The residue was characterized by FTIR (SI-Figure 1). As can be the residue shows a peak at 3330 cm⁻¹ which is characteristic of the cellulose and a very clear peak at 1590 cm⁻¹ which is characteristic of the lignin, meaning that we have both lignin and cellulose present at the residue. Although the peak at 1740 cm⁻¹, characteristic of the hemicellulose, has disappeared from the spectra of the residue, does not mean that there is no hemicellulose present, the reason is that as has been reported (Patil et al., 2012) the strong alkali treatments can deacetylate the hemicellulose. This is also supported by the fact that this peak is neither present in SM (fig 4). Finally, it has been reported already that the alkali treatment extracts hemicellulose from fibers (Fang et al., 2000) so it can be concluded that there is cellulose, hemicellulose and lignin present in the residue.

It can also be seen how the FTIR spectra of the sisal, the CNF and CNF/residue can be compared in order to see if the CNF/residue had a similar composition as the sisal and as can be seen on fig 4, there are only minor
differences between both spectra. The peak at 1594 cm\(^{-1}\) (lignin) is slightly smaller in the CNF/residue than in the sisal, but it is slightly higher than in the CNF. The reason is that the alkali treatments can not remove all of the lignin (for that reason there is a mass loss in the following procedures and the fiber after the alkali treatment is still brown), meaning that with the current procedure we can recover part of the lignin but not all of it.

The behavior of the peak at 1740 cm\(^{-1}\) is more complex. This peak is indicative of the acetyl groups of the hemicellulose, but also of the grafted acetyl groups on the CNF. As long as the residue is rich on hemicelluloses, it was expected to have a more intense signal on this band higher on the CNF/residue than on the CNF, but in fact it is lower.

This is probably due to the fact that the alkali treatments deacetylate the hemicelluloses (Patil et al., 2012), moreover, as long as in the CNF/residue the concentration of CNF is smaller, the signal of the acetate groups of the CNF should be smaller, as it is. Finally this conclusion is supported by the fact that the peak at 3330 cm\(^{-1}\)(attributed to the OH stretching of cellulose molecules) is more intense in CNF than in CNF/residue, meaning that the CNF has higher cellulose content than CNF/residue.

The mechanical properties of the film were tested. Which in the case of the neat CNF film was very difficult to investigate due to the unevenness of the thin and brittle nanopaper. The neat CNF nanopaper was found to have poor mechanical properties, probably due to the unevenness of the film, while the nanopaper with the added residues showed improved mechanical properties, even though both films are very weak.
