(Dated: August 22, 2018)

Graphene has proven to host outstanding mesoscopic effects involving massless Dirac quasiparticles travelling ballistically resulting in the current flow exhibiting light-like behaviour. A new branch of 2D electronics inspired by the standard principles of optics is rapidly evolving, calling for a deeper understanding of transport in large-scale devices at a quantum level. Here we perform large-scale quantum transport calculations based on a tight-binding model of graphene and the non-equilibrium Green’s function method and include the effects of $p-n$ junctions of different shape, magnetic field, and absorptive regions acting as drains for current. We stress the importance of choosing absorbing boundary conditions in the calculations to correctly capture how current flows in the limit of infinite devices. As a specific application we present a fully quantum-mechanical framework for the “2D Dirac fermion microscope” recently proposed by Bøggild et al. [Nat. Comm. 8, 10.1038 (2017)], tackling several key electron-optical effects therein predicted via semiclassical trajectory simulations, such as electron beam collimation, deflection and scattering off Veselago dots. Our results confirm that a semiclassical approach to a large extend is sufficient to capture the main transport features in the mesoscopic limit and the optical regime, but also that a richer electron-optical landscape is to be expected when coherence or other purely quantum effects are accounted for in the simulations.

INTRODUCTION

Graphene has proven to be the scene of unprecedented mesoscopic effects, hosting massless Dirac quasiparticles that travel with little scattering. These relativistic charge carriers can move ballistically across μm-long distances at room temperature [1], so far reaching mean free paths of the order 30 μm at low temperatures [2]. They can undergo negative refraction when passing $p-n$ junctions [3] and can be manipulated by external electromagnetic fields [4], thus being easily emitted, collimated, steered or focused like rays of light. As a result a new type of 2D electronics complying with the principles of optics is rapidly finding its way in the 2D materials community, supported by the relentless progress towards large-scale production of high-quality graphene.

One example, recently brought up by Bøggild and co-authors [5], is to combine different graphene-based electron-optics components in a “2D Dirac fermion microscope” (DFM) as in Fig. 1. Here electron emitters/guns, collimating apertures [6], tunable lenses, deflectors, and detectors are imagined to be incorporated in a graphene “vacuum chamber” to image different types of targets, such as metal-graphene interfaces, grain boundaries, edges, defects, adsorbed molecules, nanoparticles, quantum dots, or plasmonic superstructures. The authors provide a perspective view on how such a tool can be realistically implemented and operated, proposing practical architectures and design rules for all of its 2D components, based on state-of-the-art achievements in graphene technology.

The approach used by Bøggild et al. for large-scale electron transport simulations is purely semiclassical and belongs to a broadly used class of simulation known as billiard models. In the last few years these models have proven to successfully provide insights on the overall magneto-transport characteristics of graphene [7,8] and other large-scale ballistic devices in the mesoscopic limit [11].

However, despite allowing computation with little time and memory consumption, semiclassical transport simulations always need to be calibrated with measured macroscopic parameters, such as mobility or diffusion coefficients. Most importantly, quantum effects such as coherence are not naturally included in semiclassical simulations, despite their importance for describing phenomena such as magnetic focusing, chiral tunneling in the ballistic regime or conductance fluctuations in the diffusive regime [12,13]. Diffraction is also expected to have major implications in devices where Dirac fermions pass through apertures smaller than their Fermi wavelength $λ_F$ or scatter off small objects. Future realization and operation of complex relativistic electron-optics graphene systems thus calls for a deeper understanding of transport at the quantum level, where the full quantum nature of Dirac fermions is accounted for.

Along this line it is also decisive to be able to access simulations at the scale of experimental devices, which often range from hundreds of nano-meters to a few microns. At the same time it is crucial to provide reliable benchmarks to measurements in the presence of defects, interfaces, or disorder, where details matter on the atomic scale. The huge number of atoms contained in the typical experimental systems prohibits the application of usual ab-initio electronic structure techniques like density functional theory (DFT), where the detailed quantum-chemical structure of every atom is taken...
into account. Hence, the development of novel high-performance computational methods to enable quantum transport simulations at experimentally relevant device dimensions is essential.

Here we perform quantum transport calculations of large tight-binding (TB) models of graphene using the non-equilibrium Green’s function method (NEGF). We will report on the multi-functionality and performance of our tools while studying transport in large graphene flakes on the scale of hundreds of nm in the presence of $p-n$ junctions, magnetic field and/or absorptive regions. Our main focus will be to reproduce from a fully atomistic perspective some key features of electron transport in a DFM, such as electron beam collimation, deflection, and scattering off circular Veselago dots (VD) \cite{3}. We will emphasize how different choices of boundary conditions lead to different density patterns, providing a simple computational solution to minimize the occurrence of artificial features in the current, e.g. using hard-wall or periodic boundaries. The manuscript is organized as follows. We will first briefly review the state of the art of the computational methods that can be used for transport simulations of large-scale graphene devices. This is followed by an overview of the used methods, the code, and the setup we use to carry out our calculations. We will then discuss the effects of adopting different boundary conditions in the device. To conclude we will present a direct comparison between our results and those reported in \cite{5}, highlighting similarities and differences between the semiclassical and quantum simulations.

**Methods for large-scale graphene transport simulations**

For any quantum transport technique to efficiently address realistic graphene devices, it is vital to describe the underlying electronic structure in a computationally efficient manner. A broadly adopted solution is to model the electronic structure of graphene using the tight-binding approximation \cite{14,16}. This approximation is in its “cheapest” textbook version, where the Hamiltonian is orthogonal and includes only interactions between nearest-neighbor $\pi$ ($p_z$) orbitals, able to capture the main qualitative features of the graphene band structure. Due to its versatility, this method has often been at the center of new improvements and developments. In particular we point out the simple scaling approach proposed by Liu et al. \cite{17,18}, who provide a simple condition to obtain band structure invariance, while simultaneously adjusting the lattice constant and the hopping parameter in tight-binding models of graphene. A similar approach is the one suggested by Beconcini et al. \cite{19}, who manage to achieve band structure invariance by using the Fermi energy as key scaling parameter, thus accessing simulations of multi-terminal devices and nonlocal transport measurements. In more detail, they show that a geometrical downward scaling of the system size can be accompanied by an upward scaling of the Fermi energy in such a way that the number of electronic states responsible for transport is kept constant. Both of these scaling approaches have proven to be very efficient tools to interpret magnetic focusing experiments involving micron-size multi-terminal devices \cite{20,21}, where factors such as edges, chemical functionalization, structural disorder or contact with metal do not disrupt the relevant transport features.

Electron transport for very large system dimensions can then be achieved by coupling a TB Hamiltonian with different quantum transport formalisms \cite{22}. For example, hybrid Monte Carlo algorithms on lattice \cite{23} or Wave-Packet Dynamics \cite{24,27} have been used to study large-scale transport in graphene. The latter in particular is a very intuitive method which has the advantage of giving direct access to the real-space and real-time electron wave-packet propagation over a graphene lattice. Here energy resolution can be obtained by Fourier transforming in time domain, at the cost of including a very fine time discretization. The majority of the other transport formalisms are based on the Landauer-Büttiker theory. The Kubo-Greenwood formalism is a very popular example \cite{28,32}, which turns out to be an ideal choice when studying diffusive large-scale graphene systems described by a mobility or conductivity. Along similar lines the patched Green’s function technique can be
used to introduce open-boundary self-energy terms in the device Hamiltonian to describe its connection to an infinite sample \[33\]. Complementary to this the TB-NEGF method is a popular choice for ballistic transport \[34\] where the target is most often conductance including explicit descriptions of multiple electrodes, rather than conductivity. It allows for self-consistent mean-field description of the potential, e.g. using a Hubbard-type model \[25\] including the possibility to study the effect of spin-polarization. Many simulation packages are now implementing the NEGF scheme as a standard feature to calculate electron transport in nanostructures, enabling its application to tight-binding Hamiltonians as well as other electronic structure models with higher level of accuracy such as DFT \[36\] which can scale linearly with length of the system in the transport direction using recursive Green’s function methods.

### COMPUTATIONAL TOOLS

Our quantum transport simulations are based on the NEGF method and a nearest-neighbour TB Hamiltonian using the standard expressions of transmission in terms of the retarded Green’s function \[34\]. For the particular implementation we use the open-source TBTRANS and sisl \[37,38\] tools distributed with the TranSiesta software package \[39\]. TranSiesta is a tool for high-performance DFT+NEGF self-consistent calculations. It relies on advanced matrix inversion algorithms to efficiently obtain the Green’s functions for large, multi-terminal systems at various electrostatic conditions (e.g. gating \[39\]), while the charge-density is obtained using contour integration of the spectral densities.

TBTRANS is a “post-processing” NEGF code which provides a flexible interface to DFT as well as user-defined tight-binding Hamiltonians, using Python as back-end. It enables large-scale tight-binding transport calculations of spectral physical quantities, interpolated I-V curves, transmission eigenchannels \[37\] and/or orbital/bond-currents for setups that can easily exceed millions of orbitals on few-core machines. The possibility of using Bloch expansion for electrodes with periodicity transverse to the transport direction and customizing the effective shape of the device region makes it possible to increase the scale of transmission calculations even further \[10\]. Complementary to TBTRANS sisl was developed as a Python package to create and manipulate large-scale (non-)orthogonal tight-binding models for arbitrary geometries, with any number of orbitals and any periodicity. It allows to read external Hamiltonians and real-space grids from various DFT programs (e.g. SIESTA \[11\] or Wannier90 \[22\]), providing user-friendly routines for post-processing and output of electronic structure and transport calculations. To include the effects of doping, magnetic field or absorptive potentials in our system we exploit the TBTRANS capability of customizing the device Green’s function via real (complex) k- (energy-) dependent $\delta H(E, k)$ perturbative terms:

$$G(E, k) = \left[ S_0(k)(E + i\eta) - H_0(E, k) - \sum_i \Sigma_i(E, k) - \delta H(E, k) \right]^{-1}$$

(1)

Here $S_0$ and $H_0$ are the unperturbed overlap and Hamiltonian in the device region, while $\Sigma_i$ is the self-energy for each semi-infinite electrode $i$. If we call $\delta H_{p-n}$, $\delta H_{CAP}$ and $\delta H_B$ the k- and energy independent perturbations to the Hamiltonian caused by $p-n$ junctions, absorptive regions (like those simulated using complex absorbing potential (CAP) \[33\]) and magnetic field $B$, respectively, we can incorporate the effects of these mechanisms in the expression for $\delta H$ as:

$$\delta H = \delta H_{p-n} + \delta H_{CAP} + \delta H_B$$

(2)

In the following sections we provide details on the physics behind the terms in Eq. (2) and how we construct them in the TB calculation.

We use sisl to set up a nearest-neighbor orthogonal TB Hamiltonian for a two-probe graphene device, with carbon-carbon bond length $a_0 = 0.142 \text{ nm}$ and hopping parameter $t_0 = 2.7 \text{ eV}$. Our supercell, inspired by the hetero-dimensional graphene junctions studied in \[15\], consists of a 2 nm wide zigzag graphene nanoribbon acting as point-like source electrode at the edge of a 100 nm $\times$ 100 nm graphene flake with 395,940 atoms (sites).

### p-n junctions

In an orthogonal tight-binding model doping is straightforward to introduce via a global or local adjustment of the diagonal (on-site) elements of the Hamiltonian \[39\]. In our calculations we generate smooth symmetric $p-n$ junctions using:

$$\delta H_{p-n} = \begin{bmatrix} \Delta E/2 \cdot \delta_{ij} & 0 & 0 \\ 0 & E_{on}(r) \cdot \delta_{ij} & 0 \\ 0 & 0 & -\Delta E/2 \cdot \delta_{ij} \end{bmatrix}$$

(3)

where the junction potential profile is given by

$$E_{on}(r) = \frac{\Delta E}{2} \left[ 1 + \exp\left(-\alpha (r - r_{p-n})/w \right) - 1 \right]$$

(4)

and the junction thickness $w$ is set to $w \approx 2 \text{ nm}$. The junction profile $r_{p-n}$ can be chosen to be linear or can conveniently be shaped to achieve Veselago lensing of electrons \[4\]. In particular, as suggested by Liu et al. \[40\].
profile of the smooth parabolic on a

where p-doped (red) parabolic and circular regions are created
on a n-doped (grey) graphene flake. (b) General Fermi-like
profile of the smooth parabolic $p-n$ junction. On-site energy
along an axis passing through the parabola’s vertex is shown
as a function of distance between the ribbon/flake interface
and the junction average position. Red (grey) sites
in the overlaid ribbon/flake geometry have $E_{on} = +0.05$ eV
($E_{on} = -0.05$ eV), whereas all other sites have gradually vary-
ing $E_{on}$ according to Eq. (1). (c) Sites in geometry equipped
with complex absorbing potential (CAP) are shown in red.
Absorption occurs gradually starting from $\Delta E \approx 0.3$ eV
from the yellow lines, where maximum absorption takes place due
to the singularity in Eq. (7).

electrons can be focused into a sharp collimated beam us-
ing a parabolic $p-n$ junction with focal point located at
the point source. In our model for the DFM source we
thus make use of such shape, placing the parabola at a
focal distance $f \approx 4$ nm from the injection point, as illus-
trated in Fig. 2a and b. In the same figure we show that
this method also can be used to construct circular p-n
junctions, or Veselago dots (VD) [47], here used as targets
for the collimated beam of electrons.

Complex absorbing potential (CAP)

In standard NEGF transport problems one usually
deals with infinite open systems, where semi-infinite leads
are included in the calculation of the Green’s function
via a self-energy in the device Hamiltonian. For large
geometries a major computational limitation is the num-
ber and the size of semi-infinite leads. This limitation can
be efficiently overcome by replacing the Hamiltonian of
the leads with complex absorbing potentials (CAP) that
completely absorb the incident wave-function [43, 44].
This method allows reduction of the original open sys-
tem to a finite closed system without disrupting current
conservation. For example, the Hamiltonian matrix for
a two-probe system where CAP is used to replace the
electrode self-energies can be written as the sum of the
standard two-probe Hamiltonian matrix plus a purely
imaginary $\delta H_{CAP}$ term added to the diagonal matrix
elements:

$$
\delta H_{CAP} = \begin{bmatrix}
-\ii W_L(r) \cdot \delta_{ij} & 0 & 0 \\
0 & -\ii W_R(r) \cdot \delta_{ij} & 0 \\
0 & 0 & -\ii W_R(r) \cdot \delta_{ij}
\end{bmatrix}.
$$

Here we assume transport to occur along the $r$ direction,
and define $W_L(r)$ and $W_R(r)$ as

$$
W_{L/R}(r) = \frac{\hbar^2}{2m} \left( \frac{2\pi}{\Delta r} \right)^2 f(r)
$$

where $f(r)$ is a smooth function of the form

$$
f(r) = \frac{4}{c^2} \left[ \left( \frac{\Delta r}{r_f - r_i} \right)^2 + \left( \frac{\Delta r}{r_f - r} \right)^2 - 2 \right]
$$

Here $r_i$ and $r_f$ are the starting and ending points of the
CAP region in the device, respectively, $\Delta r = r_f - r_i$ is
its length and $c$ is a constant numerical parameter set
to be equal to 2.62 [14]. Note how $f(r)$ diverges as $r$
tends to $r_f$, turning the semi-infinite lead into a finite
lead. The $\Delta$ expression in Eq. (6) is based on purely
semiclassical arguments, and may lead to reflection at $r_f$,
which reduces the final transmission. However this can
be mitigated by increasing the length $\Delta r$ of the CAP
region, until the spectra are in agreement with those ob-
tained in the original open system. In order to estimate
a suitable value for the thickness of CAP regions in our
device configuration, we have calculated transmission us-
ing semi-infinite source and drain electrodes along $\pm y$
and applying periodic boundary conditions (PBC) along
the transverse direction $x$. We then compared this with
the transmission obtained by setting CAP rather than
PBC on the cell boundaries along $x$. We find that an
almost exact overlap between the two spectra is achieved
by setting $\Delta r \geq 0.3$ nm.

CAP can also be used to design narrow absorbing ar-
 eas such as those generated by contacts with grounded
electrodes [6]. A proper comparison with simulations of
a DFM reported in Ref. [5] requires an isotropic point-
like source of electrons. However, a hetero-dimensional
graphene junction, such as the ribbon considered here,
is known to produce isotropic injection only for electron
energies very close to the Dirac point, whereas preferen-
tial injection takes over at higher energies, with angles
depending on the ribbon symmetry [15]. In order to en-
sure isotropic injection we therefore place an absorptive
pinhole with an opening of 1.5 nm at a distance of 3 nm
from the ribbonflake interface, mimicking apertures generated by grounded electrodes. In Fig. 2 we highlight in red the areas of our model where a CAP is used, indicating with a yellow line the points where \( f(r) \) diverges from both sides. Notice how CAP is set separately on front- and back-side of the pinhole, labeled \( \Lambda^+ \) and \( \Lambda^- \), respectively.

**Magnetic field**

A transverse magnetic field in a graphene device can be included in the off-diagonal elements of the Hamiltonian via Peierls substitution \([35, 49]\). We can formally write this as an additive term to the unperturbed Hamiltonian,

\[
\delta H_B = H_0 \cdot e^{i\phi(R, R')} - H_0
\]

where the phase factor is multiplied on each matrix element of \( H_0 \), in a coordinate system where the \( x \) axis is aligned with graphene armchair direction. The phase can be written as

\[
\phi(R, R') = \frac{\pi B}{2 \Phi_0} (x + x')(y' - y),
\]

with \( \Phi_0 = 2.07 \cdot 10^5 T \cdot \text{Å}^2 \) being the quantum magnetic flux.

We implement this approach in sisl/TBTRANS and as a benchmark we have compared to the popular quantum transport code kwant\([54]\), finding good agreement.

**Visualization of bond-currents**

Bond currents allow imaging of spatial profiles of nonequilibrium charge and current densities in solid-state\([31, 51]\) as well as molecular-scale systems\([52]\). They represent local current flowing in the inter-atomic bonds and are defined as the sum over all orbital (indices \( \alpha, \beta \)) currents, \( J_{\alpha\beta} = \sum_{\nu \in \alpha} \sum_{\mu \in \beta} J_{\nu\mu} \). After being generalized for use in honeycomb lattices\([53]\) direct insights could be provided into how the massless Dirac fermions propagate between two neighboring lattice sites in graphene and other carbon nanostructures. There is still no well established way of visualizing bond-currents. In general they can be visualized as flow lines mapped on the network of lattice bonds. Arrow vectors are typically used, whose thickness or length is proportional to the magnitude of the current flowing between each pair of neighbouring atoms\([54, 57]\). This approach provides useful information about both magnitude and direction of the current flowing through the system. However if large geometries are considered it is not feasible due to the overwhelming number of connections to be visualized. A solution to this is to visualize bond-currents on a coarse grained grid, where only a proper average of bond-currents within each cluster is shown as a single arrow\([33]\). In this case the final result will of course depend on the cluster size and on the way the average is carried out, but nevertheless it allows to scale the dimensions of the image at wish enabling access to useful current maps for very large system dimensions.

Here we visualize bond-currents as line segments of length \( a_0/2 \) aligned along a line connecting each pair of neighbour sites, as illustrated in Fig. 3. We select only positive bond currents and for each of them we draw a segment having one extremity at the lattice site from which the relative current originates. We scale the segment thickness and color in proportion to the current magnitude, so that areas with low to zero current will appear white because the bond width is reduced to zero. This approach allows us to access graphene geometries with arbitrary large size, retaining full information about current directionality without a need for user-defined post-processing of the data. The same color map is adopted and color and thickness are always normalized to the maximum value of bond-current in the system. Sometimes the color range is adjusted in order to enhance contrast. If not stated otherwise, bond currents are always computed at \( E = E_F \).

**Performance of TBTRANS and sisl**

The calculations are performed using TBTRANS which implements a highly advanced block-tri-diagonal inversion algorithm which minimises calculations\([37]\). The main difficulty in calculating very large systems is the calculation of bond-currents and orbital-resolved DOS, which requires the spectral function \( \langle A_i \rangle \) for a given electrode \( i \). In Fig. 4 we show the memory requirements of TBTRANS for the very large nearest-neighbour graphene devices with periodic boundary conditions. In both a) and b) vertical lines indicate system sizes of square unit

---

**FIG. 3.** Positive valued bond-currents plotted as line segments of length \( a_0/2 \) connecting nearest neighbor sites. Each segment is anchored to the atom from which the corresponding current originates. Thickness and color is scaled with current magnitude so that areas with low to zero current appear white.
cells of noted area. Lines are ascending together with cell width, the narrowest cell being 2.5 nm and the widest 245 nm (see a). In Fig. 4, the total memory requirements is plotted when calculating physical quantities for the full system in one calculation. This is scaling linearly with respect to system size. Since TBTRANS has been implemented with 4-byte integers, there is an upper limit to the size of the allocated block tri-diagonal matrix. i.e. the lines stop due to integer overflow in the code. Fig. 4b shows memory requirements when only calculating quantities for a selected region in the device, here chosen to include 4 lines of carbon atoms. Clearly the memory requirements drastically reduces and becomes feasible on laptop computers. Here the gray dots indicate the memory requirements for the square unit cells of given area. The transparent lines represent the memory usage of the block tri-diagonal matrices, which become constant for large systems. Thus, the only memory increase is due to the sparse matrices used to retain the Hamiltonian and bond currents etc.

TBTRANS is parallelized using both MPI and OpenMP enabling high-performance calculations with large throughput. In these calculations (400,000 nearest neighbour atoms) we use 24 OpenMP threads and runs in roughly 1 minute per energy point using XeonE5-2650 machines.

A full setup, transmission calculation and post-processing using sisl and TBTRANS takes approximately 40 minutes, with a similar amount of time spent on setting up input and plotting.

We have shown how large scale calculations can efficiently be calculated and post-processed. Further information about sisl may be found in Ref. [35].

RESULTS

We use the methods presented in the previous sections to create a tight-binding model of a DFM. In Fig. 5 we illustrate the definitive model that we use to generate collimated beams of electrons in our calculations. Electrons are injected by a ribbon, filtered by an absorptive pinhole and further collimated by a parabolic $p−n$ junction. As reported in [15], injection at the interface between the ribbon and the large flake is largely anisotropic and can be made isotropic by using a CAP region as an absorptive pinhole. The result is in good agreement with both the semiclassical calculations reported in [5] and the tight-binding calculations by Liu et al. [16].

Boundary conditions

Choosing the correct boundary conditions is essential in reproducing the wanted physical pictures. The goal of the DFM example discussed below is the analysis of collimated beams injected into large graphene samples. Here we emphasize the importance of selecting appropriate boundary conditions to simulate such device in its limit of infinite extension. Fig. 6 is used in the following where we call L (R) the left (right) boundary of the large flake, A$^+$ the CAP region that acts as pin-hole injector and A$^-$ the pinhole side that faces opposite to the source. On the opposite side of injection a regular lead is placed. In Fig. 6 we analyze bond-currents in the area beyond the parabolic lens at different applied magnetic fields and various boundary conditions, progressively switching on the CAP regions at L, R and A$^-$. In the following CAP at A$^+$ is always used to ensure a collimated pin-hole in-

FIG. 4. a) Memory requirements for varying system sizes and their memory usage when calculating orbital currents and orbital resolved quantities. Each line correspond to a different width of the system in ascending width. Increasing the width of the system is the main cause of memory usage since each block has to be as large as the orbital width. The curves terminate at around 40-50 GB because of integer overflows. Vertical lines indicate the number of atoms in a square unit cell of noted area. b) Equivalent calculations as in a) while reducing the region of interest to a specific set of atoms. In this case the memory requirements are drastically reduced because the full Green’s function is not needed. In this case the allowed range of calculated system sizes is considerably increased. The inserted dots indicate the memory requirements for square unit cells. The transparent lines are the memory used for the block tri-diagonal matrices which becomes constant. i.e. the memory requirements are solely determined by the sparse matrices.
FIG. 5. (a) Schematic setup of pin-hole injection with collimation $p-n$ junction. (b) Semiclassical calculation of schematic setup. (c) Bond-currents in proximity of the device source. Electrons are injected by a ribbon, filtered by an absorptive aperture and collimated by a parabolic lens. This is due to internal reflections occurring between the parabolic junction and the region $A^-$ of the pinhole, which in Fig. 5c is not equipped with CAP. This is an artificial effect, since realistic grounded electrodes contacting graphene to create apertures would at least partly absorb electrons impinging onto them from all possible directions. In Fig. 5h we demonstrate that this backscattering effect can be eliminated by switching on CAP at the $A^-$ region. The combined application of CAP in $L$, $R$, $A^-$ eventually allows us to get rid of most interference effects for all magnetic fields considered, see Fig. 6f.

We conclude that investigating an injected beam in the limit of infinite graphene devices requires a specific and elaborate set of boundary conditions to filter out artificial backscattering processes. Importantly a $A^-$side CAP is necessary to absorb backscattered electrons from the $p-n$ junction as well as beam-bending from the magnetic field.

Comparison with semiclassical simulations of DFM

In order to gain a deeper insight on the role of quantum coherence effects in the DFM, we consider some of the systems studied in Ref. [3] where collimated electron beams are focused onto circular Veselago dots (VD) of various size. We concentrate on the mesoscopic limit, $l_{\text{mfp}} > L \gg \lambda_F$, where the mean free path $l_{\text{mfp}}$ of electrons is larger than the characteristic length $L$ of the system, which in turn is much larger compared to the Fermi wavelength $\lambda_F$. In the following we consider explicitly the situation that the phase coherence length is infinite, i.e. that the system is fully coherent.

We note that the area available for the quantum simulations is smaller than the structures considered in realistic setups such as those in Ref. [5]. We deal with this by effectively scaling the graphene bond-length while retaining the number of atoms in our TB model via a scaling parameter $s = d_0/d$, defined as the ratio between the real diameter $d_0$ of the full, non-scaled VD that we would like to simulate and the actual diameter $d$ of the VD designed in our geometry. We assume $n_0 = 10^{12} \text{cm}^{-2}$ to be the electron density in the non-scaled pristine graphene system, which (in the linear band approximation) corresponds to $E_{F0} = \hbar v_F(2\pi/\sqrt{\pi n_0}) = 0.113$ eV and $\lambda_{F0} = 2\pi/\sqrt{\pi n} = 35.4$ nm. A qualitatively correct electron flow around the VD of diameter $d$ in our bond-currents calculations can thus be captured by simply dividing the Fermi wavelength by the scaling factor $s$, yielding $\lambda_F = \lambda_{F0}/s$ and $E_F = s E_{F0}$. The key step of the scaling procedure is to keep the diameter vs. Fermi-wavelength ratio constant [12, 13, 58]. This approach can be thought as a particular case of the more general scaling method presented in [19], hence we refer readers to this for further details.

Our scaling method is exemplified in Fig. 7. Let us assume that the VD on the left with $d_0 = 50$ nm is the original non-scaled VD that we want to study ($s = 1$). In Fig. 7a we demonstrate that by applying the scaling procedure with $s = 1.25$ we are able to reduce the VD size and produce bond-currents inside and outside the VD which are indistinguishable from Fig. 7h. In general,
FIG. 6. Bond-currents at different applied magnetic fields and various boundary conditions, showing a collimated beam scanning across a 100 nm × 100 nm graphene cell with an energy $E_F = 1.0$ eV. Electrons are injected from the top side of the device, source and collimating lens are not shown so as to enhance beam contrast. All simulations have CAP at $A^+$ of the pinhole injector. (a) Periodic boundary conditions at L/R lead to a high degree of scattering, similar to (b) where hard-wall potentials on L/R regions confine electrons. (c) Adding CAP on L/R drastically reduces scattering from neighbouring cells but does not retain a collimated beam from a pin-hole injection. (d) Introduces the entire pin-hole effect by absorbing backscattering from the $p−n$ junction. (e) Final model with CAP on L/R and $A^−$. This model correctly retains a collimated beam while showing the beam in the limit of infinite graphene.

this approach enables us to effectively simulate systems that are $s$ times larger than the actual 100 nm × 100 nm geometry considered in our calculations. Using $s = 2$, for example, is equivalent to analyze a 200 nm × 200 nm graphene system with an equivalent number of atoms.

In the following we will always indicate above every figure the full, non-scaled diameter $d_0$ of the VD, while below we will provide the diameter vs. Fermi-wavelength ratio $d/\lambda_F$ considered and the value of $s$ used to scale the system down to our ∼ 400,000-orbitals TB model.

Figure 8 shows caustic patterns inside VD with different scaled diameters, namely $d_0 = 428$ nm, 257 nm and 86 nm, generated by scattering of a wide beam of electrons collimated with a $f \approx 10$ nm parabolic lens in front of a 1.5 nm aperture. These diameters correspond to scaling parameters $s = 8.56, 5.14$ and 1.72, respectively, allowing us to compare to some of the systems studied by semi-classical simulations in Ref. [5]. We focus on the area inside the dot and observe characteristic caustic patterns at all energies which are in reasonable agreement with the results reported in Ref. [5] and by

FIG. 7. Comparison of bond-current pattern of two VDs with different size and energy but same diameter vs. Fermi-wavelength $d/\lambda_F = 4.9$. Both maps show a 100 nm × 75 nm area of the device in front of the collimation area. The scaling method is used in (b) showing that the electron flow inside and outside the VD in (a) can be qualitatively reproduced by using appropriate scaling parameters.
Agrawal et al. [59]. This is especially true with regard to the position of the main cusp in the first caustic line. A better description of the higher order caustics while keeping Fermi energies (< 1 eV) within the limits of the linear band approximation would require creation of VD with scaled diameters at least 2–3 times larger than the ones considered here, i.e. \( d \geq 200 \) nm, which is not possible within our 100 nm x 100 nm graphene flake. For similar dot dimensions quantum mechanical calculations using plane waves have indeed proven to reproduce reliable optical geometrical features such as peaks in forward scattering [12].

Figure 9 shows a sharper electron beam, focused and collimated by combining a 1.5 nm aperture and a \( f = 4 \) nm parabolic lens, scattering on a VD with various non-scaled diameters \( d_0 \) and similar ratio \( d/\lambda_F \). In particular Figure 9b has the same scaled diameter \( d_0 = 707 \) nm as the VD simulated in many of the structures considered in [5], thus comparing well both with respect to the emission jets and the internal, polygonal current resonances. Clearly interference effects are of higher importance in the quantum mechanical calculations, which are seen as beam broadening inside and outside the VD.

In Fig. 10 we show the bond-currents obtained by scanning the beam using different magnetic fields, ranging from \( B = 0 \) T to \( B = 32 \) T. Also in this case we find a good qualitative agreement with the semi-classical studies [5], capturing both emitted jets and whispering channels within the circular p–n junctions. The beam size difference as well as the interference in- and outside the VD are the main differences that amount to the leaking of electrons in the VD. We point out that when we model a large physical system such as that in Fig. 10b with a scaled-down model we have to scale the magnetic field such that the flux is the same. This is done by using the relation \( B = s^2 B_0 \), where \( B_0 \) is the original non-scaled magnetic field [19]. In addition to this scaling we make use of larger magnetic fields compared to the semiclassical simulations in Ref. [5], in order to access beam scattering off-axis with respect to the VD center. By doing this we compensate the small source/VD distance in our 100 nm x 100 nm geometry, which could not be further extended due to limits of applicability of the...
scaling procedure (e.g. see Fig.2 in [19]).

CONCLUSIONS

In conclusion, we carry out large-scale quantum transport calculations based on simple tight-binding models of graphene and the non-equilibrium Green’s function method. We report on how to include the effects of $p-n$ junctions, magnetic field and complex absorptive potentials into the calculations, as simple perturbative terms to the Hamiltonian. We show how different choices of boundary conditions lead to different current features in the system, setting up local CAP regions in order to minimize artificial interference in the current patterns. We reproduce, from a fully atomistic perspective, some key features of electron transport in a DFM, such as electron beam collimation, deflection and scattering off circular Veselago dots, presenting a direct comparison with the semi-classical results reported in [5]. As expected, the quantum transport simulations show that current density of structures, which are large compared to the Fermi wavelength, show reasonable resemblance with the classical calculations. On the other hand, it is evident that quantum coherence leads to bond current patterns with richer emission and reflection structures, which may be utilized to extract more detailed information of targets than possible with semi-classical calculations.

ACKNOWLEDGEMENTS

We are thankful to Dr. Jose Caridad for discussions. We acknowledge funding from Villum Fonden (grant no. 00013340) and the Danish research council (grant no. 4184-00030). The Center for Nanostructured Graphene (CNG) is sponsored by the Danish Research Foundation, Project DNF103.
