Complex oxides heterostructures have been extensively investigated during the last decade due to the variety of intriguing phenomena occurring at their interface.1–3 The high-electron mobility electron gas formed at the interface between a polar LaAlO3 (LAO) film and a non-polar TiO2-terminated SrTiO3 (STO) substrate triggered a number of investigations on the transport properties of interfaces based on epitaxial polar oxide thin films.4 More recently, it has been demonstrated that metallic interfaces also can be realized by deposition of insulating overlayers of amorphous thin films of LAO, STO, yttria-stabilized zirconia (YSZ), and CaHFO3 on STO single crystal substrates.5,6 Interestingly, all these amorphous films were grown by pulsed laser deposition (PLD), and a strong dependence of their conducting properties on the deposition parameters, especially the background oxygen pressure, was observed.5 The presence of growth-induced oxygen vacancies in the STO substrate was ascertained as the dominant cause for the interfacial conductivity of these amorphous/crystalline oxide heterostructures. In particular, Chen et al. suggested a mechanism where oxygen vacancies in the STO substrate originate from an outward diffusion of oxygen from the substrate to the oxygen-deficient amorphous overlayer.5 This mechanism is driven by surface redox-reactions involving specific chemical species of the ablation plume with high oxygen affinity. The observation of an insulating interface when an amorphous La7/8Sr1/8MnO3 (LSMO) film is deposited on STO supports a scenario in which the plume chemical composition directly affects the conducting properties of the amorphous STO-based heterostructures.5 Furthermore, conducting interfaces were only observed when depositing at O2 pressures below 10−2 mbar, which suggests that the kinetic energy of the ablated species may also play a nontrivial role in the interfacial conductivity. For the film deposition in oxygen, the O2 background pressure determines the kinetic energy of the ablated species,7,8 apart from their oxidation degree.9–10 The individual role of kinetic energy and degree of oxidation is thus a priori unclear. The two effects can, however, be separated by deposition in an inert gas, where the kinetic energy of the ablated species can be modified without resulting in significant oxidation of the plume species.

Here, we report the transport properties of heterostructures produced by deposition of an amorphous LAO (a-LAO) film on a STO substrate at different background pressures of O2 and Ar, while the LAO ablation plume dynamics and composition is determined in situ. Our experimental findings show an interesting correlation between the interfacial conductivity and the kinetic energy of the species impinging on the substrate, thus adding further insights on mechanisms leading to the interfacial conductivity.

The a-LAO/STO samples were grown at room temperature (RT), both in Ar and O2 using a KrF excimer laser (λ = 248 nm) with a repetition rate of 1 Hz at a fluence of 2.0 J cm−2. The target-to-substrate distance was fixed at 4.5 cm. The interfacial conductivity was characterized as described elsewhere.5 During deposition, the LAO ablation plume dynamics and composition were investigated both in Ar and O2 by exploiting fast intensified-charge-coupled device (ICCD) imaging and time- and space-resolved optical emission spectroscopy (OES).7,8 While these techniques only monitor optically active species, they provide a reliable description of the influence of various experimental parameters on plume dynamics and composition. This description is also consistent with the results of other different complementary techniques,11 e.g., ion probe and time-resolved optical emission spectroscopy, which provide only local information.

Fig. 1 reports the RT sheet conductance $G_s$ of a-LAO/STO samples as a function of the background gas pressure, $p$, for both Ar and O2. Metallic interfaces are formed for $p \leq 10^{-3}$ mbar in both types of background gases, whereas at $p = 10^{-2}$ mbar the a-LAO/STO interfaces are insulating for O2 but remains conducting for Ar. Insulating samples in Ar are only observed for $p \geq 10^{-1}$ mbar. Therefore, the transition...
from a metallic to an insulating behavior is different for O₂ and Ar background. This difference may result from the inherent difference of the kinetic energy or the oxidation degree of the ablated species between the two background gases. Therefore, it can shed light on mechanisms contributing to the interfacial conductivity of α-LAO/STO.

In the following, an experimental analysis of the LAO plume in Ar and O₂ is carried out with the aim to get valuable information on its expansion dynamics and composition. Figs. 2(a) and 2(b) (left column) show typical two-dimensional (2D) images of the LAO plume emission at a delay of τ = 3.3 μs after the laser pulse for deposition in O₂ and Ar, respectively, at three different values of the pressure p (10⁻³, 10⁻², and 10⁻¹ mbar). The corresponding spatially resolved one-dimensional (1D) spectra of the plume emission, in the range of ≈370-630 nm, are also shown in the right columns of Fig. 2. The data at 10⁻³ mbar are representative of the plume features registered at lower pressure. The 2D images in Fig. 2 show that the LAO plume propagation dynamics is strongly affected by the background gas pressure. By increasing the pressure from 10⁻³ to 10⁻¹ mbar, the plume becomes more confined, resulting in a progressive reduction of its length and variation of its shape. Both for Ar and O₂, 10⁻² mbar represents the pressure corresponding to the crossover from a free (10⁻³ mbar) to a braked (10⁻¹ mbar) plume expansion. In both gases, the spectra show characteristic emission from La and Al neutrals, as well as LaO diatomic oxides. As expected, the background gas affects the plume composition in different ways.

Considering first the O₂ reactive gas, oxidation of the plume occurs as a consequence of gas-phase reactions favored by the effective dissociation of oxygen molecules when the plume follows a shock-wave-like expansion regime at larger pressures.⁷,¹⁴ The specific reactivity of the involved cations seems also to influence the LAO plume chemistry. The reaction of La with oxygen is highly exothermic and lanthanum-oxides are effectively produced in electronically excited states, as indeed observed in the spectra of Fig. 2(a). On the contrary, no significant emission from Al-oxides is observed. This is in agreement with our previous reports evidencing the prevalence of LaO formation during PLD of La-containing complex oxides in oxygen ambient gas.⁷,⁸

The spectra of Fig. 2(a) clearly indicate that the formation of LaO molecules in the plume is progressively promoted as the O₂ pressure increases. At p = 10⁻³ mbar the plume emission mainly comes from Al and La atomic species. However, the emission intensity of LaO significantly increases at p = 10⁻² mbar, eventually becoming dominant at 10⁻¹ mbar, while the emission from La reduces correspondingly.
Moreover, Al emission is always present. It has been shown earlier that the emission intensity ratio between a metal monoxide, $XO^*$, and its metallic element, $X^*$, provides a useful, reliable method to follow the plume oxidation as a result of the interaction with the $O_2$ background gas. Variation of the $[LaO^*]/[La^*]$ emission intensity ratio close to the substrate as a function of the pressure $p$ is reported in Table I. The data confirm the progressive enhancement of the oxidized species in the plume as $p$ increases. At $10^{-1}$ mbar the plume propagation is strongly braked and eventually stopped at a distance of $\approx 20$ mm from the target. Therefore, the plume species arrive at the substrate only through diffusion in the background gas. In this last case, the $[LaO^*]/[La^*]$ emission intensity ratio close to the stopping regime was evaluated and reported in Table I.

In the inert Ar gas, a distinctly different variation of the plume spectra with pressure is observed (see Fig. 2(b) and Table I). In this case, the pressure variation of the plume species emission is mainly related to the confining effect of the background gas. At $p = 10^{-3}$ mbar of Ar, both the emission spectrum and the $[LaO^*]/[La^*]$ emission intensity ratio are very similar to those observed in $O_2$. This is a consequence of the reduced interaction with the background gas. For larger pressures, the plume emission in Ar is mainly due to atomic species, meanwhile the LaO emission intensity remains comparatively rather weak. Therefore, the $\approx 3 \times$ larger values of the $[LaO^*]/[La^*]$ emission intensity observed in $O_2$ is due to the gas-phase oxidation processes occurring during interaction between the plume and the background gas.

During PLD growth of the LAO overlayer in $O_2$ ambient gas, both gas-phase and surface reactions will be important for sample oxidation. Our observations indicate that in $O_2$ the LaO formation through gas-phase reactions represents a progressively more important channel of oxygen incorporation in the $a$-LAO growing film as the pressure increases, which is indeed not the case for the Ar background. This pivotal difference explains the transition to insulating interfaces observed in $O_2$ already at $p = 10^{-2}$ mbar (see in Fig. 1). According to Ref. 5, the interfacial conductivity of the $a$-LAO/STO samples is attributed to the formation of oxygen vacancies in the STO substrate during the deposition. The deposition of a well-oxygenated $a$-LAO overlayer at such a pressure limits the oxygen outward diffusion from the STO substrate. In Ar, the $a$-LAO overlayer is always oxygen deficient. Therefore, the sharp transition from conducting to insulating interfaces, occurring at $p \approx 10^{-1}$ mbar, cannot be ascribed to the degree of oxidation. Instead, the transition clearly indicates that the plume dynamics might play an important role in the formation of oxygen vacancies in the STO substrate and hence for the interface conductivity. Moreover, the observation of a conducting behavior of $a$-LAO/STO interfaces and an insulating behavior of $a$-LSMO/STO, in the same experimental conditions, suggests that the redox reactions mainly involve Al, rather than La for the LAO/STO system, as a consequence of its higher reactivity at the substrate surface.

By tracking the front edge of the plume species from a sequence of images such as those in Fig. 2, the maximum kinetic energy, $K_{E_{\text{max}}}$, of the species at the substrate position was estimated at each pressure. As discussed above, it is of special concern to follow the pressure variation of $K_{E_{\text{max}}}$ for the Al atoms reaching the substrate. This is shown in Figs. 3(a) and 3(b), where the interfacial sheet conductance $G_s$ of the $a$-LAO/STO heterostructures is also reported in each panel to facilitate the analysis. The kinetic energy of La and LaO follows a similar trend as a function of the pressure, but it is generally about a factor of 5 higher.

In Ar [see Fig. 3(a)], the maximal kinetic energy is $\approx 15$ eV at $p \leq 10^{-4}$ mbar and reduces slightly as the pressure increases up to $p \approx 10^{-2}$ mbar. Then, a fast decay of $K_{E_{\text{max}}}$ is observed as the pressure increases further. At $p \geq 6 \times 10^{-2}$ mbar, the plume attains a stopping regime over a length shorter than the target-to-substrate distance, and the kinetic energy of the ablated species reduces to the room temperature thermal energy ($1/40$ eV). The sheet conductance, $G_s$, follows a rather similar dependence. At $p \approx 1.5 \times 10^{-2}$ mbar, it only reduces slightly with respect to the value observed at lower pressures ($p \leq 10^{-1}$ mbar), but eventually it turns to insulating as $p$ further increases. In particular, passing from $p \approx 1.5 \times 10^{-2}$ mbar to $p \approx 0.1$ mbar, a transition from a metallic to an insulating...
process like PLD, can significantly alter the kinetics of the redox-reactions with the STO substrate, thus favoring the formation of the electron gas at the interface between the amorphous overlayer and the STO substrate.

In conclusion, we studied the transport properties of $a$-LAO/STO heterostructures grown by PLD at RT as well as the properties of the ablation plume dynamics and composition, in different background pressures of O$_2$ and Ar. Our results show a striking correlation between kinetic energy of the Al species impinging on the substrate and interface conductivity of LAO/STO. This adds further insights on mechanisms leading to the interfacial conductivity observed in complex oxide heterostructures based on amorphous overlayers on STO. Our experimental findings support a mechanism in which the formation of oxygen vacancies is favored by redox-reactions at the interface triggered by the arrival of energetic plume species with high oxygen-affinity.
