts (Table 1).

The values in the same column designated with the same capital letters show significant differences at P ≤ 0.01. The values designated with small letters show significant differences at P ≤ 0.05. The values in the same rows, designated with the same numbers, show significant differences at P ≤ 0.01, or * P ≤ 0.05. Besides, the results showed that moving the sows from pig barns to the farrowing stalls (d 100 of gestation) induced a rapid elevation of cortisol concentrations (Table 1). For the entire gestation period, haptoglobin concentrations in the two groups ranged from 1.1 to 1.6mg/ml; c-reactive protein ranged from 35 to 37mg/ml; while serum amyloid A (SAA) was found within the ranges from 21 to 25mg/ml. No significant differences in APP concentrations between the two groups and in consecutive months of gestation were observed.

Oral interferon-alpha treatment and environmental adaptation of swine

Elisabetta Razzuoli; Silvia Dotti; Riccardo Villa; Enrico Sossi; Paolo Candotti; Massimo Amadori
Istituto Zooprofilattico Sperimentale Lombardia Emilia Romagna, Brescia, Italy

Introduction
Weaning is a critical phase for piglets, in which infectious and non-infectious stressors exert their negative effects. Farmers are prone, for different causes, to weaning 3-weeks old piglets, even though the above age does not seem appropriate with regard to inadequate immune system development and intestinal mucosal functions (1, 2). The aim of this study was to investigate the effects of an oral IFN-α treatment on the environmental adaptation response in pigs weaned at 22 days of age.

Materials and Methods
The study was carried out on 40, Landrace x Large White, randomly selected piglets of four litters. Groups 1 and 2 were formed by 20 piglets each; all animals were weaned at 22 days of age: group 2 animals were orally treated with human interferon alpha at low-dose (1 IU Kg b.w./day) in drinking water for the first 10 days after weaning. Also, all piglets were given the same starter feed containing amoxicillin (400 ppm), colistin (120 ppm) and zinc oxide (2000 ppm) over the first 10 days after weaning. Pigs were clinically inspected, weighed, and blood samples in vacuum tubes without anti-coagulant were collected at days 0, +6, +12 and +26 with respect to weaning, in order to investigate the most common viral infections and IFN-α, IL-6, TNF-α. Viral infections were evaluated by PCR and antibody assays whereas cytokines were investigated by bio-assays. In particular, IFN-α was measured in serum samples by a CPE inhibition assay on MDBK cells (3); TNF-α and IL-6 were determined by a cytotoxicity assay on WEHI 164 cells (4) and a proliferation test on 7TD1 cells (5), respectively. TNF-α and IL-6 concentrations (pg/ml) are shown hereunder as 75% group percentile values.

Results
All pigs remained healthy during the whole period of observation. In particular, there was no detectable clinical difference under satisfactory hygiene and welfare conditions for all the pigs under study. No animals were infected by the usual viral agents of swine (PRRSV, SIV, PCV2, PRV) in the first 2 weeks after weaning. The period from 22 to 48 days of age was divided into 3 phases (22-28, 28-34, 34-48 days). In the first one, weight gain was not significantly different between the two groups; in the second one, the daily mean weight gain of group 1 was greater than that of group 2, and vice versa in the 3rd period (Table 1). On the whole, IFN-α treated piglets showed on average 1.5 Kg more at 48 days of age (P<0.001). All piglets showed an IL-6 response between day 0 and +6 with respect to weaning, then the levels decreased until day +26. The trend of TNF-α was opposite to that of IL-6, the highest concentrations being revealed at day +26. At this time point, all pigs of group 1 and 65% of group 2 showed high serum concentrations of this cytokine; moreover concentrations were much higher in group 1 (12050 pg/ml) compared with group 2 (2613 pg/ml). The sera of all piglets in group 1 and of 18 animals in group 2 were IFN-α positive at day 6 after weaning. This result was confirmed by a neutralization assay of IFN-α on MDBK cells by a monoclonal antibody to porcine IFN-α1.

Discussion
Our results indicate that an oral, low-dose IFN-alpha treatment can affect the adaptation response of piglets to the weaning stress. In fact, the treatment determined a better growth till day 26 after weaning, probably related to a lesser TNF-α response. As in SPF pigs, oral administration of IFN-alpha is likely to reduce the IFN-gamma response at weaning and to control the related detrimental effects in terms of intestinal permeability in the post-weaning phase (2). These findings highlight the importance of type I IFNs as homeostatic agents in the response to environmental stressors.

Evaluation of the pig welfare and its association with overcrowding

Martina Tarantola1 Laura Tomassone1 Igor Ferenaz1 Giuseppe Martano2

1. University of Turin, Grugliasco (TO), Italy; 2. ASI TO3, Vigone, Italy

Introduction

Intensive swine breeding shows several critical points that can decrease animal welfare, such as microclimate, food management, mutilation, staff training, structure of buildings.

In the last years, different methods for the evaluation of animal welfare have been studied and developed, mainly based on the observation of the animals and their reactions to stimulus and environmental variations (Smulders et al 2006).

Different behaviour anomalies and injuries have been recognized to be stress indicators (Faucitano et al 2008, Velarde et al 2007). Questions concerning the minimum space requirements for intensively bred pigs in relation to their welfare have been an issue of interest for many decades (Ekkel et al 2003).

The aim of this study was to evaluate pig welfare in farms in the North of Italy, using the method proposed by Candotti et al (2007), and to verify its association with overcrowding.

Materials and Methods

We tested 33 breeding units within two Italian Provinces: 9 farrow to breed herds and 24 fattening herds. The sample was further divided into: A) weaning piglets (28-55 days old) and B) pigs (55-120 days of life). A form containing specific items related to typical abnormal behaviour and presence of injuries was compiled. For each item, the frequency, prevalence and association with overcrowding was recorded (Directives 91/630/EEC and 2001/93/EC lay down space requirements for pigs).

Finally, a “Global Score” was awarded to the studied herds, using the check list described by Candotti et al (2007), that assigns a score for each animal welfare item. Higher scores always implied “better” welfare.

Results

Sample A (9 breeding units) included 3 overcrowded breeding units (33.3%, 95% CI: 7.5-70.1).

Injuries against other pigs was significantly more frequent in the overcrowded farms (p<0.05; Fisher Exact Test), while no association between other welfare items and overcrowding was detected. The mean welfare score in group A was 8.11 ± 2.96, ranging from 4.4 to 13.4. This score was significantly higher in farms with adequate animal density (t test, p<0.01), having a mean value of 9.81 versus 4.70 in overcrowded breedings.

Sample B (29 breeding units) included 9 overcrowded farms (31.0%, 95% CI: 15.3-50.8). No association between overcrowding and welfare items was found. The mean welfare score was 3.80 ± 1.6, ranging from 1.3 to 7.7. Again, the welfare score was higher in farms with adequate densities (t test, p<0.001; mean value: 4.49 versus 2.70).

In both groups abnormal behaviours were observed: ear biting (sample A: 78%; sample B: 93%); tail biting (sample A: 67%, sample B: 59%); ears lesions (sample A: 78%, sample B: 76%); tails lesions (sample A: 67%). Moreover, 55% of the group B units showed aggressive behaviour and 52% bar biting.

Discussion

In our survey, a high percentage of anomalous behaviours was detected, indicating poor welfare. This result has a multi-factorial origin, but lack in space is one of the main causes.

The association between poor welfare, measured as a “Global Score”, and overcrowding, underlines the importance of adequate room for this animal species.

The over-muscled sow syndrome: a new emerging syndrome in a hyperprolific sow herds: Clinical consequences: preliminary observations

Thierry Solignac¹ G-P Martineau²
1. Coopagri Bretagne, Landerneau, France; 2. Ecole Vétérinaire, Toulouse, France

Introduction

We report emergence of a new body building syndrome that we called “Over-muscled sow syndrome” (Solignac, 2009). “Over-muscled sow syndrome” is the indirect consequence of genetic improvement for lean deposition and for hyperprolificacy (Solignac, 2008).

As a syndrome, there are consequences at different levels such as farrowing (Solignac et al., 2010) or prolificacy (Solignac and Martineau, 2010).

Materials and Methods

A follow-up has been performed in 199 litters (≥ 15 TB/litter) from multiparous sows and categorized according to presence or absence of piglets less than 1 kg BW (Table 1). These sows belong to 14 herds with different genetic lines.

For each sow, we measured back fat (BF) and back lean (BL) (Noveko AC037L, 3.5 MHz) at 4 different period starting 3 weeks after farrowing, then 4 weeks after AI, 3 weeks before farrowing, and at the next farrowing (all measures at P2 site).

Results and Discussion

Results are presented in Figure 1.

We report observations on some litter characteristics to propose, in a second time, some characteristics associated with morphotypes according to BF and BL.

Beside hyperprolificacy, lean deposition is of major importance. However, as BL is not measured on a regular basis, we have only information on Back fat (BF). Therefore, there is no mention of this syndrome even if it is probably present in many countries. In France, during the last 2 years, we have been confronted to different herd problems around farrowing considered from the sow point of view (Solignac et al., 2010) and the litter point of view.

According to the classification used for describe the effect of BF and BL on duration of farrowing (Solignac et al., 2010a), we propose a lecture of some common problems encountered in herds characterized by high level of performances, high technicity, and high management skills (Tables 2).

Conclusion

Simultaneous BF and BL evaluation allows the combination of zootechnical and clinical evaluation of a sow herd. However, it questions the classical approach based on the sow nutritional needs. Therefore, we have to include an objective of BF/BL ratio to reconcile productivity, rusticity, and longevity.

The over-muscled sow syndrome: a new emerging syndrome in a hyperprolific sow herds: Effect of back fat and back lean on prolificacy

Thierry Solignac1 G-P Martineau2
1. Coopagri Bretagne, Landerneau, France; 2. Ecole Vétérinaire, Toulouse, France

Introduction
In another paper, we reported the effect of the “over-muscled sow syndrome” on farrowing duration and on some clinical parameters around farrowing and in lactation (Solignac et al., 2010; Solignac and Martineau, 2010).

The objective is to report observational data on the effect of morphotype on prolificacy in herds with hyperprolific sows.

Materials and Methods
Litter characteristics were obtained from 491 sows of 14 commercial herds in Brittany (France) with different hyperprolific genetic (see Solignac et al., 2010a). These sows are representative of the sow herds in Coopagri Bretagne (150 herds) (Table 1).

Data were categorized according to littersize: <13 TB, between 13 and 15 TB and >15 TB per litter.

For each sow, we measured back fat (BF) and back lean (BL) (Noveko AC037L, 3.5 MHz) at P2 site at 4 different period starting 3 weeks after farrowing, then 4 weeks after AI, 3 weeks before farrowing, and at the next farrowing.

Results and Discussion
Globally, sows with litter <13 piglets were from morphotype BF+/BL+ (Figure 1) and sows with litter >15 piglets were from morphotype BF-/BL-.

In sows with >15 TB, a muscular catabolism is starting as soon as mi-gestation until end of gestation.

The negative consequences on prolificacy in fat sows are probably an indirect consequence via the decrease of feed intake in lactation.

Therefore, management of lean deposition and fat deposition is of major importance during mi-gestation.

Moreover, the management of lean and fat deposition is of crucial importance as soon as in the gilt development unit.

Conclusion
Consequences of the “over-muscled sow syndrome” are not limited at farrowing and in lactation. We agree with Foxcroft et al. (2005): “Accepting the risk of being considered some what heretical, most of our recent experiments with the lactating and weaned sow lead to the conclusion “that from a fertility and prolificacy perspective, fatness is simply not the key risk factor”.

There is a dynamic of lean deposition, starting at the gilt level. We have to globally consider lean and fat deposition and to reconsider our paradigms regarding sow nutrition taking into account according to is the indirect consequence of genetic improvement for lean deposition and for hyperprolificacy.

Bacteriological analysis from milk of sows affected and non-affected by PDS (Postpartum Dysgalactia Syndrome) with special emphasis on Escherichia coli

Imke Gerjets¹ Kerstin Reiners² Nicole Kemper¹
1. Institute for Animal Breeding and Husbandry, Christian-Albrechts-University Kiel, Kiel, Germany; 2. PIC Germany GmbH, Schleswig, Germany

Introduction
The Postpartum Dysgalactia Syndrome (PDS) is an important disease in sows after farrowing. Serious economic losses come along with the disease due to reduced performance of the sows and increased mortality of the piglets. Prevalence in herds can be as high as 60% [1]. The etiology of PDS is multifactorial. Amongst others, management, feeding, hygiene and bacterial pathogens are regarded as influencing factors. This study examines the spectrum of pathogens involved in PDS and analyses risk factors concerning this complex puerperal disease.

Materials and Methods
Milk samples of 800 sows with PDS and 800 non-infected sows of different age were taken on four piglet rearing and fattening units. Sows were identified as PDS-affected when the measured rectal temperature was above 39.5°C. Additional criteria like the clinical appearance of the mammary gland and the behavior of the piglets were considered. Bacteria involved in the pathogenesis of the MMA syndrome were identified by advanced bacteriological analysis including molecular methods like PCR. The isolated Escherichia coli were analyzed for various virulence genes with two multiplex PCRs [2].

Results
A wide spectrum of pathogens was isolated, belonging mainly to Enterobacteriaceae, Staphylococcaceae, Streptococcaceae and Enterococcaceae. Escherichia coli played the most important role with isolation rates over 70% in both PDS-affected and non-affected sows. With regard to the virulence genes, significant differences between strains from affected and non-affected sows were assessed for the virulence genes iron, kpsMTII, fimC and traT.

Discussion
Concerning the analysed bacteria spectrum, all species have been isolated in porcine mastitis before [3]. Coliform bacteria were found more often than the others pathogens. In particular, Escherichia coli represented the major part of all isolated bacteria. These results are in accordance with several other investigations, showing that these pathogens are one causing agent in the etiology of PDS [3,4]. Concerning the significant virulence factors detected in Escherichia coli, iroN and fimC are associated with urinary tract infections in humans [5]. Escherichia coli isolated from bovine mastitis possessed the gene traT [6], indicating a possible effect of this virulence factor.

Bacterial, environmental and animal factors may change the susceptibility for PDS. These factors are interdependent and the relative influence of each factor is related to the type of pathogens. Therefore, more comprehensive studies on virulence patterns are needed. However, the equal bacterial spectrum in diseased and healthy sows stresses the importance of the individual resistance of the single sow.

The effect of air temperatures in farrowing house for sows on occurrence of stillborn piglets

Svetlana Odehnalová1 Jiří Odehnal1 Marek Žižlavský1 Linda Czanderlová1 Pavel Novák2 Josef Drábek2 Antonín Vinkler2

1. SEVARON s.r.o., Brno, Czech Republic; 2. University of Veterinary and Pharmaceutical Sciences, Brno, Czech Republic

Introduction

Of the piglets classified as stillborn, 70 – 75 % on average die during the delivery, the rest of them die shortly after the parturition. In about 30 % cases, pathogenic agents are identified as a cause of stillbirth (Vanroose et al., 2000), 70 % stillbirths are caused by various factors such as litter size, age and condition of the sow, birth weight of the piglet as well as internal temperature in the farrowing house. The purpose of this study was to analyse the influence of different air temperature of housing environment in the farrowing house for sows on the occurrence of stillborn piglets in purebred Landrace sows and gilts.

Materials and Methods

Raw data were analysed for 236 litters during 14 month period. Pregnant sows were moved to farrowing pens cca 14 days before parturition. Sows were fed two times per day and quality of feed was not changed during the trial. Sows were not fed on the farrowing day. The air temperature was measured at hourly intervals by Datalogger (COMET), kept in the farrowing house in the sow living zone. Sow living zone is characterized by height of sow head (35 cm above floor). Temperature was measured every hour. From the values measured, average daily air temperature was calculated. The internal air temperature values were divided into the following intervals: optimal 16 – 23°C, elevated 23,1 – 27,9°C, and high above 28°C, for the lactating sow. Reproduction parameters were evaluated with regard to average internal air temperature on the day of delivery - total number of piglets born, number of live born piglets, and number of stillbirths. The statistical evaluation of data observed was made by STATISTICA. CZ software; method of ANOVA was used.

Results

The highest numbers of stillborn piglets occurred in the deliveries that took place under high room temperatures (p<0,01); the lowest one was found in those taking place under the optimal room temperature. If the numerical values were converted into percentage values there were 18.3 % stillbirths at high stable temperatures, 11.6 % stillbirths at elevated temperatures, and 6.9 % stillbirths at the optimal temperature, out of total number of piglets born. Evaluation of the influence of average daily temperature in the parturition day on the piglet looses is mentioned in table 1.

</tbody>
</table>

Discussion

Real impact of high air temperatures of housing environment on the occurrence of stillborn piglets was improved by observing room temperatures in time of farrowing. By comparing these data with English and Edwards (1996) suggested an acceptable occurrence of stillbirth of 4-8 % out of total number of piglets born; this level was not exceeded only in the case of deliveries running at the optimal room temperature for lactating sows. Already by elevated temperature for lactating sows (23,1°C – 27,9°C) was ratio for stillborn piglets double (11,66 %) and by high temperature nearly triple (18,3 %).

Elevated room temperatures exert stress on the parturient sow. Adrenalin, excreted in the alarm phase, causes vasoconstriction of vessels in the smooth muscle via the postsynaptic α1-receptors, consequently also in the uterine smooth muscle (Ruckebusch et al., 1991). Vasoconstriction prevents oxytocin from performing its uterotonic effect. Consequently, the parturition is prolonged, and the secondary uterine hypocontractility develops.

The effect of air temperatures in farrowing house for sows on occurrence of puerperal complications

Svetlana Odehnalová1, 2 Jiří Odehnal1 Marek Žižlavský1 Linda Czanderlová1 Antonín Vinkler2 Pavel Novák2 Josef Drábek2
1. SEVARON s.r.o., Brno, Czech Republic; 2. University of Veterinary and Pharmaceutical Sciences, Brno, Czech Republic

Introduction
In recent years was mentioned big improvement in production parameters of sows – number of produced pigs per sow per year (Whittemore, 2006). Nowadays epidemiologic data about occurrence of postpartal dysgalactic syndrome and existing possibilities of risk factors related to management and feeding practice are narrow (Papadopoulos et al., 2009). The aim of this study was to analyse the influence of different air temperature of housing environment in the farrowing house for sows and consequent changes in purebred Landrace dams.

Materials and Methods
The observations were made in a commercial pig farm with during 14 month period. The external air temperature was measured by Datalogger (COMET), located in the farm premises. Temperature was measured at hourly intervals. Average daily temperature was calculated from 24 values measured. The period of mild winter (MW) was characterized by temperatures -10°C to 0°C, spring – autumn (SA) 0°C to 10°C, mild summer (MS) 10°C to 20°C, and hot summer (HS) over 20°C. The internal air temperature was also measured by Datalogger (COMET), kept in the farrowing house in the sow living zone (35 cm above floor). Temperature was measured every hour. There were chosen groups of 12 sows farrowing in each external temperature period for periodic daily checking health status and measuring the rectal temperature in first 5 days after farrowing.

Results
Measured data about external and internal temperatures in each period are noticed in table 1.

Discussion
Becker and Misfeldt (1995) indicate that very hot environment (27 – 32°C) for period 28 days after delivery increased rectal temperature and have effect for certain immunological process in sow probably because of stress. This statement is in coincidence with occurrence of elevated rectal temperatures in hot summer (average internal temperature 26,0°C), but elevated rectal temperatures in sows 5 days after farrowing were mentioned also in mild summer (average internal temperature 26,0°C). Negative influence of higher environmental temperatures was expressed also by higher incidence of pathological discharges from vulva and of incidence MMA syndrome in early puerperium.

Blood cord cortisol is not a good indicator of piglet vitality in hyperprolific sows

Audrey Giraudø1 Yannig Le Treut1 Eric Chevaux1 Guy-Pierre Martineau2
1. LALLEMAND SAS, Blagnac, France; 2. Veterinary School of Toulouse, Toulouse, France

Introduction
For hyperprolific sows, piglets vitality at birth is particularly important and is influenced by the quality of the farrowing process: the longer the worst it is for the piglets which face an increased risk of hypoxia. The reduction of oxygen supply to the fetus blood generates the set-up of an anaerobic metabolism with some subsequent modifications in the blood metabolites balance. Cortisol is usually associated to stress (van de Kar et al., 1999) and used as an indicator of vitality (Canario et al., 2006).

Materials and Methods
Herd: a typical French herd (400 sows) with hyperprolific sows (LWxL)x(PxL), 195 piglets (188 born alive + 7 stillborn) from 70 sows were sampled for umbilical cord mixed blood within the first minute after birth. Serum cortisol was analyzed according to two classical techniques: radioimmunoassay (RIA) and luminoimmunoassay (LIA). The relationships with piglets status at birth (live weight, presence or absence of meconium, cord status, position at birth, birth rank) were established by analysis of variance and correlations between parameters with the Pearson test (SPSS 17.0). Blood data exceeding the mean ± 3 standard deviations were considered as outliers (n=4) and eliminated for the statistical analyses (P<0.05).

Results
The straightforward outcome concerns the dispersion of the analyzed values for both techniques (Figure 1), the latter’s remaining well.

Table 1: Umbilical cord cortisol (mg/mL) according to piglet weight (top) and total born litter size (bottom) (mean ± SEM; a,b differ for p<0.05)

</tr>
</tbody>
</table>

The presence of blood together with the meconium on the piglets at birth indicated higher (P<0.05) cortisol LIA (140.0±38.1 vs 132.3±37.3), but no effect of the rank at birth was measured, nor for the piglet’s position at birth (head vs back).

Discussion
Weak vitality is often reported as a problem in small piglets, more numerous in hyperprolific sows. Thus, a strong correlation could be expected with the cortisol and the indicators of low vitality. The absence of link between the cortisol and the piglet vitality, its rank at birth, the quality of the cord (regular vs twisted) or the presence of meconium does not support our initial hypothesis. Qualifying cord blood right after birth was quite innovative for this study, but it may also explain the high dispersion of the values as the level gets more stable after birth (McCauley et al., 1984), where the few available studies were focused on. Therefore, cortisol cord level at birth does not appear relevant to characterize piglet vitality.

Blood cord metabolites as indicators of piglet’s vitality in hyperprolific sows

Audrey Giraudo 1 Yannig Le Treut 1 Eric Chevaux 1 Guy-Pierre Martineau 2
1. LALLEMAND SAS, Blagnac, France; 2. Veterinary School of Toulouse, Toulouse, France

Introduction

For hyperprolific sows, piglets’ vitality at birth is particularly influenced by the quality of the farrowing process: the longer the worst it is for the piglets which face an increased risk of hypoxia. The reduction of oxygen supply to the fetus blood generates the set-up of an anaerobic metabolism with some subsequent modifications in the blood metabolites balance.

Materials and Methods

Herd: a typical French herd (400 sows) with hyperprolific sows (LWxL)x(PxL), 195 piglets (188 born alive + 7 stillborn) from 70 sows were sampled for umbilical cord mixed blood within the first minute after birth (Giraudeau et al., 2009). Blood was then centrifuged (2900g, 12 min), plasma freezed until analyses.

Vitality has been evaluated according to scale developed by Baxter et al., 2008 (grade 0 to 3).

Analysis: Na, Cl, K, Ca, P, glucose (Glu), bicarbonate (HCO3), proteins, urea, uric acid and creatinin. The relationships with piglets status at birth (live weight, presence or absence of meconium, cord status, position at birth, birth rank) were established by analysis of variance (SPSS 17.0). Blood data exceeding the mean ± 3 standard deviations were considered as outliers (n=4) and eliminated for the statistical analyses (P<0.05).

Results

Results (Table 1) are in accordance with other data (Tuchscherer et al., 2000) except phosphorus which was below (1.8 vs 4 mmol/L).

</tbody>
</table>

Piglets with very low vitality had higher glucose and P, and lower HCO3 than the more vigorous ones Ca and urea were higher (p<0.05) for the vitalities 0 and 1 as opposed to 2 and 3.

The effect of birth order is reported in Figure 1. Glucose and P content increase for the last third of the litter as does K, where more weak piglets are usually reported.

Discussion

Vitality scoring is confirmed through the cord blood profile. Weak vitality is often reported as a problem in small piglets, also more likely to suffer from hypoxia (Herpin et al., 1996). Low HCO3, high Glu and K are good predictors of the level of intrapartum anoxia (Trujillo-Ortega et al., 2007). When combined with the presence of meconium, the cord integrity, the rank at birth and the live weight, piglet vitality is well correlated with the cord blood profile.

Inverted teats (Mammillae invertitae) in sows – effect on piglet survival and growth rate

Helena Chalkias¹ Nils Lundheime⁰ Magdalena Jacobson²

1. Dept of Animal Breeding and Genetics, Uppsala, Sweden; 2. Dept. of Clinical Sciences, Faculty of Veterinary Medicine and Animal Science, Swedish University of Agricultural Sciences, Uppsala, Sweden

Introduction

Piglet mortality during lactation is a large problem in pig production. The nursing and suckling behavior of piglets follow a complex scheme and the milk ejection lasts for only 10-20 seconds, once per hour. There is no transfer of antibodies across the placenta and the piglets are born with low immunity. Each piglet must thus have access to a functional teat for nourishment and growth (3). One example of a non-functional teat is the inverted teat. The degree of inversion may differ from slightly to totally inverted. The aim of this study was to evaluate the function of inverted teats identified at 100 kg live weight, and to analyze differences between the mammary glands of inverted teats vs. normal teats. Further, the piglets' ability to suckle an inverted teat and differences in daily weight gain that might be related to the presence of inverted teats was investigated.

Material and Methods

Two Yorkshire gilts (a, b) and one Yorkshire*Landrace gilt (c) with 4, 4 and 8 inverted teats at 100 kg live weight were inseminated. One week before expected farrowing the teats were palpated. After farrowing, to ensure that each piglet only had access to one teat, all excessive, functional teats (above the number of liveborn piglets) were blocked with adhesive bandage, beginning with the posterior teats (1). The health status of the piglets and gilts were recorded daily. The piglets were individually marked and the teat order of the piglets was registered by videotaping. The piglets were weighed individually each day during the first week and thereafter once a week until weaning at 4 weeks of age. The gilts were euthanized immediately after weaning and the mammary gland for each teat was weighed individually.

Results

One week before farrowing, two of the gilts (b, c) only had one single inverted teat left and gilt (a) had no inverted teats remaining. All three gilts had 13 liveborn piglets each. The two piglets that suckled the inverted teats were euthanized 5 and 8 days after farrowing, respectively, due to loss of body weight. Both these piglets were still fighting for other teats the day they were euthanized, but necropsy revealed empty intestines and sparse amount of feed in the stomach. Both piglets still had some fat remaining in the coronary groove, but one piglet had serous atrophy of the bone marrow. Strong significant positive correlations (0.66**, 0.64***, 0.62**) between weight of mammary gland and daily gain of the piglets during the second to fourth week of lactation could be found. However, no significant differences in piglet weight gain between normal and previously inverted teats could be seen. The average mammary gland weight for normal teats was 606 gram and for previously inverted 570 gram.

Discussion

This study clearly showed that inverted teats at farrowing are of low functional value and this does emphasize the importance of functional teats. Inverted teats can sometimes protrude close to farrowing (2), but it was unexpected that most of the inverted teats were normalized weeks before farrowing. To be able to demonstrate relationships between previously inverted teats and piglet daily weight gain, more data is needed.

Use of a new technology based on thermography to monitor health and risk factors in newborn piglets

Joaquin Morales1 Alberto Manso1 Maria Aparicio1, 2 Carlos Piñeiro1
1. PigCHAMP Pro Europa, Segovia, Spain; 2. Centro de Experimentación y de Formación en Porcino, Segovia, Spain

Introduction
Perinatal mortality still plagues the swine industry despite the improving knowledge in neonatal physiology. Hypothermia is one of the most important factors, affecting colostrum intake and hence, its later health status and performance.

In this study, thermography was used as a new tool to determine hypothermia and its evolution in newborn piglets. Thermography might provide high advantages in swine clinical practice, allowing the inspection of a high number of animals in few time, revealing lesions and risk factors that would remain hidden with other diagnostic systems (Friendship et al., 2009).

Materials and Methods
Twenty-two piglets from two different litters entered the study at birth time. In each litter, half of the piglets were immediately dry using an absorbent material (paper). The other half was not manipulated at birth. A heat lamp and extra-paper (2 kg) were supplemented in both litters.

Skin temperature was recorded from each piglet at birth and every 10 minute's time during 1.5 hours using a thermographic camera (Fluke Ti45). Piglets were weighed at birth and at 2, 4 and 9 days of life.

In each picture, the average temperature in the back was measured. In figure 1 some examples of thermographic pictures are shown.

Results
Drying piglets immediately after birth increased the skin temperature in the first 90 min of life (39.3°C vs 37.8°C in dried and control piglets, respectively; P=0.048). Evolution of the skin temperature was also different between treatment (P treatment x time = 0.0001). Initial temperature was 39.3 ± 0.79 °C, and was kept almost constant in the dried-piglets in the 90 min-interval. In the control group (non-attended piglets) skin temperature immediately decreased after birth and then increased progressively and 90 min after farrowing temperature did not differ between groups (P=0.27). Evolution of skin temperature is shown in the figure 2.

Discussion
Drying piglets immediately after birth was effective to keep the body temperature. Preventing the perinatal hypothermia provides the piglet more possibilities to survive and reaching higher BW at weaning. Infrared thermography demonstrated enough accuracy to be considered as a new tool to complement other diagnostic tools.

The effect on pre-weaning piglet mortality of tilmicosin oral administration when used in pre-farrowing sows

Alain Kanora1 Patrick Rabaeys2 Henk Lecluyse1 Spas Petkov3 Koen De Gussem1

Introduction
Tilmicosin is a semi-synthetic macrolide antibiotic which is affecting bacterial protein synthesis. Macrolides have a proven benefit as treatment for a wide range of infectious diseases, with an increased interest for respiratory infections.

The aim of this study was to evaluate the effect of tilmicosin (Tilmovet® 250 mg/ml Concentrate for Oral Solution - Huvepharma) treatments and its capacity to prevent neo-natal piglet mortality.

Materials and methods
To set up this trial in a sow farm (n= 350), 60 pregnant and healthy sows (without health issues during the last gestation and regardless of parity) of around 110 days of gestation were provided a dose of 9 ml of Tilmovet® 250 mg/ml Concentrate for Oral Solution per sow per day for minimum 5 to maximum 7 days through an individual medication system / sow. The total dose was split up and distributed twice a day (4.5 ml per dose).

The final day of treatment was the farrowing day. After farrowing and starting on the day of farrowing (day 0), milk samples were collected on day 2 and 4 with a minimum of 10 ml per sample. Samples were directly frozen after collection. From these samples, tilmicosin was extracted by means of liquid-liquid parturition, purified by C18 SPE and identified and quantified through HPLC method. The HPLC method has been developed and validated for analysis of tilmicosin in milk.

Piglet mortality and weight gain figures were recorded daily for a period of 14 days.

Results
The treated group of sows had 9.4% more piglets born (15.2 vs 13.9) than the untreated sows (Table 1 and Figure 1). They also had 10% more live born piglets (14.3 vs 13.0) and the pre-weaning mortality was clearly lower than in the control group (13.28% vs 16.92%).

The number of weaned piglets was similar in both groups, yet the Tilmovet® piglets were nearly 9.5% heavier at weaning.

Discussion and conclusion
Earlier research1,2 has demonstrated the beneficial effect of tilmicosin treatment on sow productivity and the prevention of postpartum infections through reduction of piglet pathogen transmission. The current study confirms these findings and indicates that gestating sows being treated with Tilmovet® for 5 to 7 days prior to farrowing suffered less from neo-natal infections. This is a result from the tilmicosin concentration in the sow milk and consequent colostrum transmission. The impact of the effect in the treated group can be noticed in the higher individual piglet weights at weaning.

Piglet survival depends on relative birth weight

Flemming Thorup1 Susanne L. Musse2

1. Center for Pig Production, Agriculture and Food Council, Copenhagen, Denmark; 2. PORCUS Svinefagdyrlæger & Agronomer, Ringe, Denmark

Introduction

Large size at birth is the primary indicator of high piglet survival (1). For high litter survival, uniform birth weights are more important. The Meishan show high piglet survival with low but uniform birth weights (2). We investigated piglet survival, when birth weights were decreased due to either low parity or high litter size.

Materials and Methods

Trial one included 1401 DanBred DxLY piglets born in two herds. Trial two included 1182 DanBred YxL female piglets born in one herd. Piglets were weighed and ear tagged at birth. Survival was registered at weaning.

Results

Piglets born to 1st litter sows were 150 to 200 gram lighter than piglets born to older sows (Table 1). Piglet survival by birth weight and parity in trial 2 is shown in figure 1. Birth weights and piglet survival for piglets born in small litters (10-14 total born) and large litters (18-22 total born) is given in table 2. Piglets born in litters of 1-9, 15-17 or > 22 are excluded. Piglets born in large litters were app. 150 gram lighter than piglets born in small litters. Survival by birth weight and litter size in trial 2 is given in fig. 2. More figures will be presented.

Discussion

Despite having the same genotype, piglets born in 1st litter and piglets born in large litters were app. 150 gram lighter than piglets born in sow litters and piglets born in small litters. Restricted uterine capacity may cause this “piglet phenotype”, 150 gram lighter, than the genetic merit would allow for under better uterine conditions. There were only small differences in piglet survival between the groups. Both 1st litter piglets and large litter piglets reached 100 per cent survival at a lower birth weight than piglets born by sows or born in small litters (see fig. 1 and 2). A level of survival is correlated to birth weight (genotype) and is still the same, if a piglets achieves a lower birth weight (phenotype), when born in a gilt litter or in a large litter. A reduced birth weight in first parity or due to high litter size did not effect piglet survival.

Extreme uterine crowding in Prolific French York (PFY) sows

John Harding¹ Crissie Auckland¹ Jennifer L. Patterson² George R. Foxcroft²
1. University of Saskatchewan, Saskatoon, SK, Canada; 2. University of Alberta, Edmonton, AB, Canada

Introduction
The selection for litter size without concurrent selection for uterine capacity will intensify the adverse affects of uterine crowding, particularly in prolific and mid- to high-parity sows. Recently, a prolific French York (PFY) dam line was imported from France into North America as a way of increasing the prolificacy of commercial sows. The objective of this study was to evaluate various reproductive attributes of the PFY dam-line at the end of the first trimester.

Materials and Methods
Gravid reproductive tracts, harvested from 34 healthy, vaccinated (parvo, lepto, erysipelas) PFY sows of various parities, were slaughtered 26 to 40 days following insemination. All sows were designated for culling for non-reproductive reasons and had been bred specifically for this study. After humane slaughter the gravid uteri were removed and stored frozen at −20°C. After thawing, the corpora lutea (CL) were counted, the uterus incised, each conceptus removed, excess fluid drained from the chorioalantois, and the conceptus (embryo, amnion + drained chorioalantois) weighed. The embryos were removed from placental membranes, weighed and the crow-rump length (CRL) measured. The conceptus was classified as degenerate if the embryo, placental membranes, or both, showed gross signs of degeneration as previously described1. In the event of twinning, each embryo was counted and separate embryo mass and crown-rump lengths were obtained. Analysis: The total number CL on both ovaries was considered the ovulation rate. The estimated live embryonic survival rate was calculated (number assumed live embryos/number CL). The average live embryo CRL and weight, and the wet placental weight (total conceptus weight less embryonic weight) were calculated for each litter. Litters were categorized by gestation age (26-30, 31-35, 36-40), and group differences in the median scores for each reproductive attribute compared using a Kruskal-Wallis analysis of variance. P < .05 was considered significant.

Results
The median parity across all sows was 3 (range 1 to 7). Ovulation rate and total embryo number ranged from 17-33 and 9-29 respectively (Figure 1). Embryo and placental weight, and CRL increased with gestation age (Table 1), but the number of total and live embryos, and embryo survival rate were not affected.

Discussion
Previous research by our team demonstrated that when the number of viable embryos at gestation day 30 exceeded 9 to10, fetal development was adversely affected². Our present results confirm the combination of high ovulation and embryo survival rates in prolific French York sows results in extreme intrauterine crowding during the first trimester. Its impact on postnatal performance warrants continued investigation.

Bacterial pathogens present in the milk of healthy sows and sows with PDS (Postpartum Dysgalactia Syndrome): detailed analysis of isolated Aerococcus spp

Andrea Menrath1 Imke Gerjets1 Kerstin Reiners2 Nicole Kemper1
1. Institute for Animal Breeding and Husbandry, Christian-Albrechts-University Kiel, Kiel, Germany; 2. PIC Germany GmbH, Schleswig, Germany

Introduction
The porcine Postpartum Dysgalactia Syndrome (PDS) is a well known disease in sows 24 to 48 h post partum. The main symptom, the mastitis, is accompanied by fever and reduced milk production. Hence, decreased rates of growth and a higher mortality in piglets are the results.

The disease is multifactorial due to influences of management and feeding, but additionally, there is a relevance of individual factors of each animal and of the occurrence of different pathogens in the infected mammary glands.

In the geMMA-project, the spectrum of pathogens in the milk of PDS-diseased and healthy sows was compared. In this special part of the study, the isolated Aerococcus (Ac.) species (spp.) were further investigated.

Materials and Methods
The sows were defined as PDS-diseased by several criteria. The identification and subtyping of all isolates were performed by classical bacteriology, the API-system® of Biomerieux (Nürtingen, Germany) and PCR.

Results
In the milk of 344 (22.9%) of 1,500 examined sows, both PDS-diseased and healthy, Aerococcus spp. were isolated.

This is the first description of the isolation of Aerococcus spp. in the milk of sows. In this study, the isolated Aerococcus spp. belonged to Ac. viridans (285 isolates) and Ac. urinae (59 isolates) by biochemical differentiation. Further results of the advanced PCR-analyses will be represented.

Discussion and Conclusion
Aerococcus spp. are ubiquitous in the environment and also in the air. The Genus Aerococcus includes seven species: Ac. viridans, Ac. urinae, Ac. sanguinicola, Ac. christensensi, Ac. urinae, Ac. urinahominis and Ac. suis. These Gram-positive, catalase-negative Cocci have been associated with disease in human (Ac. viridans und Ac. urinae), swine, and cattle (Ac. viridans und Ac. suis) (1, 2). In swine, Ac. viridans has been described in association with arthritis, meningitis and pneumonia (2). Most recently, Ac. suis has been shown to cause arthritis, enteritis, meningitis and pneumonia in swine (3).

Due to the relation of Aerococcus spp. with mastitis in cows (1), the role of this pathogen in the pathogenesis of PDS is clearly worth further examinations, with this study as a first step in this direction.

This study is part of the BMBF-supported FUGATO-plus-project ‘geMMA - structural and functional analysis of the genetic variation of the MMA-syndrome’.

Facilitating nursing behavior of sows at farrowing has a positive effect on colostrum distribution

Johan Biermann² Jan Jourquin¹ Rainier van Gelderen¹ Lieve Goossens¹
1. Janssen Animal Health, Beerse, Belgium; 2. DAP Helmond, Helmond, Netherlands

Introduction

Farrowing is a stressful event for sows, especially first parity sows. In the most severe cases this leads to aggression and savaging of newborn piglets. Next to clear aggression, there is a range of less explicit unwanted behavior, negatively impacting the possibility for the piglets to take up colostrum. Bottle fed piglets ingest more colostrum in the first day than naturally nursed piglets (1), indicating that the sows is a limiting factor for colostrum intake.

Our investigations show that colostrum distribution is correlated with piglet survival. We were also able to demonstrate that with an injection of azaperone of the sow just after farrowing, resulted in an increase of calm behavior and in an increase of number of piglets suckling during the first hours after farrowing.

The aim of this pilot study was to investigate if an injection of azaperone (Stresnil®) at the end of the partus had a positive effect on colostrum distribution.

Materials and Methods

In a commercial sow farm, 193 first and second parity litters were included in the study. The day time litters (n=98) were injected 320 mg of azaperone IM (8 ml Stresnil®) at the moment of expulsion of the placenta. The night time litters (n=95) were not treated. Gestation length and the number of piglets born total, born alive, fostered (±), dead and weaned were recorded. All normal farm procedures were continued. At tail docking (day 3 post partum) a blood drop of the remaining tail bud from 6 randomly chosen litter mates was sampled. The samples were analyzed with a DAS-ELISA test (2) (Colostrum Quality Counter™). Piglet serum IgG concentration after gut closure can be used as a parameter for colostrum intake (3). In order to compare the distribution of colostrum between sows, the coefficient of variation of the piglet serum IgG (CV IgG) was calculated. This is the standard deviation divided with the average of the litter.

The statistical analysis was performed with the SAS® program. A t-test on the log-transformed data was performed.

Results

The mean (± standard deviation) of colostrum distribution (CV IgG) of the piglets of treated sows was 46.9 (± 20.4) compared to 55.2 (± 32.2) for non-treated sows. The difference is nearly statistically significant (p<0.07). There was no difference in colostrum distribution between first and second parity sows.

Figure 1 shows the relation of variation in colostrum intake and the number of piglets born alive. The variation increases with litter size in non-treated sows, while the variation does not differ between litter sizes in the azaperone treated sows.

Discussion

The results demonstrate that the behavioral change of the sow after injection of azaperone resulted in a better distribution of the available colostrum amongst the piglets. Increasing number of piglets born alive per litter had a negative impact on colostrum distribution in the non-treated group. In litters where the sow was treated with azaperone, the distribution of colostrum was not affected by the number of piglets born alive. This confirms earlier findings that the sow is a limiting factor for colostrum distribution.

In this study, it was shown that one injection of azaperone to the sow at the moment of expulsion of the placenta, improves colostrum distribution amongst her piglets. The challenges caused by poor colostrum distribution are more relevant in high productive farms.

Facilitation of nursing behavior in sows during colostrum phase improves piglet condition

Steven Tseng2 Jan Jourquin1 Lieve Goossens1

Introduction

The development and the wellbeing of the piglet is determined by its ability to fulfill its need for homeostasis, growth and its ability to fight off the sanitary challenges. Early colostrum intake is the key for success. For the first 2 days of their lives, colostrum provides the nutrients to the piglets and during their first weeks, the immunoglobulin (Ig) fraction passively protects the piglets from disease (1). Critical factors for early life survival are the ability of the piglet to suckle, the available volume of colostrum, the udder quality and the behavior of the sow during the colostrum phase. At parturition, the behavior of about 25% of sows prevents their piglets from sucking. 6 hours later this increases even to 30%. With an injection of azaperone (Stresnil®) at the end of the partus, sows become calmer and allow the piglets easy access to the udder.

In this study, the effect of an injection of azaperone at the end of the partus of all parity sows on piglet development was investigated.

Materials and Methods

In a 3000 sow farm in Taiwan, 50 sows of all parities were included in the study. They were randomly allocated to a treated group (25 sows) and a non treated reference group (25 sows). The treated sows were injected IM 2 mg/kg of azaperone (5 ml Stresnil® per 100 kg body weight) at the moment of expulsion of the placenta. To assess the condition and health status in field conditions, early mortality rate and weight gain were used as parameters. The piglets were weighed and identified individually at birth and at weaning. Fostering was allowed and recorded. Farrowing and weaning date, numbers born alive, pre-weaning mortality and numbers weaned was recorded.

A linear mixed model was fit using the procedure MIXED in SAS® version 9.1.

Results

The number piglets born alive was 10.8 for the non treated group and 9.7 for the treated group. Pre-weaning mortality rate was similar for both groups (11.74% and 11.64%). Weight data are presented in Table 1. All litters were weaned at 28 days. While individual birth weights were not different between both groups, weaning weight was significantly higher in the azaperone treated group.

In Figure 1, the impact of birth weight on weight gain is shown. Weight gain increases with birth weight.

The observed growth improvement in the treated group was seen in all birth weight classes.

Discussion

The present study showed the benefit of an azaperone injection of sows at the end of the partus. Piglets thrive better, resulting in a 9.9% weight gain increase.

The sedative effect of azaperone is limited to a few hours. The origin of any difference therefore lies in the early intake of colostrum. If enough colostrum is available, a good distribution increases the chances of all piglets. Stronger piglets increase the suckling impulse, which leads to a higher milk production. The antibodies acquired from the colostrum protect the piglets against disease. In this study, it results in a significant increase of weaning weight of the piglets.

Analysis of oligosaccharides in pigs’ colostral milk

Regine Preissler¹ Nicole Kemper¹ Karl Klisch²
¹. Institute for Animal Breeding and Husbandry, Christian-Albrechts-University Kiel, Kiel, Germany;
². School of Veterinary Medicine and Science. University of Nottingham, Nottingham, UK

Introduction

Milk oligosaccharides (MOs) have been investigated in humans as well as in several other mammals, but studies of sows’ milk are lacking (Urashima et al., 2001). Their prebiotic and antiadhesive effect for the newborns is well described for human milk oligosaccharides (Bode, 2009) and can be assumed for other species, too. Because of increasing litter sizes and the rising demand for milk substitutes in farrowing units, the composition of sows’ milk, including oligosaccharides as functional ingredient, is of peculiar interest. Furthermore, a possible anti-adhesive effect in sows’ mammary glands may play a role in the pathogenesis of mastitis as part of the Postpartum Dysgalactia Syndrome (PDS).

This study therefore analysed MOs in sows’ colostral milk, considering also the clinical health status of these sows in the periparturient period and bacteriological results of their milk samples.

Material and Methods

At the Institute’s research farm, 17 sows were examined clinically at the expected farrowing date and milk samples were taken. Five sows showed clinical signs of mastitis during the sampling time or developed mastitis post partum.

All sows were sampled during or directly after parturition, and all milk samples were obtained by hand milking without oxytocin injection. Bacteriological analysis and species differentiation were performed by routine bacteriological diagnostics. At least one ml milk was stored at -20°C and MOs were isolated, reduced and permethylated. Analysis was performed by MALDI-TOF mass spectrometry.

Results

All detected MOs were sialylated with terminal sialic acid (Neu5Ac). No fucosylated MOs were detected. The reducing end of the oligosaccharides is generally formed by lactose (Gal β1-4Glc) and in much lower abundance by lactosamine (Gal β1-4GlcNAc). Sialyllactose (Neu5Ac-β1-3Gal β1-4Glc) was the most abundant structure in almost all samples. The carbohydrate portion of GM2-ganglioside (GalNAC β1-4[Gal β1-4Glc]2) revealed the second highest peak in most samples, but was completely absent in one sample and just detectable in one other sample. Biantennary oligosaccharides formed the highmolecular fraction with monosialylated lacto-N-hexaose (Neu5Ac-Gal-GlcNAC-[Gal-GlcNAC-Gal β1-4Glc]) being the third most abundant structure in most samples.

Discussion

This is the first study analysing MOs in pigs. The porcine MOs show some similarities with those of cattle (Tao et al., 2008). In both species sialylated MOs dominate and fucosylated MOs are absent. One main difference is the presence of high quantities of the GM2-ganglioside carbohydrate in pig MOs. Only traces of this structure are found in bovine MOs. Pig’s milk contains more complex high molecular weight biantennary MOs than bovine milk.

Like in other species the MOs in pigs are likely to act as prebiotics by supporting the development of a beneficial gut flora in piglets. The knowledge of the natural composition of porcine MOs could be the basis for further functional studies and also for a rational composition of food supplements for piglets and weaners.

Possible changes in oligosaccharide patterns between healthy and diseased animals should be investigated in further studies.

Impact of uterine crowding on fetal development and lactational performance

John Harding; Shrijana Dhakal; Yanyun Huang; Crissie Auckland

University of Saskatchewan, Saskatoon, SK, Canada

Introduction

Prenatal programming is a process by which stimuli during gestation establish permanent responses in the fetus that impact physiologic function later in life. In pigs, low birth weight or body mass index are associated with altered metabolism, fat deposition and stress response. Uterine overcrowding reduces fetal weight, impairs myogenesis and organ development. We are investigating the effects of uterine crowding on postnatal health and performance. Reported herein are descriptive statistics highlighting the effects of uterine crowding on fetal development and lactational performance.

Materials and Methods:

Right oviductal cauterization was performed 2 weeks post weaning on 13 multiparous PIC sows (CAUT). CAUT and 12 control sows (CTR) delivered 10 to 17 total born on their previous parity and were in good body condition at weaning. After surgery, sows were heat synchronized and inseminated. Corpus lutea and embryo number were counted via laparotomy at 36 ±2 days of gestation. At farrowing, litter size, gender, individual birth weight, crown rump length (CRL), heart girth was recorded for live and stillborn pigs. Judicious cross-fostering between treatments ensured CAUT and CTR sows suckled piglets of the opposite group. Non-trial pigs were fostered onto trial sows as appropriate to ensure CAUT and CTR litter sizes were similar. Piglets were re-weighed at day 21. Sows were weaned and rebred, and farrowed a subsequent litter if they conceived. Laporotomies were not performed, but performance was monitored. Parametric and non parametric outcomes were compared between group using Student’s t-test or Mann-Whitney U test as appropriate.

Results:

The significantly lower embryo numbers in CAUT (Table 1) provided an enriched uterine environment resulting in increased embryo survival, heavier and longer piglets with greater girth and BMI at birth (Table 2). The CAUT offspring had superior 21 day survivability even though litter sizes after cross-fostering were numerically similar in CTR and CAUT sows. Lactational ADG and weaning weight were significantly higher in CAUT offspring.

Discussion:

These preliminary results indicate fetal development was attenuated in the relatively crowded CTR sows resulting in disproportionate fetal growth and the birth of thin and slightly shorter pigs that had lower day 21 survival, weaning weight and lactational ADG. Additional analysis is planned to determine if these effects are dependent or independent of birth weight, and if uterine crowding affects post weaning health, stress response, growth and fat deposition.

Evaluation of the in feed use of Larch sawdust in sows for treatment and prophylaxis of Postpartum Dysgalactia Syndrome

Eleni D. Tzika1 Panagiotis D. Tassis1 Vassilios G. Papatsiros2 Dimitrios Koylialis1 Asimoula Siochu1 Panagioti Toyplikioti1 Costas Alexopoulos4 Spiros C. Kyriakis5

1. Clinic of Farm Animal Medicine, Faculty of Veterinary Medicine, Aristotle University of Thessaloniki, Thessaloniki, Greece; 2. Clinic of Medicine, School of Veterinary Medicine, University of Thessaly, Karditsa, Greece; 3. Microbiology Laboratory, Thessaloniki, Greece; 4. Deceased author, Thessaloniki, Greece; 5. Foundation of Biomedical Research, Academy of Athens, Athens, Greece

Introduction
The Postpartum Dysgalactia Syndrome (PPDS) causes important economical losses in the global swine industry. The clinical signs are characterized mainly by disorders of lactation and health status of sows, as well as from decreased litter performance (1).

The aim of this field study was the assessment of possible anti-inflammatory activity of Larch sawdust, Echinacea, Pumpkin, Salix, Sinupret and Grape Seed based on the reduction of PPDS prevalence in sows. This trial was part of the SAFEWASTES specific targeted research project financed by the European Union (6th Framework Project).

Materials and Methods
The trial farm had 900 sows under production and previous history of PPDS occurrence. Genetically similar sows were selected in terms of achieving homogeneity of parity, bodyweight, previous production parameters and health status. Thus, 40 sows with no clinical signs of disease were randomly allocated in 8 groups of 5 sows each. The trial period was 35 days (from 7 days prior to farrow up to weaning day). Six compounds at the inclusion level of 1% were added to sow feed in order to be tested for anti-inflammatory activity (gestation and lactation feed) as follows: 1) Control and Positive group: 99% Basic diet and 1% Corn starch, 2) Larch group: 99% Basic diet and 1% Larch, 3) Echinacea group: 99% Basic diet and 1% Echinacea, 4) Pumpkin group: 99% Basic diet and 1% Pumpkin, 5) Salix group: 99% Basic diet and 1% Salix, 6) Sinupret group: 99% Basic diet and 1% Sinupret, 7) Grape seed group: 99% Basic diet and 1% Grape seed.

The positive controls were injected with a single 2 ml dosage of an anti-inflammatory drug (meloxicam) at parturition day. The animals of all the other groups were injected with the same dose of normal saline at the same day. The milk production index was calculated. Production and health parameters of sows and their litters were also recorded. Blood samples were collected from all sows at allocation day and at 24 and 72 hours post partum (PP) for inflammation markers evaluation (serum tumor necrosis factor-2/TNF-α, plasma interleukin-6/IL-6). The cytokines results were expressed as n-fold increase of cytokine expression in relation to untreated sows at allocation day.

Results and Discussion
Results showed that larch sawdust had particular anti-inflammatory effect.

The effects of an enhanced uterine environment on immune competence in pigs

Jamie M. Wilkinson1 Susan Novak1 Michael K. Dyck1 Walter T. Dixon1 George R. Foxcroft1 John C. Harding2
1. University of Alberta, Edmonton, AB, Canada; 2. University of Saskatchewan, Western College of Veterinary Medicine, Saskatoon, SK, Canada

Introduction
The ‘fetal programming’ hypothesis states that the gestational environment of the embryo affects its development, and that this can have long-term consequences for the animal post-natally. In swine, low birth weight animals exhibit an altered metabolism and stress response over a range of ages, and this could be programmed in utero1-2. To date, the potential of the uterine environment to influence the immune system of pigs has not been investigated. In this study, immune competence in the offspring of control sows from a commercial dam line was compared to immune competence in the offspring of sows from the same line that had undergone unilateral oviductal cauterization surgery to artificially reduce the number of embryos in utero and provide an ‘enhanced’ uterine environment.

Materials and Methods
The experiment used PIC Line 42 parity 3-5 sows in good health and body condition that farrowed between 10 and 17 total born on their most recent parity. Right oviductal cauterization was performed on a group of 10 sows (CAUT). The oviducts of 11 age-matched controls were not cauterized (CTRL). Following surgery, sows in both groups were estrus synchronized by treatment with oral progestagen and bred. Farrowing was induced by cloprostenol to obtain a gestation length of 114 to 116 days. Individual gender and birth weight data were recorded for all piglets born. Blood samples were collected from 2 male and 2 female piglets from each litter at 4, 9, and 15 weeks of age. For each sex, one piglet representative of above and one representative of below average litter birth weight was chosen. Animals at the extremes of birth weight were excluded. Lymphocytes were isolated by density gradient centrifugation using ‘Lymphoprep’ (Axis-Shield), and 1 x 10^5 cells in triplicate were used to determine immune competence by measuring lymphocyte proliferation with or without addition of the B and T cell mitogen concanavalin A. Cells were grown in RPMI medium for 72 hours. Tritiated thymidine was then added and the cells were cultured for a further 18 hours, harvested, and incorporation of labeled thymidine was measured with a scintillation counter (TopPlate, Packard). Proliferation data were normalized by Log2 transformation. Statistical analyses were performed using the MIXED procedure in Statistical Analysis Software (SAS 9.2, SAS Inc.).

Results
• Litter average birth weight was greater in CAUT (1.74 Kg) than CTRL (1.40 Kg) litters (p = 0.004).
• There was no overall effect of cauterization treatment on lymphocyte proliferation (p = 0.402).
• Across all ages there was a positive correlation between birth weight and lymphocyte proliferation for the CAUT group (r = 0.421; p = 0.008) but not for the CTRL group (r = -0.061; p = 0.636).

Discussion
The larger average birth weight of the CAUT compared to the CTRL pigs indicates that oviductal ligation successfully provided a uterine environment enhancing fetal growth of CAUT offspring. Although no overall difference in lymphocyte proliferation in the offspring of CAUT and CTRL sows was identified in this study, the positive correlation between birth weight and lymphocyte proliferation in the CAUT offspring and its absence in the CTRL offspring suggests that a combination of genetic and epigenetic factors may influence the post-natal immune capacity of pigs.

Introduction

Farrowing is a stressful event for sows, especially first parity sows. In the worst cases this leads to aggression and savaging of newborn piglets. Next to clear aggression, there is a range of less explicit unwanted behavior negatively impacting the possibility for the piglets to take up colostrum. Bottle fed piglets ingest more colostrum in the first day then naturally nursed piglets (1), indicating that the sows is a limiting factor for colostrum intake. The aim of two studies was to investigate if an injection of azaperone (Stresnil\(^{®}\)) at the end of the partus has a positive effect on sow behavior and on sow-piglet interaction.

Materials and Methods

In a first study, 69 sows of all parities were injected with 320 mg of azaperone (8 ml of Stresnil\(^{®}\)) at the moment of expulsion of the placenta. Simultaneously in the same environment 81 sows of all parities were enclosed in the study as non treated controls. At the expulsion of the placenta (0 hours) and 6 hours later, when the sedative effect of azaperone has worn out, the behavior of the sows was scored as follows. Calm: the sow is relaxed, lies on her side and the piglets have free access to the udder. Alert: the sow is alert, lies or sits. Stressed: the sow shows signs of unrest, rises and vocalizes at the slightest noise. Aggressive sows during parturition were injected with azaperone on the spot and excluded from the trial. On each time point, statistical comparison between groups on the ordinal scores was performed by means of the Wilcoxon Mann-Whitney U-test.

In the second study, 22 sows of all parities were treated in the same way as the first study and compared to 11 non treated sows. At 2, 4, 6 and 8 hours after expulsion of placenta, the position of the sow (standing, lying on flank or belly), the accessibility of the udder (fully, half or not accessible) and the number of piglets suckling was recorded. The statistical analysis was performed with SAS\(^{®}\) version 9.1. A generalized linear model was performed to do statistical comparison between groups.

Results

The outcome of the first study is shown in Table 1.

</table>

Non-treated sows show a decrease of calm behavior after farrowing, while the opposite is seen in the treated group.

In the second study, no difference was recorded in positioning of sow except for a decreased number of azaperone treated sows lying on their belly compared to non-treated sows (14% vs. 27%) at 4 hours. This also reflected in less hidden udders in the azaperone treated group.

Figure 1 shows the evolution of percentage of piglets suckling at observation.

At 2 and 4 hours, there is a statistically significant increase in piglets that are suckling in the azaperone treated group.

Discussion

The results indicate that sow behavior during the first critical hours after farrowing influences the accessibility of the udder for the piglets. The azaperone treated sows allowed more piglets to suckle during the first critical hours. This may impact the survival rate and piglet growth. The effect was independent of parity. The present studies showed that an injection of azaperone at expulsion of placenta has positive effect on sow behavior and on sow-piglet interaction, facilitating the piglets to suckle during the early colostrum phase.
