Abstract

The mass-replication nature of the process calls for fast monitoring of process parameters and product geometrical characteristics. As a result of the current trend towards product miniaturisation, there is a demand for advances in micro-manufacturing technologies and their integration in new manufacturing platforms. The research on the downsizing of the injection moulding has generated a new process technology, micro injection moulding (µIM) [3], capable of micro manufacturing on a mass production scale both one-component and multi- material micro components [4] characterized by multidimensional scale integration, high accuracy with tolerances in the micrometer range [5]. Injection moulding of micro components poses great challenges in terms of quality control of both the manufacturing process and the products itself. Shot sizes down to 100 mg and even lower than 10 mg, dimensional tolerances in the micrometer range and surface roughness in the sub-μm range call for process control systems and metrology solution with very low relative uncertainties (<0.1-1%) [6][7]. The mass-replication nature of the process calls for fast monitoring of process parameters and product geometrical characteristics. In this direction, the present study addresses the possibility to develop a micro manufacturing platform for microassembly injection moulding with real-time process/product monitoring and metrology. The study represents a new concept yet to be developed with great potential for high precision mass-manufacturing of highly functional 3D multi-material (i.e. including metal/soft polymer) micro components. The activities related to HINMICO project objectives prove the importance of using tool geometries as reference calibrated artefacts to establish effective process technology development and control. The results allow identifying the correct process windows for optimal part quality reducing product dimensional variation in the micrometer dimensional range. The proposed metrological approach enabled to quantify product dimensional variations based on process and tooling capabilities.

Keywords: Micro injection moulding, optical metrology, process quality control development.

1. Introduction

In recent years, the manufacturing industry and the society as a whole have witnessed a rapid increase in demand and usage of micro-products and micro-components in many industrial sectors such as electronics, medical, biotechnology and automotive [1][2]. As a result of the current trend towards product miniaturisation, there is a demand for advances in micro-manufacturing technologies and their integration in new manufacturing platforms. The research on the downsizing of the injection moulding has generated a new process technology, micro injection moulding (µIM) [3], capable of micro manufacturing on a mass production scale both one-component and multi-material micro components [4] characterized by multidimensional scale integration, high accuracy with tolerances in the micrometer range [5]. Injection moulding of micro components poses great challenges in terms of quality control of both the manufacturing process and the products itself. Shot sizes down to 100 mg and even lower than 10 mg, dimensional tolerances in the micrometer range and surface roughness in the sub-μm range call for process control systems and metrology solution with very low relative uncertainties (<0.1-1%) [6][7]. The mass-replication nature of the process calls for fast monitoring of process parameters and product geometrical characteristics. In this direction, the present study addresses the possibility to develop a micro manufacturing platform for microassembly injection moulding with real-time process/product monitoring and metrology. The study represents a new concept yet to be developed with great potential for high precision mass-manufacturing of highly functional 3D multi-material (i.e. including metal/soft polymer) micro components. HINMICO project activities have been focus towards these directions. The present paper reports about the optimization of the thermoplastic elastomer (TPE) micro injection moulding with special emphasis on the tool design as key components for final product functionalities of a high performances phono cartridges. Towards total quality production a metrological approach identified as a key enabling technology for future real-time process/product quality monitoring of micro parts is introduced. The present paper discuss the possibility of controlling effects of different process settings on critical product characteristics. The proposed metrological reference as a measurand linking either process variation, tool characteristic/performance with material behaviour during and after µIM.

2. Micro injection moulding of TPE suspension rings

To evaluate the injection moulded TPE suspension rings a benchmark study was initially carried out to qualitatively characterize the produced suspension rings. Opening experiments were run with process parameters listed in table 1. The first batch called “data sheet” utilizes the process parameters recommended by the TPE material supplier. The second produced batch called “high” employed temperatures and pressures values levels greater than the recommended ones to observe possible effects on rings replication. A new process design for “Improved” batch was found as part of an operational optimization process that tried to achieve better filling and smaller to no defects on the produced parts. This optimization was based on manual inspection under an optical microscope.

2.1. Scanning Electron Microscope inspection

From the top view of Fig. 1 the suspension rings looks well formed, with a small weld line. The gate residual mark is small and does not protrude from the...
The qualitative analysis indicated that high pressure and injection speed of the high batch fills the cavity well, but gives problems with defects caused by entrapped air. Air trap defects were also detected for the data sheet batch indicating that clamping force was the most influencing process parameter affecting the weld lines depth. The correlation between the low clamping force and small weld line defects could be explained by the increased air evacuation at the mould split line as a consequence of the lower clamping force. Although this explanation is plausible more investigations were conducted in order to fully support this relationship.

2.2. Part mass variation

One method of monitoring the process variation is to look at the consistency of the part mass. This has been done for the produced TPE suspension rings. 50 parts for each batch were measured and different mass distribution plotted in Fig.4. The smallest mass deviation is obtained using the improved process settings with a low clamping force that allow for better air evacuation compared to other TPE batches as seen in the SEM quality inspection. Results also indicate that it is possible to increase the density of the TPE material by using high processing temperatures and pressures. The density increase influences the damping properties of the material enabling the possibility to produce within the same material compound suspension rings with slightly different damping properties for different types of cartridges.

2.3. Simulation and experimental comparison

This investigation aimed at studying the development of weld line formation due to air entrapped during polymer filling of the cavity, Fig. 5. The simulation was capable of predicting the location of the entrapped air that causes the parts defects. Main interest of the numerical product quality optimization was to consequently minimize these defects as much as possible.
as possible in order to ensure uniform damping properties, so that the mounting orientation of the suspension and the vibration direction of the cantilever will not influence the acoustic properties of the finished cartridge. The comparison between simulations and the SEM pictures have shown that all air entrapments occurring at positions that are in contact with mould part lines are reduced to very small weld lines due to the capability of the air to evacuate the cavities through the parting line. At positions where the air cannot escape through any parting lines, defects and surface imperfections develop compromising component functionalities. Generally, the simulations confirmed that bigger weld lines are generated towards the inner cylindrical section of the rings as outlined by the SEM investigation [9].

**Figure 5:** The filling behaviour during the merging of the two flow fronts is broken into six pictures.

2.4. Dimensional weld line investigation

Reliable quantification of the weld line is not currently available as output analysis of the numerical software. Dimensional measurements of the weld line depth was performed using a focus variation optical microscope ensuring single acquisitions time lower than production cycle time. Measurement results have shown a direct correlation between tested process parameters and weld line dimensional variation. Larger weld line depth variation was quantified for the rings produced with higher clamping force and injection speed. The results dimensionally quantified the effect of air entrapped into the mould cavity on the final replication quality of the TPE components [10].

3. Effective product and process control

A further optimization study was carried out with focus on effective process control based on final part dimensional variation. A statistically design set of experiments was carried out. The micro injection moulding experiments were executed on Wittmann-Battenfeld Micro Power 15 with an injection unit consisting of an Ø14 mm screw for plasticization and metering combined with a separate Ø9 mm injection plunger. Following results obtained in the preliminary studies on which parts defects were minimized as a function of improved final product performances, process parameters, table 2, were tested during the experimental micro injection moulding phase. 5 repetitions of a full general factorial design (2^4*4 = 144 experiments) were run.

3.1. Measurement strategy

Dimensional quality control of the produced polymer parts was carried out using a focus variation microscope. For each suspension ring three measurements repetitions to quantify the polymer rings inner (ID) and outer (OD) diameter were performed. The two measurands (ID, OD) were extrapolated from each 3D optical surface reconstruction of the produced TPE rings by interpolating inner and outer counter lines with generated circles. The approach ensured measurement robustness and measurement reproducibility. An optical coordinate measuring machine was employed to calibrate mould cavities (outer suspension ring diameter) and pin diameter (inner suspension ring diameter), Fig. 6.

![Figure 6](image)

**Figure 6:** a) Mould plate containing 4 cavities; b) pin entering the cavity during injection moulding production of the suspension ring; c) mould cross section schematic view.

Measuring uncertainty was calculated following ISO 15530-3 [11]. Measurement results are reported in table 3.

![Table 3](image)

**Table 3:** Mould cavities/ken calibrated values. Single values indicate average values of 10 different measurements for each inner and outer diameter. U(ID) and U(OD) indicate Expanded Uncertainty values in μm.

The reference diameter (Ø) calculated in Eq. 1 allow to effectively evaluate the different polymer shrinkage directions Fig. 8b of inner and outer diameters (ID, OD) in respect of calibrated mould dimensions. Correct shrinkage quantification directly relate to final assembled cartridge (Fig.7) sounds quality. TPE micro rings critical geometries were selected as product quality output indicator based on final product assembly tolerances contains.
The mass-replication nature of the process calls for fast monitoring of process parameters and product geometrical characteristics. In this direction, the present study reported the development and its production of high accuracy and precision micro injection moulding of thermoplastic elastomers micro rings. The critical factors in μm process related to injection speed, mold temperature, clamping force, surface replication and simulation accuracy have been presented. The study represent a new concept yet to be developed with great potential for high precision mass-manufacturing of highly functional 3D multi-material (i.e. including metal/soft polymer) micro components. The results proves the importance of using tool geometries as reference calibrated artefacts to establish effective product quality control and process monitoring development. In light of the produced results based on dimensional part verification expressed as product variation from a geometrical reference system process and tool accuracy were verified.

4. Conclusions

Acknowledgements

This research work was undertaken in the context of HINMICO project (”High throughput integrated technologies for multimaterial functional Micro Components”, www.hinmico.eu) HINMICO is a Collaborative Project supported by the European Commission in the 7th Framework Programme (Grant agreement no. 609110).
