Abstract

The use of nucleic acid, DNA and RNA, based strategies to disrupt gene expression as a therapeutic is quickly emerging. Indeed, synthetic oligonucleotides represent a major component of emerging gene therapeutics. However, the efficiency and specificity of intracellular uptake for non-modified oligonucleotides is rather poor. Utilizing RNA based oligonucleotides as therapeutics is even more challenging to deliver, due to extremely fast enzymatic degradation of the RNAs. Like unmodified oligonucleotides, RNAs also get rapidly degraded in vivo and demonstrate large off-target binding events when they can reach and enter the desired target cells. One approach that holds much promise is the utilization of “click chemistry” to conjugate receptor or cell specific targeting molecules directly to the effector oligonucleotides. We discuss here the applications of the breakthrough technology of CuAAC “click-chemistry” and the immense potential in utilizing “click chemistry” in the development of new age targeted oligonucleotide therapeutics.

Keywords

Click Chemistry; siRNA; non-coding RNA; Protein conjugates

1. Introduction

Gene therapy is an emerging approach that targets intracellular nucleic acids, those DNA and RNAs, associated with human diseases. Synthetic oligonucleotides represent a major type of currently used gene therapeutics. However, the efficiency and specificity of intracellular uptake for non-modified oligonucleotides is poor, with the vast majority trafficking directly to the liver1. Utilizing RNA therapeutics are even more challenging to deliver, due to extremely fast enzymatic degradation of the RNAs. Like unmodified
oligonucleotides, RNAs also get rapidly degraded \textit{in vivo} and show large off-target binding even when they can reach and enter the desired target cells.

Clearly, creating a successful gene therapeutic is not limited to ensuring a successful base-pairing of a therapeutic to its target, but also ensuring stability and cell target specificity. Finding a suitable delivery carrier and enhancing the target specificity for gene therapeutics are both crucial key components required to advance oligonucleotide and RNA based therapeutics to a clinically relevant setting. Indeed, currently stability and receptor or cell targeting effectors can be added to both oligonucleotides and RNAs by conjugation with other biomolecules. Recent successful examples include oligonucleotide-lipid, oligonucleotide-carbohydrate and oligonucleotide-peptide conjugates (reviewed in \textsuperscript{2}). An alternative to direct conjugations is the use of nanoparticles to shuttle therapeutic oligonucleotides with (in)organic polymers, small molecules and other biomolecules. The advantage of nanoassemblies is their relatively simple preparation compared to bioconjugation. However, nanoparticles formed by non-covalent interactions between molecules may inevitably prove to be unstable and require very fast delivery options, which are not available to date (reviewed in \textsuperscript{3}).

Charged, chemically complex and sensitive biomolecules put limitations on the chemistry applied to link them. Click chemistry refers to a broad group of methods unified by the general concept of simple, biology-friendly and bioorthogonal procedures that conjugate molecules in a specific fashion. A breakthrough in click chemistry has been the development of copper-catalyzed click chemistry, CuAAC, by Sharpless, Finn et al. (2002). Rapidly after the discovery of CuAAC click-chemistry, the method was extended to the copper-free approach strain promoted click chemistry, or SPAAC, Diels-Alder, thiol-Michael click reactions. Today, several classical organic reactions have been modified to a “click” version. Each has its advantages and disadvantages and some can even be performed directly in live cells. With regards to gene therapy, CuAAC and SPAAC play a key role in creating decorated therapeutic DNA, RNA and their synthetic analogues, most of which have to date been evaluated \textit{in vitro} (Figure 1). This is mainly due to the simplicity of the procedure, broad accessibility of the reagents and simple work up. However, new methods allow for the attachment of different modifications to one gene therapeutic, which potentially could be beneficial for \textit{in vivo} applications. Indeed, a method to directly conjugate cell receptor targeted proteins, aptamers etc., to oligonucleotides or therapeutic RNAs could revolutionize oligonucleotide therapeutics.

Here in honor of one of the founders of “click chemistry”, Professor M.G. Finn’s 60\textsuperscript{th} birthday, we review the current applications of click chemistry, CuAAC in particular the generation of new oligonucleotides and their nanoassemblies as therapeutic modalities.

2. Emerging targets in gene therapy and use of synthetic biomolecules

Therapeutic oligonucleotide strategies are promising owing to the fact they are designed \textit{a priori} to be specific towards their target, with minimal off-target effects\textsuperscript{4}. As such, targeting a single gene or RNA species with an oligonucleotide is thought to be a more effective approach in various diseases where drug approaches have shown reduced or limited efficacy.
Click chemistry approaches have been developed and effectively used to conjugate fluorescent molecules, 5’ caps, lipids, polysaccharides and peptides to RNA molecules. Further, “click chemistry” has been developed as a strategy to circularize RNA. Others have found using “click chemistry” that bio-conjugating mRNA with different polyamines at the 5’cap, increased formation of poly-ion complexes (PICs) and their binding to initiation factor 4E to increase translational efficiency of the mRNA target in vitro. These technologies may help to better understand gene regulation and result in the development of smarter strategies that have discreet and specific effects on their intended targets, by visualizing where these siRNA conjugates are delivered to in vitro and by using the most relevant moieties to obtain the best siRNA conjugates to effectively deliver and target the appropriate cells for treatment. Other uses of click-chemistry have been to develop better labelling of RNA in vitro and in vivo to better profile RNA populations in distinct cellular environments.
populations. Furthermore, click chemistry has also been shown to be an effective tool to analyze the transport of stem cells to different locations and has been used to understand the molecular dynamics and potential heterogeneity in drug activity in vivo.

While progressive steps have been made in creating better deliverable molecules for gene therapy, few studies have been focused on a specific disease using an RNA-conjugate to mediate a positive medical outcome. The current strategies suggest that using the tool-box that click-chemistry affords, creating or redeveloping old strategies with new moieties for better delivery, enhanced uptake, and increased specificity into target cells, may result in new pathways for gene therapy. Indeed, research by our group(s) has focused largely on the use of peptide moieties that have shown to have great potential in overcoming the cell membrane to deliver its siRNA cargo to effect gene silencing for both HIV and cholesterol regulation.

3. Growing role of click chemistry in the development of gene therapeutics

Since the first reports on click chemistry for gene therapeutics, the original CuAAC approach has been extended by alternative chemical strategies. Wiessler et al., explored the Diels Alder click chemistry for therapeutic peptide nucleic acids (PNA; Figure 2). Several groups have demonstrated that PNA conjugates created by click chemistry have advantageous delivery properties compared to unconjugated precursors. In one body of work, Pipkort et al., applied a similar approach to Diels Alder click, for cell-specific fluorescence imaging using PNA probes. Using modular PNA probes allowed for the combination of the imaging and therapeutic activities in one PNA molecule. The mRNA product of the cysteine protease cathepsin B (CtsB) gene was imaged and simultaneously degraded using the peptide-PNA conjugate. The degradation was completed by adding a cleavage site to the CtsB complementary PNA probe. Further, Wojciechowska et al., used click chemistry to make cell penetrating peptide (CPP) attached to PNA for atherosclerosis treatment, although the affinity to target hSTAT1 mRNA was demonstrated only in vitro. The toxicity of PNA has been reported by several groups, however it is not commented on in the aforementioned PNA click papers.

For therapeutic applications, there is a need for purification from any residual copper that can be left in the product of the CuAAC reaction. This is particularly important when cell penetrating and other peptides are clicked, due to the high affinity of amino acids to copper. One approach is the use of Tangential flow filtration (TFF) purification that yields hundreds of grams of clicked biomolecules without any sign of toxicity in cells or in vivo. Another strategy is using a copper-free click reaction. Wang et al., used SPAAC to modify DNA with diverse functionalities. SPAAC has advantages of high reaction rate at ultramild conditions when the two molecules to be reacted have no steric hindrance. However, the rate of SPAAC can be lower compared to CuAAC when clicking longer peptides (> 20 amino acids) to oligonucleotides.

Phosphorodiamidite morpholino oligonucleotides (PMO) conjugated with cell-penetrating peptides exhibit a high potential for application as therapeutics for Duchenne muscular dystrophy. Conjugates were initially screened using a selection of peptide conjugates.
(SELPEPCON) procedure and then the best hits were tested in cells. The SELPEPCON procedure is beneficial for the selection of bioactive peptides that suggest the possibility of crossing the blood-brain barrier through the conjugates and simultaneously being time and cost effective for therapeutic screening.

Since the late 2000s, most studies on click chemistry for gene therapy have used nanomaterials, being beneficial for the delivery and activity of gene therapeutics. Ghosh and Hamilton developed thermosensitive dendrimers based on G-quadruplex forming CG rich sequences. They used different metal ion concentrations to drive the assembly which was confirmed by imaging. DNA-microcapsules prepared by Cavaleri et al. contained the hydrophobic core built from a poly N-isopropylacrylamide (PNIPAM) polymer and reactive “click” domains. The products were decorated with DNA and poly ethylene glycol (PEG) and showed higher stability that the analogues that did not contain the PNIPAM hydrophobic core (Figure 3A).

Clicking cargos for gene therapeutics is another recent approach. Alshaer et al., functionalized liposomes with an anti-CD44 aptamer via a thiol-maleimide click reaction, for selective targeting of cancer cells – Fig. 3 B). Uptake was proven in two CD44(+) human cancer cell lines, lung cancer A549 and breast cancer MDA-MB-231. A new cyclodextrin derivative CD-PLLD, consisting of a beta-cyclodextrin core and poly-L-lysine dendron, efficiently delivered siRNA encoding plasmid to cancer HNE-1 cells. Simultaneously, a docetaxel was delivered. This star-shaped copolymer of cyclodextrin showed high activity, better blood compatibility and also lower cytotoxicity compared to the controls. It is exciting that clicked modified cyclodextrins have also been found to be capable of siRNA delivery to neurons. Furthermore, low toxicity and high stability in serum has been confirmed for these vectors.

As to the specificity, additional modifications such as LNA are helpful to decrease off-target binding. Decorating DNA with several peptide units resulted in improved stability and target recognition specificity of antisense oligonucleotides that target BRAF V600E oncogene. The CuAAC method gave good yields of double-labelled products as well. A “clickable” LNA variant has been suggested for miRNA targeting within LNA/DNA probes. Besides often-applied sugar modification and terminal attachment by click chemistry, nucleobases can be modified by click chemistry as well. This is often applied when using clickable triphosphates (TPPs), due to better yields upon enzymatic incorporation than for sugar-modified TPPs. Also, the modification can be done post-synthetically with a broad range of azides. Xiong et al., applied 8-aza-7-deazaguanine oligonucleotides to create branched Y-shaped DNA. Annealing of branched DNA with complementary oligonucleotides yielded well defined nanostructures. Selective target recognition was also confirmed by in vitro assays.

In the last decade, focus has shifted from DNA to RNA therapeutics. As for DNA and its analogues, chemical modifications are compulsory for RNA therapeutics to increase stability in vivo and to ensure the specific delivery and intracellular uptake. Recent studies show that conjugation of therapeutic siRNA with fatty acids and carbohydrate residues benefit the therapeutic performance of RNA (RNA-galnac and RNA-fa papers). For these
molecules, maleimide and N-Hydroxysuccinimide (NHS) chemistry is being used. Most methods are developed for DNA conjugation and do not meet the additional requirement of mild conditions needed for RNA modification. Growing applications in RNA therapy stimulate rapid development of bioconjugation methods that allow RNA labelling in high yields and purity43–44(Figure 5).

4. Comparison of “clicked” gene therapeutics to alternatives

Although much progress has been made on the click chemistry of therapeutic oligonucleotides and their delivery vesicles, critical points that need to be addressed are their potential toxicity and possibility to scale-up production. TFF purification, which has been mentioned previously, is a good way to scale up the CuAAC reaction29. Moreover, as has been described by Jones et al., click modification can affect the uptake pathway for therapeutics30. Trafficking determines the fate of a therapeutic inside the cell. Therefore, tracking studies are crucial to get structure-activity relationships for conjugates. Lastly, reducing the price of gene therapy is of crucial importance48.

The performance of available clicked therapeutics vs. alternative therapies is summarized in Table 1. Recently, Costales et al., compared clicked small molecule drugs with oligonucleotides49. They showed that morpholino-oligonucleotides had superior specificity in vivo when targeting myotonic dystrophy type 2 (DM2) associated gene alterations. Especially, therapeutic poly-oligonucleotides assembled on site had superior activity when compared to small molecule drugs. In addition, conjugation with CPPs was found to dramatically enhance the therapeutic performance of PMOs used to target exon skipping in the mouse mdx model50.

Multidrug resistance is an issue that blocks the use of available small molecule drugs49. It was shown that using siRNA and ULANAR PS antisense/siRNA makes cancer cells more permeable and reduces resistance. Wu et al., proposed a novel copolymer decorated with folic acid and siRNA for breast cancer treatment51. Co-delivery with doxorubicin resulted in suppression of tumor growth while maintaining rather low toxicity on other tissues. In another work was reported that multidrug resistance could be reversed using click polymer/iMDR1-pDNA complex nanoparticles56. This approach could become useful in breast cancer and other solid tumor treatments in cases when conventional therapy is not working and to reduce the toxicity.

Macrophages could be targeted by siRNA via click mannosylated polymeric micelles52. Being involved in cancer and atherosclerosis pathology, macrophages represent an important therapeutic target. CD206 (mannose receptor) is primarily expressed on macrophages which ensured specific delivery of mannose-decorated siRNA micelles. Up to a 13-fold higher siRNA concentration was found in the macrophages compared to CD206 negative control cells which supports the high specificity of the approach. The authors underline that this approach is general and can be adopted for click functionalization with other target ligands to direct siRNA delivery52.
Main competitors to gene therapeutics remain small molecule drugs\textsuperscript{53}. Small molecules have the advantage of well controlled chemical composition and low cost. However, many of them suffer from poor water solubility and high toxicity. Additionally, cells often become resistant to small molecule drugs, via mutagenesis\textsuperscript{57}. It is worth noting that the therapeutic action of these drugs can be improved by click chemistry as well\textsuperscript{53–54}. The drugs can be used in mixed formulations with siRNA\textsuperscript{51} or they can be covalently conjugated to antibodies and nucleic acids including aptamers\textsuperscript{55}.

Lastly, the synthesis of biodegradable polymers is an exciting approach that could solve the issue of drug clearance from the blood stream. Zhao \textit{et al.}, prepared disulfide - containing copolymers and showed that they are useful for gene delivery\textsuperscript{58}.

5. Conclusions

In summary, click chemistry finds a growing amount of applications in the development of gene therapeutics and is now being applied for direct oligonucleotide modification, cargo functionalization or the preparation of nucleotide variants at the nucleoside level. Click chemistry on DNA is relatively well established, whereas RNA modification by click chemistry requires further improvements. The sensitivity of unmodified RNA to chemical reagents and enzymes puts a high demand on the conditions for modifications.

Among prepared molecules, peptide-oligonucleotide conjugates and oligonucleotide nanomaterials show the best therapeutic performance. It is exciting that observations to date suggest gene therapeutics can reverse drug resistance from virus and solid tumors. Delivery and intracellular uptake remain the rate-limiting step, but this issue plagues all therapeutic developments. However, it is convincing from recent developments described in this review that these two issues can be successfully overcome using appropriate design and conjugation strategies.

Compared with small molecule drugs, the high cost of synthetic oligonucleotides and peptides is another obstacle for gene therapy application. Nevertheless, given the rapid development in oligonucleotide and peptide syntheses and the low cost of click chemistry reagents, the overall therapeutic price is bound to fall as the field progresses.

Recent discoveries in RNA biology also provide new targets for clicked therapeutics. Examples are miRNA and IncRNA\textsuperscript{59–62}. Following the development of new clickable nucleosides, nucleotides and oligonucleotide modification reagents, targeting regulatory RNAs is an exciting new direction that might bring new advances to the field of synthetic gene therapeutics.
