We derive analytical expressions for the three-dimensional (3D) acoustophoretic motion of spherical microparticles in rectangular microchannels. The motion is generated by the acoustic radiation force and the acoustic streaming-induced drag force. In contrast to the classical theory of Rayleigh streaming in shallow, infinite, parallel-plate channels, our theory does include the effect of the microchannel side walls. The resulting predictions agree well with numerics and experimental measurements of the acoustophoretic motion of polystyrene spheres with nominal diameters of 0.537 and 5.33 μm. The 3D particle motion was recorded using astigmatism particle tracking velocimetry under controlled thermal and acoustic conditions in a long, straight, rectangular microchannel actuated in one of its transverse standing ultrasound-wave resonance modes with one or two half-wavelengths. The acoustic energy density is calibrated in situ based on measurements of the radiation dominated motion of large 5-μm-diameter particles, allowing for quantitative comparison between theoretical predictions and measurements of the streaming-induced motion of small 0.5-μm-diameter particles.

I. INTRODUCTION

Acoustofluidics is gaining increasing interest in lab-on-a-chip and microfluidics applications. Techniques based on acoustofluidic forces permit us to perform a large variety of different tasks such as trapping, separation and sorting of cells, particle manipulation, and generation of fluid motion in a non-intrusive way [1,2]. Acoustic forces allow for nondestructive and label-free particle handling based on size, density, and compressibility. Experimentally, the acoustophoretic motion of particles is driven by an ultrasonic standing wave that generates acoustic radiation forces on the particles and acoustic streaming in the fluid, which exerts a Stokes drag force on the particles. Theoretically, such phenomena are described by complex, nonlinear governing equations sensitive to the boundary conditions and are thereby difficult to predict. Therefore, the development of analytical and numerical methods that are able to accurately predict the acoustophoretic motion of different particle or cell types is currently a major challenge in the design of acoustofluidic systems.

Regarding the acoustic radiation force on microparticles, recent theoretical studies by Doinikov [3], Danilov and Mironov [4], as well as Settnes and Bruus [5] have advanced the theoretical treatment, beyond the seminal contributions by Doinikov [3], Danilov and Mironov [4], as well as Settnes and Bruus [5]. We use these models without any new contributions. However, so far theoretical treatments of the acoustic streaming generated by standing acoustic waves have not included an analysis of the effect of the vertical sidewall in rectangular microchannels, instead the focus has been on the idealized parallel-plate geometry [9–14] or single-wall systems [15–18]. Also, in most theoretical work either the radiation force or the streaming effects have been studied separately, but not combined with wall effects to obtain a complete description of microparticle acoustophoresis. Recently, a number of numerical studies of acoustic streaming [19–21] and acoustophoresis [22,23] have appeared in the literature. In this work, we present a theoretical analysis of acoustic streaming, taking the effect of the vertical sidewalls into account, and apply it to a theoretical study of microparticle acoustophoresis in rectangular microchannels.

To guide and control the theoretical developments, precise experimental measurements of the acoustophoretic motion of microparticles are necessary, and particle-based velocimetry techniques are among the best methods available. The work of Hagsäter et al. [24] was one of the first to use microparticle image velocimetry (μPIV) in resonant microfluidic chips. In their case, the measurements were employed to visualize the resonance modes in the microchip, using the radiation-dominated horizontal motion of 5-μm-diameter particles and the associated horizontal acoustic streaming pattern using 1-μm-diameter particles. Using a similar μPIV technique, Manneberg et al. [25] characterized multiple localized ultrasonic manipulation functions in a single microchips. Barnkob et al. [26] and Koklu et al. [27] also studied acoustophoretic motion of large particles (5- and 4-μm-diameter, respectively), but instead used particle tracking velocimetry (PTV) to obtain particle paths, which were compared with theoretical results. Later, Augustsson et al. [28] employed both PTV and μPIV to make high-accuracy measurements of the acoustic energy density as well as the temperature and frequency dependence of acoustic resonances in microchannels filled with 5-μm-diameter particles dominated by the radiation force. Such approaches have successfully been applied to the two-dimensional (2D) motion of particles in the optical focal plane in simple geometries and resonances. Recently, Dron et al. [29] used defocusing of particle images to measure...
the magnitude of radiation-dominated acoustophoretic particle velocities parallel to the optical axis in similar simple half-wave resonance systems. However, in more complex configurations, or in the case of small particles dragged along by acoustic streaming rolls, more advanced techniques are necessary, which are able to resolve three-dimensional (3D) particle positions and three-component (3C) motion. Among these techniques, those based on µPIV have issues regarding the depth of correlation between adjacent planes [30, 31], while classical 3D particle tracking techniques require either stereomicroscopes with tedious calibration protocols, or fast confocal microscopes with great losses in light intensity due to the use of pinholes [32].

In this work, an analytical and experimental analysis is presented with the aim to improve the understanding of the full 3D character of ultrasound-induced acoustophoretic motion of microparticles. In particular, analytical expressions for this motion are obtained by extending the classical results for Rayleigh streaming in shallow parallel-plate channels to also cover rectangular channels of experimental relevance. The analytical results are compared with measurements of the 3D motion of particles in an acoustofluidic microchip performed by use of astigmatism particle tracking velocimetry (APTV) [33–35]. APTV is a very precise single-camera tracking method which allows a time-resolved, reconstruction in 3D of the trajectories of microparticles in acoustophoretic motion. The technique is applicable to general 3D acoustophoretic motion of microparticles influenced by both the acoustic radiation force and the Stokes drag from acoustic streaming.

The paper is organized as follows. In Sec. II we derive an analytical expression of acoustic streaming in long, straight channels with rectangular cross section, and we analyze the implications of this streaming for acoustophoretic motion of suspended microparticles. This is followed in Sec. III by a description of the experimental methods, in particular the astigmatism particle tracking velocimetry technique. In Sec. IV we compare the theoretical and experimental results for the acoustophoretic microparticle motion, and finally in Secs. V and VI we discuss the results and state our conclusions.

II. THEORY

The governing perturbation equations for the thermoacousticic fields are standard textbook material [36–38]. The full acoustic problem in a fluid, which before the presence of any acoustic wave is quiescent with constant temperature $T_0$, density $\rho_0$, and pressure $p_0$, is described by the four scalar fields temperature $T$, density $\rho$, pressure $p$, and entropy $s$ per mass unit as well as the velocity vector field $v$. Changes in $\rho$ and $s$ are given by the two thermodynamic relations

$$d\rho = \gamma \kappa_s \rho \, dT,$$

$$ds = \frac{c_p}{T} \, dT - \alpha_p \rho \, dT,$$

which besides the specific heat capacity $c_p$ at constant pressure also contain the specific heat capacity ratio $\gamma$, the isentropic compressibility $\kappa_s$, and the isobaric thermal expansion coefficient $\alpha_p$ given by

$$\gamma = \frac{c_p}{c_v} = 1 + \frac{\alpha_p^2 T_0}{\rho_0 c_p \kappa_s},$$

$$\kappa_s = \frac{1}{\rho_0} \left( \frac{\partial \rho}{\partial p} \right)_s,$$

$$\alpha_p = -\frac{1}{\rho_0} \left( \frac{\partial \rho}{\partial T} \right)_p.$$

The energy (heat), mass (continuity), and momentum (Navier-Stokes) equations take the form

$$\rho T [\partial_t + (v \cdot \nabla)] s = \sigma \cdot \nabla v + \nabla \cdot (k_b \nabla T),$$

$$\partial_t \rho = -\nabla \cdot (\rho v),$$

$$\rho [\partial_t + v \cdot \nabla] v = -\nabla p + \nabla \cdot \left[ \eta \nabla v + (\nabla v)^T \right] + (\beta - 1) \nabla (\rho T),$$

where $\eta$ is the dynamic viscosity, $\beta$ is the viscosity ratio, which has the value 2/3 for simple liquids [36], $k_b$ is the thermal conductivity, and $\sigma$ is the viscous stress tensor. As in Ref. [22], we model the external ultrasound actuation through boundary conditions of amplitude $v_{bc}$ on the first-order velocity $v_1$ while keeping $T$ constant,

$$T = T_0 \quad \text{on all walls},$$

$$v = 0 \quad \text{on all walls},$$

$$n \cdot v_1 = v_{bc}(y,z) e^{-i\omega t} \quad \text{added to actuated walls}. \quad (4c)$$

Here, $n$ is the outward pointing surface normal vector, and $\omega$ is the angular frequency characterizing the harmonic time dependence written using complex notation.

A. First-order fields in the bulk

To first order in the amplitude $v_{bc}$ of the imposed ultrasound field we can substitute the first-order fields $\rho_1$ and $s_1$ in the governing equation (3) using Eq. (1). The heat transfer equation for $T_1$, the kinematic continuity equation expressed in terms of $p_1$, and the dynamic Navier-Stokes equation for $v_1$ then become

$$\partial_t T_1 = D_b \nabla^2 T_1 + \frac{\alpha_p T_0}{\rho_0 c_p} \partial_t p_1,$$

$$\partial_t p_1 = \frac{1}{\gamma \kappa_s} \left[ \sigma \partial_t T_1 - \nabla \cdot v_1 \right],$$

$$\partial_t v_1 = -\frac{1}{\rho_0} \nabla p_1 + v \nabla^2 v_1 + \beta v \nabla (\nabla \cdot v_1).$$

Here, $D_b = k_b / (\rho_0 c_p)$ is the thermal diffusivity, and $v = \eta_0 / \rho_0$ is the kinematic viscosity. A further simplification can be obtained when assuming that all first-order fields have a harmonic time dependence $e^{-i\omega t}$ inherited from the imposed ultrasound field (4c). Then, $p_1$ can be eliminated by inserting Eq. (5b), substituting $\partial_t p_1 = - \omega \rho_1$, into Eqs. (5a) and (5c). Solutions of Eq. (5) describe the formation of thin thermoviscous boundary layers at rigid walls. In the viscous boundary layer of thickness

$$\delta = \sqrt{\frac{\bar{\rho} v^2}{\omega}},$$
beam. The bulk liquid (light shade) supports a horizontal standing sinusoidal pressure half-wave \( p_1 \) (dashed lines) of wavelength \( \lambda \) in the horizontal direction parallel to the walls. In the viscous boundary layers (dark shade) of submicrometer thickness \( \delta \), large shear stresses appear, which generate the boundary-layer (Schlichting) streaming rolls (black thin lines). Only the top and bottom walls are subject to this effective slip boundary condition.

The spatial form of the standing-wave resonance is determined entirely by the resonance frequency and the geometry of the resonator, while its amplitude (here \( v_s \approx 10^4 v_{bc} \) [22]) is governed by the specific form of \( v_{bc} \) and of the \( Q \) factor of the resonance cavity. The acoustic energy density \( E_{ac} \) is constant throughout the cavity and given by

\[
E_{ac} = \frac{1}{2} \rho_0 v_s^2 = \frac{1}{2} k_0 p_0^2.
\]

B. Second-order governing equations for \( v_2 \)

In a typical experiment on microparticle acoustophoresis, the microsecond time scale of the ultrasound oscillations is not resolved. It therefore suffices to treat only the time-averaged equations. The time average over a full oscillation period, denoted by the angled brackets \( \langle \ldots \rangle \), of the second-order continuity equation and Navier-Stokes equation becomes

\[
\rho_0 \nabla \cdot (v_2) = -\nabla \cdot (\rho_1 v_1),
\]

\[
\eta_0 \nabla^2 (v_2) + \beta \eta_0 \nabla(\nabla \cdot (v_2)) - \nabla \langle \rho_2 \rangle = \langle \rho_1 \partial_t v_1 \rangle + \rho_0 \langle (v_1 \cdot \nabla) v_1 \rangle - \langle \eta \nabla^2 v_1 \rangle - \langle \beta \eta \nabla (\nabla \cdot v_1) \rangle - \langle (\beta - 1)(\nabla \cdot v_1) \rangle \nabla \eta_1 \rangle.
\]

Here, \( \eta_1 \) is the perturbation of the dynamic viscosity due to temperature, \( \eta = \eta_0 + \eta_1 = \eta(T_0) + [\partial \eta \eta(T_0)] T \). From Eq. (9) we notice that second-order temperature effects enter only through products of first-order fields. Dimensional analysis leads to a natural velocity scale \( u_0 \) for second-order phenomena given by

\[
u_0 = \frac{4 E_{ac}}{\rho_0 c_0} = \frac{v_s^2}{c_0}.
\]

C. Boundary condition for bulk streaming flow

The second-order problem (9) was solved analytically by Lord Rayleigh [9,39] in the isothermal case \( T = T_0 \) for the infinite parallel-plate channel in the \( yz \) plane with the imposed first-order bulk velocity \( v_1 \) [Eq. (7a)]. The resulting \( y \) component \( \langle v_{2y}^{\text{bnd}} \rangle \) of \( v_2 \) just outside the boundary layers at the top and bottom walls becomes

\[
\langle v_{2y}^{\text{bnd}} \rangle = -v_{st} \sin \left[ n\pi \left( \frac{2y}{w} + 1 \right) \right],
\]

as sketched in 1 for the half-wave \( k_1 = \pi / w \). In Rayleigh’s isothermal derivation, the amplitude \( v_{st} \) of the streaming velocity boundary condition \( \langle v_{2y}^{\text{bnd}} \rangle \) becomes

\[
v_{st}^0 = \frac{3}{8} \frac{v_s^2}{c_0} = \frac{3}{8} u_0,
\]

where the superscript “0” refers to isothermal conditions. Recently, Rednikov and Sadhal [18] extended this analysis by including the oscillating thermal field \( T_1 \) as well as the temperature dependence \( \eta_1(T) \) of the viscosity. They found that the amplitude of the streaming velocity boundary condition \( v_{st}^T \) then becomes

\[
v_{st}^T = \frac{8}{3} K^T v_{st}^0 = K^T u_0,
\]

\[
K^T = \frac{3}{8} + \frac{\gamma - 1}{4} \left[ \frac{1 - (\partial_T \eta)_{\rho}}{\eta_0 \alpha_{\rho}} \right] \sqrt{v/D_{th}},
\]

where the superscript “\( T \)” refers to inclusion of thermoviscous effects leading to a temperature-dependent pre-factor multiplying the temperature-independent result. For water at 25 °C we find \( v_{st}^T = 1.26 v_{st}^0 \) using the material parameter values of Table I, and in all calculations below we use this thermoviscous value for \( v_{st} \).
TABLE I. Model parameters for water and polystyrene given at temperature $T = 25^\circ\mathrm{C}$ and taken from the literature as indicated or derived based on these.

$(\rho_1 v_1) = 0$, and the source term in the second-order continuity equation (9a) vanishes. As a result, the time-averaged second-order velocity field $\langle v_2 \rangle$ is divergence free or incompressible in the bulk. Hence, the continuity equation and the Navier-Stokes equation for the bulk streaming velocity field $\langle v_2 \rangle$ reduce to

$$\nabla \cdot \langle v_2 \rangle = 0, \quad (14a)$$

$$\eta_0 \nabla^2 \langle v_2 \rangle - \nabla \cdot \langle \nabla \rho_1 \partial_t v_1 \rangle + \rho_0 \langle (\mathbf{v}_1 \cdot \nabla) v_1 \rangle - \langle \eta_1 \nabla^2 v_1 \rangle - \langle \beta \eta_1 \nabla (\nabla \cdot v_1) \rangle - \langle \nabla \eta_1 \cdot [\nabla v_1 + (\nabla v_1)^T] \rangle - \langle \beta - 1 \rangle (\nabla \cdot v_1) \nabla \eta_1 \rangle. \quad (14b)$$

Only the y component of the source terms on the right-hand side of Eq. (14b) is nonzero in the bulk, and it depends only on $\mathbf{y}$ and not on $\mathbf{z}$. Consequently, their rotation is zero, and they can be reformulated as a gradient term absorbed together with $\nabla \cdot \langle \nabla \rangle$ into an effective pressure gradient $\nabla \Pi$ given by

$$\nabla \cdot \langle v_2 \rangle = \nabla \cdot \langle \nabla \rho_1 \partial_t v_1 \rangle + \rho_0 \langle (\mathbf{v}_1 \cdot \nabla) v_1 \rangle - \langle \eta_1 \nabla^2 v_1 \rangle - \langle \beta \eta_1 \nabla (\nabla \cdot v_1) \rangle - \langle \nabla \eta_1 \cdot [\nabla v_1 + (\nabla v_1)^T] \rangle - \langle \beta - 1 \rangle (\nabla \cdot v_1) \nabla \eta_1 \rangle. \quad (15)$$

Using this, the system of bulk equations reduces to the standard equation of incompressible creeping flow

$$\nabla \cdot \langle v_2 \rangle = 0, \quad (16a)$$

$$\eta_0 \nabla^2 \langle v_2 \rangle = \nabla \Pi. \quad (16b)$$

These equations together with appropriate boundary conditions, to be discussed below, govern the steady bulk streaming velocity field $\langle v_2 \rangle$ in the microchannel.

E. Streaming in a parallel-plate channel

Based on Rayleigh’s analysis, we first study the analytical solution for $\langle v_2 \rangle$ in the special case of a standing half-wave ($n = 1$) in the parallel-plate channel shown in 1. We choose the symmetric coordinate system such that $-w/2 < y < w/2$ and $-h/2 < z < h/2$, and introduce nondimensionalized coordinates $\tilde{y}$ and $\tilde{z}$ by

$$\tilde{y} = \frac{2y}{w} \quad \text{with} \quad -1 < \tilde{y} < 1, \quad (17a)$$

$$\tilde{z} = \frac{2z}{h} \quad \text{with} \quad -1 < \tilde{z} < 1, \quad (17b)$$

$$\alpha = \frac{h}{w} \quad \text{the aspect ratio}. \quad (17c)$$

In this case, using Eq. (11), the boundary conditions for $\langle v_2(\tilde{y}, \tilde{z}) \rangle$ are

$$\langle v_{2y}(\tilde{y}, \tilde{z}) \rangle = v_{st} \sin(\pi \tilde{y}) \quad \text{for} \quad \tilde{z} = \pm 1, \quad (18a)$$

$$\langle v_{2z}(\tilde{y}, \tilde{z}) \rangle = 0 \quad \text{for} \quad \tilde{z} = \pm 1, \quad (18b)$$

$$\langle v_{2y}(\tilde{y}, \tilde{z}) \rangle = 0 \quad \text{for} \quad \tilde{y} = \pm 1, \quad (18c)$$

$$\partial_{\tilde{y}} \langle v_{2z} \rangle = 0 \quad \text{for} \quad \tilde{y} = \pm 1, \quad (18d)$$

where Eqs. (18c) and (18d) express the symmetry condition at the wall-less vertical planes at $\tilde{y} = \pm 1$. Rayleigh focused his analysis of the parallel plate geometry on shallow channels for which $\alpha \ll 1$. Here, $\alpha = 0.4$, derived from the aspect ratio of the microchannel described in Sec. III and in Refs. [26,28,45], and consequently we need to solve the case of arbitrary $\alpha$. We find

$$\langle v_{2y}(\tilde{y}, \tilde{z}) \rangle = v_{st} \sin(\pi \tilde{y}) A^{+}(\alpha, \tilde{z}), \quad (19a)$$

$$\langle v_{2z}(\tilde{y}, \tilde{z}) \rangle = v_{st} \cos(\pi \tilde{y}) A^{-}(\alpha, \tilde{z}), \quad (19b)$$

where the $\alpha$- and $\tilde{z}$-dependent amplitude functions $A^{+}$ and $A^{-}$ for the velocity component parallel and perpendicular to the first-order wave, respectively, are given by

$$A^{+}(\alpha, \tilde{z}) = \frac{B(\alpha)}{2\pi^2 \sinh(\pi \alpha \tilde{z})} \left[ \sinh(\pi \alpha \tilde{z}) \right] \left( 1 - \pi \alpha \cosh(\pi \alpha \tilde{z}) \right), \quad (20a)$$

$$A^{-}(\alpha, \tilde{z}) = \frac{B(\alpha)}{\pi \alpha \sinh(\pi \alpha \tilde{z})} \left( \sinh(\pi \alpha \tilde{z}) \right), \quad (20b)$$

$$B(\alpha) = \frac{\sinh(\pi \alpha)}{\sinh(\pi \alpha \tilde{z})}, \quad (20c)$$

with $A^{+}(\alpha, \pm 1) = 1$ and $A^{-}(\alpha, \pm 1) = 0$. In Rayleigh’s well-cited shallow-channel limit $\alpha \ll 1$, the amplitude functions reduce to

$$A^{+}(\alpha, \tilde{z}) \approx \frac{3}{2} \tilde{z}^2 - \frac{1}{2} \quad \text{for} \quad \alpha \ll 1, \quad (21a)$$

$$A^{-}(\alpha, \tilde{z}) \approx \frac{\pi \alpha}{2} (\tilde{z} - \tilde{z}^3) \quad \text{for} \quad \alpha \ll 1. \quad (21b)$$

The analytical solution of $\langle v_2 \rangle$ for $\lambda/2 = w$ is illustrated in Figs. 2(a) and 2(b) for channel aspect ratios $\alpha = 1.2$ and 0.2. We note that the maximum streaming velocity is near the top and bottom walls. For the shallow channel [Fig. 2(b)], there is furthermore a significant streaming velocity along the
horizontal center line $\tilde{z} = 0$. However, the amplitude of this velocity decreases for increasing aspect ratio $\alpha$ as shown in Fig. 2(d).

This special case of the pure sinusoidal horizontal boundary condition (18a) can readily be generalized to any horizontal boundary condition by a Fourier expansion in wave number

$$k_m = 2\pi / \lambda_m = m\pi / w,$$

where $m$ is a positive integer,

$$\langle v_{2y} \rangle = v_{str} \sin(\pi \tilde{y}) \quad \text{for} \quad \tilde{z} = \pm 1, \quad (22a)$$

$$f(\tilde{y}) = \sum_{m=1}^{\infty} a_m \sin(m\pi \tilde{y}). \quad (22b)$$

As the governing equations (16) for the second-order bulk flow are linear, we can make a straightforward generalization of Eq. (19), and the two velocity components of the superposed solution for $\langle v_2 \rangle$ become

$$\langle v_{2y}(\tilde{y}, \tilde{z}) \rangle = v_{str} \sum_{m=1}^{\infty} a_m \sin(m\pi \tilde{y}) A^1(m\alpha, \tilde{z}), \quad (23a)$$

$$\langle v_{2z}(\tilde{y}, \tilde{z}) \rangle = v_{str} \sum_{m=1}^{\infty} a_m \cos(m\pi \tilde{y}) A^{-1}(m\alpha, \tilde{z}), \quad (23b)$$

where the wave index $m$ multiplies both the horizontal coordinate $\tilde{y}$ and the aspect ratio $\alpha$. Note that $A^1(m\alpha, \pm 1) = 1$ and $A^{-1}(m\alpha, \pm 1) = 0$. The resulting steady effective pressure $\chi$ is just the weighted sum of the partial pressures $\chi_m$ of each Fourier component $\chi = \sum_{m=1}^{\infty} a_m \chi_m$.

In Fig. 2(c) is shown the streaming velocity field for the higher harmonic boundary condition $f(\tilde{y}) = \sin(n\pi \tilde{y})$ with $n = 2$. Furthermore, Fig. 2(e) shows how the maximum $\langle v_{2y}(\tilde{y}, 0) \rangle_{\text{max}}$ of the center-axis streaming velocity decays as a function of aspect ratio $\alpha$ for $n = 1, 2,$ and 3. Given sufficient room, the flow rolls decay in the vertical direction on the length scale of $\lambda_n/4$. Since $n$ is the number of half wavelengths of the first-order resonance pressure across the channel, we conclude that the streaming amplitude in the center of the channel decreases for higher harmonic resonances.

### F. Streaming in a rectangular channel

Moving on to the rectangular channel cross section, we note that the only change in the problem formulation is to substitute the symmetry boundary conditions (18c) and (18d) by no-slip boundary conditions, while keeping the top-bottom slip boundary conditions (18a) and (18b) unaltered:

$$\langle v_{2y} \rangle = v_{str} \sin(\pi \tilde{y}) \quad \text{for} \quad \tilde{z} = \pm 1, \quad (24a)$$

$$\langle v_{2z} \rangle = 0 \quad \text{for} \quad \tilde{z} = \pm 1, \quad (24b)$$

$$\langle v_{2y} \rangle = 0 \quad \text{for} \quad \tilde{y} = \pm 1, \quad (24c)$$

$$\langle v_{2z} \rangle = 0 \quad \text{for} \quad \tilde{y} = \pm 1. \quad (24d)$$

If we want to use the solution obtained for the parallel-plate channel, we need to cancel the vertical velocity component $\langle v_{2z} \rangle$ on the vertical walls at $\tilde{y} = \pm 1$. This leads us to consider the problem rotated $90^\circ$, where the first-order velocity field is parallel to the vertical walls (interchanging $y$ and $z$), and the fundamental wavelength is $\lambda/2 = h$, and the aspect ratio is $w / h = \alpha^{-1}$. As the governing equations for the bulk flow (16) are linear, we simply add this kind of solution to the former solution and determine the Fourier expansion coefficients such that the boundary conditions (24) are fulfilled. Given this, (23)

![Graph](image-url)
Introducing the coefficient vectors, the wall in comparison to the parallel-plate channel solution is shown in Fig. 3. It is seen how the velocity profile of the parallel-to-the-wall conditions (24a) becomes

\[
\langle v_{2y} (\tilde{y}, \tilde{z}) \rangle = v_{tr} \sum_{m=1}^{\infty} [ \langle a_m \sin(m\pi \tilde{y}) A^\dagger (m\alpha, \tilde{z}) \rangle + b_m A^\dagger (m\alpha^{-1}, \tilde{y}) \cos(m\pi \tilde{z}) ]. 
\]

(25a)

The two perpendicular-to-the-wall velocity conditions (24b) and (24c) are automatically fulfilled as they by construction are inherited from the original conditions (18b) and (18c). The unknown coefficients \(a_m\) and \(b_m\) are thus to be determined by the parallel-to-the-wall conditions (24a) and (24d).

Using \(\langle v_{2y} \rangle\) in the form of Eq. (25a), boundary condition (24a) becomes

\[
\sin(\pi \tilde{y}) = \sum_{m=1}^{\infty} [ a_m \sin(m\pi \tilde{y}) + (-1)^m b_m A^\dagger (m\alpha^{-1}, \tilde{y}) ]]. 
\]

(26)

The discrete Fourier transform of this equation, i.e., multiplying by \(\sin(j\pi \tilde{y})\), where \(j\) is an arbitrary integer, and integrating over \(\tilde{y}\) from \(-1\) to \(1\), becomes

\[
\delta_{j,1} = \sum_{m=1}^{\infty} \delta_{j,m} a_m + A^\dagger_{j,m} (a^{-1}) b_m, \quad j = 1, 2, 3, \ldots, 
\]

(27)

where the \((j, m)\)th element \(A^\dagger_{j,m}\) of the \(a\)-dependent matrix \(A^\dagger\) is given by

\[
A^\dagger_{j,m} (a^{-1}) = (-1)^m \int_{-1}^{1} d\tilde{y} A^\dagger (m\alpha^{-1}, \tilde{y}) \sin(j\pi \tilde{y}). 
\]

(28)

Introducing the coefficient vectors \(a\) and \(b\) and the first unit vector \(e_1\) with \(m\)th components \(a_m\), \(b_m\), and \(\delta_{1,m}\), respectively, we can write Eq. (27) as the matrix equation

\[
e_1 = a + A^\dagger (a^{-1}) \cdot b. 
\]

(29)

Likewise, using Eq. (25b) and multiplying it by \(\sin(j\pi \tilde{z})\), where \(j\) is an arbitrary integer, and integrating over \(\tilde{z}\) from \(-1\) to \(1\), the zero-parallel-component boundary condition (24d) can be written as the matrix equation

\[
0 = A^\dagger (a) \cdot a + b. 
\]

(30)

Solving the equation systems (29) and (30), the coefficient vectors \(a\) and \(b\) become

\[
a = [I - A^\dagger (a^{-1}) A^\dagger (a)]^{-1} e_1, 
\]

(31a)

\[
b = -A^\dagger (a) \cdot a. 
\]

(31b)

A comparison between results for the classical parallel-plate geometry and the new results for the rectangular geometry is shown in Fig. 3. It is seen how the velocity profile of the rectangular channel solution [Eq. (25)] is suppressed close to the wall in comparison to the parallel-plate channel solution [Eq. (19)]. Note that for the \(n\)th resonance \(\kappa_n = n\pi/\alpha\), the unit vector \(e_1\) in Eq. (31a) is replaced by \((-1)^{n-1} e_n\), with the sign originating from the \(n\)-dependent phase shift in the streaming boundary condition (11).

\[
F_{\text{rad}} = 6\pi \eta a d [\langle v_2 \rangle - u^0] \text{ from the acoustic streaming} \langle v_2 \rangle \text{ and the acoustic radiation force} F_{\text{rad}}. \text{Given an observed maximum acoustophoretic velocity of } u^0 \leq 1 \text{ mm/s for the largest particles of diameter } 2a = 5.0 \mu m, \text{ the Reynolds number for the flow around the particle becomes } \rho_0 2a u^0 / \eta \approx 6 \times 10^{-3}, \text{ and the time scale for acceleration of the particle becomes } \tau_{\text{acc}} = \left[ (4/3)\pi a^3 \rho_p \right] / (6\pi \eta a) \approx 2 \mu s. \text{ Since the acceleration time is much smaller than the time scale for the translation of the particles } \tau_{\text{trans}} = u / (2u^0) \geq 0.1 s, \text{ the inertia of the particle can be neglected, and the quasi-steady-state equation of motion } F_{\text{drag}} = -F_{\text{rad}} \text{ for a spherical particle of velocity } u^0 \text{ then becomes}
\]

\[
u^0 = \frac{F_{\text{rad}}}{6\pi \eta a d} + \langle v_2 \rangle = u^0 + \langle v_2 \rangle, 
\]

(32)

where \(u^0\) is the contribution to the particle velocity from the acoustic radiation force. The streaming velocity \(\langle v_2 \rangle\) is given in the previous sections, while an analytical expression for...
the viscosity-dependent time-averaged radiation force \( F^{\text{rad}} \) in the experimentally relevant limit of the wavelength \( \lambda \) being much larger than both the particle radius \( a \) and the boundary layer thickness \( \delta \) was given recently by Settnes and Brøns [5]. For the case of a 1D transverse pressure resonance [Eq. (7b)], the viscosity-dependent acoustic radiation force on a particle reduces to the \( x \)- and \( z \)-independent expression

\[
F^{\text{rad}}(\hat{\gamma}) = 4\pi a^3 k_0 e_{ac} \Phi(\hat{\kappa}, \hat{\rho}, \hat{\delta}) \sin[n\pi(\hat{y} + 1)] e_y. \tag{33}
\]

The acoustic contrast factor \( \Phi \) is given in terms of the material parameters as

\[
\begin{align*}
\Phi(\hat{\kappa}, \hat{\rho}, \hat{\delta}) &= \frac{1}{3} f_1(\hat{\kappa}) + \frac{1}{2} \text{Re}[f_2(\hat{\rho}, \hat{\delta})], \\
f_1(\hat{\kappa}) &= 1 - \hat{\kappa}, \\
f_2(\hat{\rho}, \hat{\delta}) &= 2[1 - \Gamma(\hat{\delta})](\hat{\rho} - 1), \\
\Gamma(\hat{\delta}) &= -\frac{3}{2} [1 + i(1 + \hat{\delta}^2)],
\end{align*}
\tag{34a-c}
\]

where \( \hat{\kappa} = \kappa_0/\kappa_s, \hat{\rho} = \rho_0/\rho, \) and \( \hat{\delta} = \delta/a \). Using Eq. (33) for the transverse resonance, \( u^{\text{rad}} \) only has a horizontal component \( u^{\text{rad}}_y \),

\[
u^{\text{rad}}_y = u_0 \frac{a^2}{a_0} \sin[n\pi(\hat{y} + 1)], \quad n = 1, 2, 3, \ldots, \tag{35a}
\]

where the characteristic particle radius \( a_0 \) is given by

\[
a_0 = \delta \sqrt{\frac{3}{\Phi}}, \tag{35b}
\]

with \( \delta \) given by Eq. (3). The acoustophoretic particle velocity \( \mathbf{u}^0 \) will in general have nonzero \( z \) components, due to the contribution from the acoustic streaming \( \langle v_2 \rangle \). However, for the special case of particles in the horizontal center plane \( \hat{\gamma} = 0 \) of a parallel-plate or rectangular channel, the vertical streaming velocity component vanishes, \( \langle v_2(\hat{y}, 0) \rangle = 0 \). From Eqs. (19a) and (35a), we find that the horizontal particle velocity component \( u^{\text{rad}}_z(\hat{y}, 0) \) in a parallel-plate channel is given by the sinusoidal expression

\[
u^{\text{rad}}_z(\hat{y}, 0) = u_0 \left[ \frac{a^2}{a_0} - K^T A^4(n\alpha, 0) \right] \sin[n\pi(\hat{y} + 1)]. \tag{36}
\]

Since by Eq. (20a) \( A^4(n\alpha, 0) \) is always negative, it follows that the streaming-induced drag and the radiation force have the same direction in the horizontal center plane of the channel. For the rectangular channel using Eq. (25a), the expression for \( u^{\text{rad}}_z(\hat{y}, 0) \) becomes

\[
u^{\text{rad}}_z(\hat{y}, 0) = u_0 \left\{ \frac{a^2}{a_0} \sin[n\pi(\hat{y} + 1)] + K^T \sum_{m=1}^{\infty} a_m \sin(m\pi \hat{y}) A^4(m\alpha, 0) + b_m A^4(m\alpha^{-1}, \hat{y}) \right\}, \tag{37}
\]

which is not sinusoidal in \( \hat{y} \) but still proportional to \( u_0 \). This particular motion in the ultrasound symmetry plane is studied in detail in Ref. [45].

III. EXPERIMENTS

We have validated experimentally the analytical expressions derived above by measuring trajectories of micrometer-sized polystyrene particles displaced by acoustophoresis in a long, straight silicon-glass microchannel with rectangular cross section. A fully three-dimensional evaluation of the particle trajectories and velocities was performed by means of the astigmatisation particle tracking velocimetry (APTV) technique [33,34] coupled to the temperature-controlled and automated setup presented in Ref. [28]. APTV is a single-camera particle tracking method in which an astigmatic aberration is introduced in the optical system by means of a cylindrical lens placed in front of the camera sensor. Consequently, an image of a spherical particle obtained in such a system shows a characteristic elliptical shape unequivocally related to its depth position \( \hat{z} \). More details about calibration and uncertainty of this technique, as well as comparison with other whole-field velocimetry methods for microflows, can be found in Refs. [34,35].

A. Acoustophoresis microchip

The acoustophoresis microchip used for the experiment was the one previously presented in Refs. [26,28,45]. In Ref. [28] the microchip and the experimental setup are described in details; here, we give a brief description. A rectangular cross section channel \( (L = 35 \text{ mm}, W = 377 \mu \text{m}, h = 157 \mu \text{m}) \) was etched in silicon. A Pyrex lid was anodically bonded to seal the channel and provided the optical access for the microscope. The outer dimensions of the chip are \( L = 35 \text{ mm}, W = 2.52 \text{ mm}, \) and \( H = 1.48 \text{ mm} \). Horizontal fluidic connections were made at the ends of the microchip. From top and down, glued together using ethyl-2-cyanoacrylat (ExpressLim, Akzo Nobel Bygglim AB, Sweden), the chip was placed on top of a piezoceramic transducer (piezo) \( (35 \text{ mm} \times 5 \text{ mm} \times 1 \text{ mm}, \text{PZT}26, \text{ Ferroperm Piezo-ceramics, Denmark}) \), an aluminum slab to distribute heat evenly along the piezo, and a Peltier element \( (40 \text{ mm} \times 40 \text{ mm}, \text{Supercool AB, Sweden}) \) to enable temperature control. The temperature was kept constant at \( 25 ^\circ \text{C}, \) based on readings from a temperature sensor placed near the chip on top of the piezo. This chip stack was mounted on a computer-controlled \( xyz \) stage. Ultrasound vibrations propagating in the microchip were generated in the piezo by applying an amplified sinusoidal voltage from a function generator, and the resulting piezo voltage \( U_{pp} \) was monitored using an oscilloscope.

B. APTV setup and method

The images of the particles in the microfluidic chip were taken using an epifluorescent microscope (DM2500 M, Leica Microsystems CMS GmbH, Wetzlar, Germany) in combination with a 12-bit, 1376 \( \times \) 1040 pixels, interline transfer CCD camera (Sensicam QE, PCO GmbH). The optical arrangement consisted of a principal objective lens with 20\( \times \) magnification and 0.4 numerical aperture and a cylindrical lens with focal length \( f_{\text{cyl}} = 150 \text{ mm} \) placed in front of the CCD sensor of the camera. This configuration provided a measurement volume of \( 900 \times 600 \times 120 \mu \text{m}^3 \) with an estimated uncertainty in the particle position determination of \( \pm 1 \mu \text{m} \) in the \( z \) direction.

023006-7
and less than ±0.1 μm in the x and y directions. Two scan positions along the z direction were used to cover the whole cross-sectional area of the channel.

Monodisperse spherical polystyrene particles with nominal diameters of 5.33 μm (SD 0.09) and 0.537 μm (PDI 0.005) were used for the experiments (ρps = 1050 kgm⁻³ and κps = 249 TPa⁻¹). For simplicity we will refer to them as 5-μm-diameter and 0.5-μm-diameter particles, respectively. The particles were fabricated and labeled with a proprietary fluorescent dye by Microparticles GmbH to be visualized with an epifluorescent microscopy system. The illumination was provided by a continuous diode-pumped laser with 2 W at 532 nm wavelength.

Once the particle 3D positions had been detected using the APTV technique, their trajectories and velocities were calculated. Due to the low seeding density in the experiments, the particle interdistance was large enough to employ a simple nearest-neighbor approach in which the particle in one frame is identified with the closest particle in the next frame. The method was compared with more sophisticated ones as predictors and probabilistic algorithms with identical results.

IV. RESULTS
A. APTV measurements

Examples of the measured 3D trajectories of the 5-μm-diameter particles are shown in Fig. 4(a). The data were collected from 10 consecutive experiments with the piezo operated at 1.94 MHz and peak-to-peak voltage of Upp = 0.91 V. An overall number of 111 trajectories were determined. The 5-μm-diameter particles are affected mainly by the acoustic radiation force $F_{\text{rad}}$ that quickly pushes them to the center of the channel with a horizontal velocity $u_{y}^{c}$ [24,45]. At the vertical pressure nodal plane $y = 0$, $F_{\text{rad}}$ vanishes and the hitherto negligible drag force from the acoustic streaming, shown in Fig. 2(b), slowly drags the particles towards the top and bottom of the channel.

Examples of the measured 3D trajectories of the 0.5-μm-diameter particles are shown in Fig. 4(b). The data were collected from four consecutive experiments with the piezo operated at 1.94 MHz and peak-to-peak voltage of Upp = 1.62 V. An overall number of 731 trajectories were determined. The acoustic radiation force $F_{\text{rad}}$ is in this case minute and the trajectories present large curvatures and for high-shear flows [47].

The acoustic radiation force $F_{\text{rad}}$ is given by Eq. (36) for the 0.5-μm-diameter particles, by the following three-step procedure.

First, we determined the acoustic energy density $E_{\text{ac}}^{0.5 \mu m}$ through Eqs. (12) and (33). To make a theoretical prediction of the motion of the 0.5-μm-diameter particles, we need to determine the acoustic energy density $E_{\text{ac}}^{0.5 \mu m}$. This calibration was done in situ based on the measurements of the 5-μm-diameter particles, by the following three-step procedure.

First, we determined the acoustic energy density $E_{\text{ac}}^{5 \mu m}$ for the experiment with the 5-μm-diameter particles. This was done by fitting the $\sin(\pi y)$-dependent expression (36) for $u_{y}^{c}(y,0)$ to the measured instantaneous velocities, using the amplitude as the only fitting parameter [26,45]. The small contribution from the acoustic streaming to the 5-μm-diameter-particle velocity was taken into account although it constituted only 6% of the total particle velocity. The fit showed good agreement between theory and experiment, and
after correcting for a wall-enhanced drag coefficient of 1.032 at the horizontal center plane (see Refs. [27,45,49,50]), we extracted the acoustic energy density $E_{ac}^{5,\mu m} = (20.6 \pm 0.7) J/m^3$, where the 1σ standard error of the estimated value is stated. Since both the wall-enhanced drag coefficient and the drag force from the acoustic streaming fluid velocity are height dependent, only five trajectories of 5-μm-diameter particles close to the horizontal center line ($z = 0$) qualified for use in the fit, based on a criterion of $|z_0| \leq 6 \mu m$. The starting positions $(x_0, y_0, z_0)$ of the five tracks were (34 μm, −115 μm, 6 μm), (310 μm, −66 μm, −6 μm), (482 μm, −35 μm, −5 μm), (74 μm, 115 μm, 2 μm), and (350 μm, 128 μm, 0 μm), and they all reached the vertical center plane $y = 0$.

Second, the acoustic energy density $E_{ac}^{0.5,\mu m}$ for the experiment with the 0.5-μm-diameter particles was determined, using the result for $E_{ac}^{5,\mu m}$ combined with the fact that $E_{ac}$ scales as the square of the applied voltage $U_{pp}$ [26]. The measured voltages for the two experiments are $U_{pp}^{0.5,\mu m} = (1.62 \pm 0.01) V$ and $U_{pp}^{5,\mu m} = (0.91 \pm 0.01) V$, where the stated error corresponds to the standard deviation of a series of voltage measurements, with the power turned off in-between each measurement. The derived value for $E_{ac}^{0.5,\mu m}$, taking into account the errors of $U_{pp}^{0.5,\mu m}$, $U_{pp}^{5,\mu m}$, and $E_{ac}^{5,\mu m}$, becomes $E_{ac}^{0.5,\mu m} = (U_{pp}^{0.5,\mu m} / U_{pp}^{5,\mu m}) E_{ac}^{5,\mu m} = (65 \pm 2) J/m^3$, with the contribution from the error of the measured voltages being negligible.

Third, based on Eq. (10), the derived value for the energy density $E_{ac}^{0.5,\mu m}$ is used in the analytical expression for the particle velocities (32). The radiation force is given by Eq. (33) and the acoustic streaming force is given by Eqs. (25) and (31), using the thermoviscous-corrected amplitude $U_{pp}^{\sigma}$ [Eq. (13)]. The contribution from the acoustic radiation force to the 0.5-μm-diameter particle velocity was small and constituted only 12% of the total particle velocity in the horizontal center plane $z = 0$. The contribution from the radiation force to the 0.5-μm-diameter-particle velocity was not corrected for the wall-enhanced drag coefficient since this was minute for these small particles.

To compare the experimental results and the analytical prediction, we consider the 0.5-μm-diameter particle velocities in the vertical cross section, $xyz$ plane, of the channel as in Figs. 1, 2, and 3. In Fig. 5 are shown color plots of (a) the experimentally measured acoustophoretic velocities for the 0.5-μm-diameter particles, (b) the analytical prediction of the same, and (c) the numerical validation of the analytical result using the methods of Muller et al. [22]. The three data sets are shown on the same 37 × 15 bin array and with the same color scale. The experimental and the analytical velocities agree well both qualitatively and quantitatively, although the experimental velocities are approximately 20% higher on average. The experimental results for the particle velocities [Fig. 5(a)] are found as the mean of several measurements of the particle velocity in each bin. The number of measurements performed in each bin is shown in Fig. 6(a), while the standard error of the mean (SEM) particle velocity is shown in Fig. 6(b). These plots show that we typically have between 20 and 70 measurements in each bin and the experimental error is on average only 1 μm/s, while the relative experimental error is on average 4%. The error of the theoretical prediction is given by the relative error of 4% on the estimated value for the energy density $E_{ac}^{0.5,\mu m}$.

FIG. 5. (Color online) Comparison between experimental, analytical, and numerical studies of the acoustophoretic particle velocities $\vec{u}_{p}$ of 0.5-μm-diameter polystyrene particles in water. The particle velocities $\vec{u}_{p}$ (vectors) and their magnitude [color plot ranging from 0 μm/s (black) to 63 μm/s (white) in all three plots] are shown in the vertical cross section of the microchannel, divided into a pixel array consisting of 37 × 15 square bins of side length 10 μm. The axes of the plot coincide with the position of the channel walls. (a) The APTV measurements of the 0.5-μm-diameter particles, shown in Fig. 4(b), projected onto the vertical cross section. The maximum velocity is 63 μm/s. Close to the side walls, experimental data could not be obtained, which is represented by hatched bins. (b) Analytical prediction of $\vec{u}_{p}$ based on Eq. (32), taking both the radiation force and the streaming-induced drag force into account. The first 20 terms of the Fourier series for $(\kappa z)$ [Eq. (25)] have been included in the calculation. The maximum velocity is 59 μm/s. There are no free parameters in this prediction as the acoustic energy density was calibrated in situ based on measurements of large 5-μm-diameter particles, shown in Fig. 4(a). (c) Numerical validation of the analytical result for $\vec{u}_{p}$ using the method described in Muller et al. [22]. The numerical solution has been scaled by the thermoviscous prefactor to the streaming amplitude (13). The maximum velocity is 59 μm/s.

The quantitative differences between the experimental particle velocities [Fig. 5(a)] and the analytical prediction [Fig. 5(b)] are emphasized in Fig. 7, showing the difference $\Delta u_{p}$ between the experimental and analytical acoustophoretic particle speeds

$$\Delta u_{p} = |u_{p}^{\exp} - u_{p}^{\anl}|.$$  (38)

We have chosen to consider the difference of the absolute velocity values $|u_{p}^{\exp} - u_{p}^{\anl}|$ instead of the absolute value of the difference $u_{p}^{\exp} - u_{p}^{\anl}$ because the former allows us to
FIG. 6. (Color online) (a) Color plot of the number of times the velocity has been measured in each square bin. (b) Color plot of standard error of the mean (SEM) particle velocity in each square bin.

see when the experimental velocity respectively overshoots and undershoots the analytical prediction. Figure 7(a) shows a color plot of $\Delta u_p$ in the channel cross section, while Fig. 7(b) shows line plots of $\Delta u_p$ along the dashed lines in Fig. 7(a), allowing for a more detailed study of the spatial dependence of the difference. These lines are chosen to go through the rotation centers of the flow rolls. The error bars in Fig. 7(b) show the $1\sigma$ error of $\Delta u_p$, taking into account both the SEM for the experimental measurements [Fig. 6(b)] and the error of the analytical prediction (4%) inherited from the derived value for $E_0$. The experimental and analytical velocities do not agree within the error of $\Delta u_p$, moreover, a trend of the experimental velocities being larger than the analytical predictions is seen.

A further comparison between the analytical model presented in this paper and experimental measurements on 0.6-μm-diameter polystyrene particles from Ref. [45] is shown in Fig. 8. These particles are dominated by the drag from the acoustic streaming, and in this comparison we are only interested in studying how the side walls influence the shape of $u_p(y,0)$ [Eq. (37)]. Consequently, the amplitude of the streaming velocity, and thus the acoustic energy density, was treated as a fitting parameter. The experimental results support our analytical prediction (37) (thick line) for the rectangular channel with side walls, which shows a suppression of $u_p$ near the walls compared to the sinusoidal form of $u_p$ in Eq. (36) (thin line) predicted for the parallel-plate channel without side walls. This is particularly clear for the full-wave resonance $\lambda = w$ ($n = 2$) [Fig. 8(b)]. The difference in the amplitude of
The experimental measurements and the analytical prediction of the streaming-induced particle velocities. The qualitative agreement is seen in Fig. 5 for the two-dimensional topology of the particle motion, and in Fig. 8 for the effect of the side walls. Quantitatively, the experimental and analytical results agree within a mean relative difference of approximately 20%, a low deviation given state-of-the-art in the field. However, as illustrated by the statistical analysis in Fig. 7, the differences $\Delta u^p$ are larger than the estimated $1\sigma$ errors. This could indicate a minor systematic error in the experimental procedure or in the theoretical model, or be due to underestimation of the experimental error involved in the analytical prediction.

In the 5-μm-diameter-particle experiment, the acoustic energy density is determined using only five particle trajectories close to the channel center $z = 0$. This is reasonable as the error of the calculated energy density is relatively low (3%), however, a calculation based on more particle trajectories would be desirable. This can be realized through more experimental repetitions or through implementation of the 2D dependence of the wall-enhanced drag force, allowing for use of off-center particle trajectories. One source of error that has not yet been discussed arises from the assumption made that the acoustic energy density, and thus the acoustic forces, does not depend on the $x$ position in the investigated field of view. In the same setup, Augustsson et al. [28] observed negligible field gradients in the $x$ direction in some field of views and significant ones in others. This inhomogeneity was considered here when making the measurements: we made sure to check that the five 5-μm-diameter-particle trajectories sample the $x$ range reasonably well and exhibit only negligible variations in the acoustic energy density as a function of the $x$ position.

In the 0.5-μm-diameter-particle experiment, the statistics and sampling of the $x$ range are good, however, they could still be improved to achieve better statistics close to the walls. The relative positions of the 0.5-μm-diameter particles are accurately determined by use of the APTV technique, whereas the absolute position in the channel, which was used to compare with theory, is difficult to determine precisely and might also be improved. Furthermore, accurate measurements of the channel dimensions are also important, as these are key parameters in the theoretical model.

The analytical model could be improved in several ways. The treatment of the liquid could be extended by including thermal dependence of more material parameters such as the specific heat capacity ratio $\gamma$, thermal expansion $\alpha_p$, compressibility $\kappa$, and speed of sound $c_0$. The influence of the surrounding chip material could be included, thereby relaxing the assumptions of infinite acoustic impedance (ideal reflection) and infinite thermal conduction (ideal heat sink) of the channel walls. Solving the full elastic wave problem in the whole chip is beyond analytical solutions, but is, however, possible with numerical models. This might be necessary to achieve accurate quantitative agreement between theoretical predictions and experiments. Furthermore, the analytical and numerical models assume an ideal rectangular channel cross section, which is crucial since the generating mechanism for the acoustic streaming takes place within the μm-thin acoustic boundary layer. Even small defects, such as uneven surfaces on the μm scale, might lead to changes in the acoustic streaming velocity field.

VI. CONCLUSIONS

In this work, we have derived an analytical expression for the acoustophoretic velocity of microparticles resulting from the acoustic radiation force and the acoustic streaming-induced drag force in a rectangular microchannel, and we have successfully compared it with a direct numerical solution of the governing equations. We have also accurately measured 3D trajectories of 0.5-μm-diameter and 5-μm-diameter particles in an acoustically actuated microchannel, with an average relative experimental error of 4% for the 0.5-μm-particle velocities. This allowed us to perform a quantitative comparison in 3D between theory and experiments of streaming-induced particle velocities in a rectangular channel. The analytical derivation successfully predicted the measured streaming-induced 0.5-μm-diameter-particle velocities, with qualitative agreement and quantitative differences around 20%, a low deviation given state-of-the-art in the field. This shows that the time-averaged second-order perturbation model of the governing equations yields an adequate description of the acoustophoretic particle motion.

The differences between the theoretical prediction and the experimental results emphasize the need for further extensions of the analytical model, along with improved numerical simulations [22]. Aiming for more detailed quantitative studies of acoustophoresis, the results also stress the need for improved accuracy of the measurements of the channel dimensions and the absolute positions of the particles in the microchannel. The trinity of analytical, numerical, and experimental studies of the acoustophoretic particle motion enhances the understanding of acoustophoresis and opens up for more elaborate and broader applications.
