Abstract: We demonstrate strong electrical control of plasmonic Fano resonances in dolmen structures using tunable interband transitions in graphene. Such graphene-plasmonic hybrid devices can have applications in light modulation and sensing.

1. Introduction

Graphene plasmonics offers an exciting possibility of combining conventional plasmonics and remarkable electrical and optical properties of graphene[1]. This can help in the realization of a variety of active plasmonic devices. The surface plasmon polariton wavelength in graphene has been shown to be 40-60 times smaller than free space wavelength [2]. Plasmonic nanoantennas were also shown to enhance photosensitivity of graphene [3]. In this direction, we recently demonstrated a graphene-antenna hybrid device for electrically controlling the damping of plasmonic resonance [4]. We used the gate controlled interband transitions to modulate the width of the plasmonic resonance (see also [5]). In this paper we further extend this approach to identify structures that would show enhanced tunability.

2. Numerical Approach and Validation

To design useful devices with graphene it is essential to develop accurate models for numerical simulations. Graphene is vanishingly thin monolayer of sp^2 carbon atoms which poses unique challenges for numerical treatment. In numerical simulations, we can treat graphene as an effective medium with a thickness of 1 nm. We believe an effective thickness of 1 nm is reasonable considering the inhomogenities in CVD-grown graphene, which can lead to a graphene layer that is thicker than the ideal thickness. We obtain the dielectric function, which is commonly used in numerical modeling of optical processes, from the 2D sheet conductivity, $\sigma(\omega)$ derived within the local random-phase approximation [6], as shown below:

$$\epsilon_r(\omega) = \frac{i\sigma(\omega)}{\omega\epsilon_0 t_g}$$

where t_g is effective thickness of graphene sheet, ω is frequency of light and ϵ_0 is the permittivity of vacuum. This approach was validated by comparing with gate-dependent optical transmission measurements which are shown in Fig. 1(a). The incident photon is most sensitive to carrier concentration in graphene when its energy is around $2E_F$. Therefore, we see a matching peak in the normalized transmission spectrum. When the gate voltage is increased then the E_F moves to higher energies or lower wavelengths. A gate voltage of -30V results in $2E_F$ peak at 0.5eV, which corresponds to a carrier density of $4.6 \times 10^{12} \text{ cm}^{-2}$. At low gate voltages we expect the carrier concentration to be below $1 \times 10^{12} \text{ cm}^{-2}$. The full wave simulations performed using Spatial Harmonic Analysis (SHA) [7] method are shown in Fig. 1(b). We see good agreement with the experimental trends except for the discrepancies at longer wavelengths.

3. Tunable Fano Resonances

The tunability of a resonance depends strongly on the strength of interaction between graphene and nanoantennas. After proof of principle demonstration with bowtie antennas [4], we investigated the tunability of Fano resonances in dolmen structure (shown in Fig. 2(a)) [8]. In the dolmen structure overlap of dipolar and quadrupolar modes leads to a Fano resonance, and hence we expect large enhancement associated with a dark mode. With careful selection of geometrical parameters we identified structures resonating between 2.5-3.5 μm . The results of numerical simulations are shown in Fig. 2(b) and 2(c). We note that the stronger enhancement in dolmen structures results in

much stronger impact on plasmonic resonance. In this contribution we will also discuss experimental demonstrations of this enhanced tunability using the simulated designs, which is currently in progress.
