(Received 11 July 2011; accepted 4 August 2011; published online 19 August 2011)

We present a non-invasive broadband air photonic method of imaging of the electric field of THz pulses propagating inside a tapered parallel plate waveguide. The method is based on field-enhanced second harmonic generation of the fundamental laser beam in an external electric field. We apply the technique to measure the frequency-dependent reflection coefficient at the end of the waveguide. © 2011 American Institute of Physics [doi:10.1063/1.3628340]

Guiding of terahertz (THz) waves by various structures is a topic of extensive investigation.1 Due to its unique properties such as dispersionless propagation of the TEM mode with no frequency cut-off, the parallel plate waveguide (PPWG) has attracted significant attention.2–5 Recently, a tapered parallel plate waveguide (TPPWG) has been proposed.6–8 THz waves can be confined inside a TPPWG on subwavelength scale in both transverse dimensions,9 thus enabling THz near-field spectroscopy with subwavelength resolution. The TPPWG also offers significant field enhancement and, thus, has a big potential for investigation of nonlinear THz phenomena with tabletop laser sources, which in recent years has become a very active research field. For experimental characterization of the TPPWG, it is necessary to characterize the electric field distribution inside the waveguide. Recently, a method based on scattering of the field from needle tip inserted into the waveguide was demonstrated.10

In this paper, we present a non-invasive method for characterization of the propagating electric field inside a TPPWG. We adapt the air bias coherent detection (ABCD) technique11 and apply it to a TPPWG in order to image the THz electric field distribution inside the waveguide along the propagation direction without disturbing the propagation of the guided THz wave. As an application of the method, we demonstrate the direct measurement of the reflection coefficient for the THz wave at the end of the waveguide.

Figure 1 shows the schematic of the experimental setup. The TPPWG consists of two electrically isolated, fine polished aluminum plates of a varying width (input 3 mm, output 49 μm) and a varying plate separation (input 1 mm, output 200 μm). The total length of the TPPWG is 25.4 mm. A high voltage modulator (HVM) delivering ±100 V at 500 Hz (synchronized with first subharmonic of the laser repetition rate) is connected to the waveguide plates. The applied voltage results in an electric bias field of 6.5 kV/cm at the point of the narrowest gap between metal plates. Broadband THz pulses generated by tilted pulsefront optical rectification in LiNbO3 (Ref. 12) are coupled into the TPPWG at the wide end of the waveguide. The THz wave propagates between aluminum plates in a TEM mode and then couples out into the free space at the narrow end of the waveguide. A near-infrared (NIR) beam from a 1 kHz, 90 fs, 800 nm regenerative Ti:sapphire femtosecond laser amplifier (Spectra-Physics Hurricane) is used for probing the THz field between the plates of the waveguide. The NIR beam is focused in the center of the volume between the plates with a 19 mm-focal length lens (L1) and recollimated after the waveguide with lens L2. The beam waist at the focus point has been estimated to be 6.5 μm and the Rayleigh range is 41 μm. The highest NIR pulse energy limited to 18 μJ in order to avoid ionization of the air. This part of the setup is mounted on a translation stage that enables scanning along the waveguide (z direction). The beam is sent through 400 nm bandpass filters to a photomultiplier tube (PMT) which detects the 400-nm light generated in the ABCD process. The signal from the PMT is measured by a lock-in amplifier referenced to the HVM modulation frequency. We apply the technique to measure the frequency-dependent reflection coefficient at the end of the waveguide.

Coherent detection of THz radiation is based on the interaction between the laser pulse Iω and the THz electric field ETHz in the presence of the external oscillating electric field Ebias. According to Karpowicz et al.,11 the intensity I2ω(τ, t) of the SH generated at the point (r, t) as a result of such an interaction can be expressed by

$$I_{2\omega}(\tau, t) \propto 4|\chi^{(3)}I_{\omega}(\tau, t)|^2 E_{bias}(\tau, t) E_{THz}(\tau, t),$$

where $\chi^{(3)}$ is the third-order nonlinear susceptibility of the gas. We assume that $E_{bias}$ is constant during the interaction time between the THz transient and the probe pulse.

In the standard ABCD configuration, the probe pulse and the THz transient propagate collinearly through the area of a bias field. For a given THz-probe delay time τ, each point of the NIR probe interacts with the same part of a THz waveform through out the whole interaction length. Thus, the detected SH intensity $I_{2\omega}(\tau)$ is proportional to the time convolution between the THz waveform $E_{THz}(t)$ and the square of probe intensity $P_{\omega}(t)$.

$$I_{2\omega}(\tau) \propto E_{bias} \int E_{THz}(t) P_{\omega}(\tau - t) dt.$$

In our configuration, the THz transient and the probe pulse propagate in perpendicular directions. In this case for a given

a)Electronic mail: kiwa@fotonik.dtu.dk.
THz-probe delay time \( \tau \), each point of the NIR probe interacts with a moving THz waveform and the intensity \( I_{2\omega}(\tau) \) of the generated SH is expressed as

\[
I_{2\omega}(\tau) \propto \int E_{\text{bias}}(\vec{r}) \left( \int E_{\text{THz}}(t, \vec{r}) I_{\omega}^2(t + \tau, \vec{r}) dt \right) d^3 \vec{r} . \tag{3}
\]

In the above, the inner integral is a temporal cross-correlation between the THz transient and the square of the probe beam intensity at the space point \( \vec{r} \), while the outer integral sums the contributions from each point of the interaction volume.

We now consider our case of a 800 nm, 90 fs-long pulse in a focused Gaussian beam of waist 6.5 \( \mu m \) and a Rayleigh range of 41 \( \mu m \). The beam is focused in an uniform THz field restrained to a volume of thickness \( L_x \) (inset in Fig. 2(a)). The maximum induced SH \( I_{2\omega \text{max}} \) as a function of \( L_x \), calculated with Eq. (3) is shown in Fig. 2(a). A single-cycle THz transient with frequency components in the range 0.05-3.0 THz was used for the calculations. For \( L_x \) shorter than the Rayleigh range, the interaction length between the THz wave and the probe is defined by \( L_x \). In the opposite limit of \( L_x \) longer than the Rayleigh range, \( I_{2\omega} \) saturates. The interaction length is then limited by the geometrical dimensions of the focus of the probe beam, as indicated by the quadratic dependence of \( I_{\omega} \) in Eq. (3). This is valid as long as the wavelength of highest frequency components within the THz transient is shorter than the Rayleigh range of the probe beam. The response function \( R(f) = I_{2\omega}(f)/E_{\text{THz}}(f) \), which describes the spectral response, has been evaluated for different widths of the THz region as shown in Fig. 2(b). For small \( L_x \), the response function is monotonously decreasing with frequency. For larger \( L_x \), the effects of positive and negative parts of the THz waveform can interfere leading to sharp dips in the response.

In Fig. 3(a), we show a 2D map of THz induced SH \( I_{2\omega}(t, z) \) as a function of the THz transient-probe delay time \( t \) for different positions \( z \) of the probe beam along the waveguide can be obtained. Two THz transients are visible in the plot: the first transient, centered at 5 ps time delay, is the incident pulse propagating inside the waveguide. The second transient, propagating in the opposite direction, originates from the reflection at the waveguide end (position \( z = 0 \) mm) due to the impedance mismatch between the waveguide (\( z < 0 \)) and free space (\( z > 0 \)). Values of \( I_{2\omega}(t, z) \) for \( z < 0 \) have been corrected for the local bias field \( E_{\text{bias}}(z) \), which changes with the plate separation. We have to note that for \( z > 0 \) (outside the waveguide), the bias electric field quickly decays, which leads to vanishing \( I_{2\omega}(t, z) \). Fig. 3(b) shows the retrieved and simulated peak value of THz electric field as a function of NIR probe position \( z \) along the waveguide. To calculate \( E_{\text{THz}}(t, z) \), the values of \( I_{2\omega}(t, z) \) have been corrected using the width of metal plates (and correspondingly by the interaction length \( L_x(z) \)) according to the dependence from Fig. 2(a). The time-domain numerical simulation was performed with CST Microwave Studio for a TPPWG made of aluminum treated as a lossy metal with conductivity of \( \sigma = 3.56 \cdot 10^7 \) S/m. The simulation agrees well with the measurement except for \( z > 0 \) where the fast decrease in the measured value is caused by the rapid decay of \( E_{\text{bias}} \) outside the waveguide. The dip at \( z = -0.15 \) mm has its origins in the interference between incident and reflected waves. The shape of the TPPWG structure can cause field enhancement in the proximity of the waveguide edges (propagating THz edge plasmons), while the calculated value of \( E_{\text{THz}}(t, z) \) is an integrated value of the THz electric field along the probe direction within the interaction volume. If additional freedom of the scanning stage movement along directions \( x \) and \( y \) is available, then edge enhancement effects can also be investigated using our method, with a transverse resolution determined by the Rayleigh range of the probe beam.
Fig. 4 shows the measured frequency dependent amplitude reflection coefficient \( C(f) = \frac{E_{\text{refl}}(f)}{E_{\text{inc}}(f)} \) at the waveguide end together with the result of a numerical simulation. For a good temporal separation between the incident and reflected pulses, the data (shown at the inset to the Fig. 4) are taken at a point \( z = 0.9 \text{ mm} \) from the waveguide end. That implies that the presented reflection coefficient \( C \) includes not only reflection but also propagation effects, such as ohmic losses and wave scattering, which will lead to additional reduction of the amplitude of the reflected field. The reflection of the THz wave is caused by impedance mismatch between free space \( Z_0 = 377 \Omega \) and the waveguide \( Z_{\text{PPWG}} = \sqrt{(R + i\omega L)/(G + i\omega C)} \), where \( R, L, G, C \) are correspondingly distributed resistance, inductance, conductance, and capacitance of the waveguide. We observe that the reflection coefficient \( \Gamma = (Z_{\text{PPWG}} - Z_0)/(Z_{\text{PPWG}} + Z_0) \) decreases with increasing THz frequency. We find good agreement between measurement and simulation in the frequency range 0.1–0.5 THz. At higher frequencies, the measured reflection coefficient \( \Gamma \) is smaller than theoretically predicted. This can be caused by the increased wave scattering (especially important at higher frequencies and at interfaces)\(^{13}\) and increased ohmic losses at higher frequencies.

In conclusion, we have presented a non-invasive broadband method of imaging of the THz field inside PPWGs. The method does not disturb the propagating THz field as exemplified by the measurement of the THz reflection coefficient from the tip of the waveguide. The resolution of the method is restricted by the geometrical dimensions of the NIR probe focus spot only, while the frequency response depends on the interaction length between THz and the NIR probe.

We are grateful to Martin Nielsen and Frank Persson for manufacturing the tapered parallel plate waveguide and to the Idella Foundation, Danish Defense Acquisition and Logistics Organization, and Danish Research Council for Technology and Production Science NIM bus project for financial support.
