Generic calibration procedures and results for nacelle-based profiling lidars

A. Borraccio, M. Courtney and R. Wagner

DTU Wing Energy

Abstract

In power performance testing, it has been demonstrated that the effects of wind speed and direction variations over the rotor disk can no longer be neglected for large wind turbines [1]. A new generation of commercial nacelle-based lidars is now available, offering wind profiling capabilities. The use of profiling nacelle lidars to assess power performance could remove the need to erect expensive meteorology masts, especially offshore.

Developing standard procedures for power curves using lidars requires to assess lidars measurement uncertainty that is provided by a calibration. Based on the calibration results from two lidars, the Avent 5-beam Demonstrator and the Zephir Dual Mode (ZDM), we present a generic methodology to calibrate profiling nacelle lidars.

Objectives

The objectives of this work are to:

1) Develop generic calibration procedures, i.e. applicable to any type of nacelle-based lidar irrespective of their type (pulsed or continuous-wave) and design.
2) Apply the calibration procedures to both the 5-beam Demonstrator and the ZDM lidars. (see pictures below).
3) Provide calibrated lidars, since both are to be installed on nacelles of wind turbines during measurements campaigns (see www.unite.dk), which goal is to develop procedures to assess power performance that could be applied in any type of terrain (flat or complex, onshore or offshore).

The fundamental reason for developing calibration procedures is to assign uncertainties to lidars wind measurements. Commercial applications of lidars, e.g. power performance testing or resource assessment, demand the estimation of measurement uncertainties.

Calibration procedure principles

A lidar probes the wind by emitting light through a laser beam. Aerosols contained in the atmosphere scatter part of the laser light back to the lidar. Three levels of measurands exist in a lidar:

• The "rawest" one is the time domain of electrical current induced by the backscattered light on which spectral analysis is performed.
• The Doppler spectra generated then yield the Doppler frequency. The line-of-sight (LOS) velocity – or Radial Wind Speed (RWS) – is directly proportional to the Doppler frequency.
• Finally, algorithms combine RWS measurements to derive reconstructed wind parameters, e.g. wind speed and direction, shears, veers, etc.

Two different calibration concepts can be identified, called black box and white box. The black box methodology directly calibrates a reconstructed output.

The white box calibration is a generic method that can be applied to all profiling nacelle lidars, in which the algorithms' input quantities are calibrated, i.e. the RWS, the beam localisation quantities (inclinometers), and the geometry of the scanning pattern. The uncertainty estimation of any reconstructed parameter is theoretically permitted by the white box approach. Thus, we have chosen this method.

White box calibration steps, setup and results

The data required for the RWS calibration are time-averaged of: calibrated measurements of horizontal wind speed (HWS) and direction (θ) lidar RWS and beam inclination θphysical. These data enable a reference equivalent RWS to be obtained by projecting the HWS onto the LOS direction (LOSdir):

\[ R_{eq, RWS} = HWS \cdot \cos(\theta_{\text{physical}}) \cdot \cos(\theta - \text{LOSdir}) \]

The LOS direction is estimated by:

1. Fitting the lidar response to the wind direction.
2. Linear regressions between the RWS and Refeq_RWS using different projection angles are performed, and the RSS are reported. The accurate LOS direction corresponds to the minimum of the fitted parabola.

The calibration results (binned data) show consistent gains in the forced regression with an error of less than 0.9% for both the ZDM and the five LOS of the 5-beam Demonstrator. R² coefficients are all > 0.9999 and the gains vary between 1.0056 and 1.0090 (5-beam Demonstrator). For ZDM, the gain is 1.0054.

Conclusions

Calibrations results have proven to be satisfactory in both cases with a high level of agreement between the lidars’ RWS and the reference measurements, confirming the feasibility of the white box calibration. The methodology is generic and could therefore form the scientific basis of standardised nacelle lidars calibration procedures. The generic procedures, the derivation of uncertainties, will be detailed in a journal paper.
