ABSTRACT
In many animal species, performance in the early life stages strongly affects recruitment to the adult population; however, factors that influence early life history stages are often the least understood. This is particularly relevant for lake sturgeon, Acipenser fulvescens, living in areas where environmental calcium concentrations are declining, partly due to anthropogenic activity. As calcium is important for muscle contraction and fatigue resistance, declining calcium levels could constrain swimming performance. Similarly, swimming performance could be influenced by variation in yolk sac volume, because the yolk sac is likely to affect drag forces during swimming. Testing swimming performance of larval A. fulvescens reared in four different calcium treatments spanning the range of 4−132 mg l−1 [Ca2+], this study found no treatment effects on the sprint swimming speed. A novel test of volitional swimming performance, however, revealed reduced swimming performance in the low calcium environment. Specifically, volitionally swimming larvae covered a shorter distance before swimming cessation in the low calcium environment compared with the other treatments. Moreover, sprint swimming speed in larvae with a large yolk sac was significantly slower than in larvae with a small yolk sac, regardless of body length variation. Thus, elevated maternal allocation (i.e. more yolk) was associated with reduced swimming performance. Data suggest that larvae in low calcium environments or with a large yolk sac exhibit reduced swimming performance and could be more susceptible to predation or premature downstream drift. Our study reveals how environmental factors and phenotypic variation influence locomotor performance in a larval fish.

KEY WORDS: Life history traits, Sprint swimming, Maternal allocation, Recruitment, Volitional swimming test

INTRODUCTION
Recent studies have revealed that calcium levels in aquatic environments are declining in many soft water lakes in boreal North America (Jezierski et al., 2008; Jezierski and Smol, 2016). Low calcium content has been coupled with the near extirpations of important crustacean species, including calcium-rich Daphnia and amphipod species (Cairns and Yan, 2009), freshwater gastropods (Dalesman and Lukowiak, 2010), as well as keystone benthic predators such as the eastern crayfish (Cambarus bartonii; Hadley et al., 2015). As a result of these food web alterations, algal production may rise (Korosi et al., 2012), and there is concern that zooplanktivorous fish populations inhabiting low calcium environments (e.g. Canadian Shield) may decline (Jezierski et al., 2008). Moreover, adequate calcium levels may be critical for fish from a physiological standpoint during early life stages when demand is highest (Genz et al., 2014). One species with a native range including the Canadian Shield is the lake sturgeon (Acipenser fulvescens), which is considered to be a species at risk under the assessment of the Committee on the Status of Endangered Wildlife in Canada (COSEWIC, 2006).

Previous studies on chondrosteans, an Actinopterygian subclass that includes sturgeon species, have demonstrated that these organisms are likely to be more prone to fluctuations in environmental calcium due to their low plasma calcium levels and their lack of a bony skeleton or scales (which can act as a calcium buffer in teleost fish), particularly among species that are constrained to a freshwater life cycle (Allen et al., 2009). Studies have demonstrated that calcium uptake in juvenile and adult fish is primarily achieved across the gills (Perry and Wood, 1985; Flik et al., 1995), but in larval A. fulvescens maternal provisioning and uptake by the yolk epithelium are significant sources of calcium (Genz et al., 2014), and align well with similar observations in teleost fishes (Chen et al., 2003).

Lake sturgeon, unlike other species from the Acipenseridae family in North America, spend their entire life cycle in freshwater lakes and rivers. Spawning, which typically occurs in late spring, takes place over gravel beds in fast-flowing river sections (McKinley et al., 1998). Upon hatch, larvae settle in the sediment where they rely on their yolk reserves for 3−19 days depending on water temperature (Wang et al., 1985; Auer and Baker, 2002; Peterson et al., 2007). During this life stage, larvae are especially vulnerable to benthic predators owing to the absence of scutes (Caroffino et al., 2010) and presumably rely on their swimming abilities to escape and seek cover (Peterson et al., 2007; Wishingrad et al., 2014). Upon yolk absorption, larvae begin drifting downstream until suitable habitat is encountered (Smith and King, 2005; Pollock et al., 2015). Although the specific mechanisms leading to settlement are still unknown, swimming performance could play a major role (Barth and Anderson, 2015).

Calcium availability plays a key part in muscle contraction and fatigue resistance during exercise (Berchtold et al., 2000; Anttila et al., 2008) and can thus play an important role for larval fish where
swimming activity is often highest (Verhille et al., 2014). In turn, larval swimming ability plays a major role in survival as it facilitates foraging (once yolk is absorbed), escape from predators and avoidance of premature downstream drift to suboptimal habitats and potentially energy costly environments (e.g. high water velocity or temperature). Swimming performance therefore has potential significant fitness-related consequences (Plaut, 2001; Johnson et al., 2015; Pimentel et al., 2016).

Body shape and size metrics are often used to explain swimming variation in fish (Ojagna and Braña, 2003; Verhille et al., 2014; Baktoft et al., 2016). Of particular interest for larval fish is the effect of the yolk sac, because it is maternally derived and crucial for larval survival. Mothers allocating resources to offspring face a trade-off between (1) allocating more energy to fewer offspring and (2) allocating less energy to many offspring (Smith and Fretwell, 1974). Selection should favour mothers that find an optimal solution to the trade-off, particularly in unpredictable environments (Fischer et al., 2011; Segers and Taborsky, 2011). Although several lines of evidence suggest elevated survival among larvae with large yolk sacs (Miller et al., 1988; Rideout et al., 2005; Uusi-Heikkilä et al., 2010), few studies have identified factors favouring larvae with large yolk sacs (Gagliano and McCormick, 2007). Riverine piscivores may, however, select prey with large yolk sacs (Freshwater, 2010), and thus exhibited different same age, were held under identical conditions, and any developmental differences between treatments would be attributed to ambient [Ca2+] (see below).

Incubation of eggs and rearing of larval A. fulvescens followed previously described procedures for Acipenseridae (Doroshov et al., 1983; Aloisi et al., 2006). Fertilised eggs were placed in MacDonald jars (Bates et al., 2014), which provided continuous water mixing at 12.0±0.4°C. Holding tanks containing three different environmental [Ca2+] treatments (low: nominally 0.1 mmol l−1 or 4 mg l−1; medium: 0.4 mmol l−1 or 16 mg l−1; and high: 3.3 mmol l−1 or 132 mg l−1 [Ca2+]) and a control tank containing water of a similar composition to the Winnipeg River (0.35 mmol l−1 or 14 mg l−1 [Ca2+]; Allen et al., 2009) were used to supply water to the jars (Table 1). The three [Ca2+] treatments were selected based on previous studies on A. fulvescens (Allen et al., 2011; Genz et al., 2013, 2014). Calcium levels found in the Winnipeg River are similar to those found in Lake Superior (∼13 mg l−1) but lower than those found in lakes Ontario and Erie (∼32–33 mg l−1) (Chapra et al., 2012). Calcium treatments were made by adding salts (Fluka; Sigma) to deionised water using (mmol l−1 unless otherwise indicated): 0.11 NaCl, 0.022 KCl, 0.16 MgSO4·7H2O, 170 mmol l−1 Na2HPO4 and 0.1, 0.4 or 3.3 CaCl2·2H2O. Water pH was adjusted to 7.69±0.05 using NaHCO3. Ionic composition of the treatment water was measured via ion exchange chromatography (Table 1). The control treatment was supplied with dechlorinated tap water standard to the animal holding facility, and thus exhibited different concentrations of measured cations in addition to Ca2+ compared with the other three groups. Water was continually recirculated between MacDonald jars and reservoir tanks (160 litres) with the appropriate treatment water using pumps equipped with biofilters. Aeration of the water was ensured using air stones. Half of the water in each reservoir was replaced every other day during incubation.

Dead eggs were removed daily to avoid fungal infections. After 5–7 days, larvae began hatching and were transferred from the MacDonald jars to opaque, partly covered 5 litre tanks (160 litres) with the appropriate treatment water using pumps equipped with biofilters. Aeration of the water was ensured using air stones. Half of the water in each reservoir was replaced every other day during incubation.

Gametes were collected 20 h post-injection. Eggs from six females and milt from four males were mixed manually, and fertilised eggs were placed in freshwater containing fuller’s earth for 30 min to prevent adhesive clumping and thus increase resistance to fungal growth (Genz et al., 2014). Parentage was equally distributed and replicated across treatments. Thus, once hatched, all fish were the same age, were held under identical conditions, and any developmental differences between treatments would be attributed to ambient [Ca2+] (see below).

The objective of this study was to evaluate the effects of environmental calcium concentration and variation in yolk sac volume on the swimming performance of larval lake sturgeon. To this end, lake sturgeon eggs and larvae were reared in environmentally relevant calcium concentrations and assessed for their swimming performance using two different approaches: (1) a novel measure of volitional vertical swimming speed and distance to swimming cessation, and (2) horizontal sprint swimming speed and foraging (once yolk is absorbed).
and released in the tank used for data collection. For the release, the container was tilted 90 deg and submerged by about 1 cm. If the larva remained in the container, the container was tilted slightly more and drained by lifting the container above the water surface. All experiments were carried out in a temperature-controlled room adjusted to 12°C, equivalent to the holding temperature. All procedures followed the University of Manitoba Animal Care and Use Protocol (F09-039/1/2) approved for the study.

### Vertical volitional swimming performance: a novel methodology

Previous studies have used small swim tunnels to measure the swimming performance of larval fish (Poulsen et al., 2012; Baker et al., 2014; Deslauriers et al., 2017) and other small organisms (Hata et al., 2017). Preliminary tests indicated that _Acipenser fulvescens_ yolk sac larvae do not exhibit consistent positive rheotactic behaviour (i.e. swimming against the water flow) in a swim tunnel until they have nearly absorbed all their yolk. Therefore, an alternative protocol based on the negative phototactic behaviour, swimming away from light typically toward the benthos, of larval _A. fulvescens_ was developed to test larval swimming performance for volitional swimming duration and speed.

Tests were carried out using a vertical transparent cylinder that was 111 cm tall with an inner diameter of 12 cm. The acrylic cylinder was sealed at the lower end and the bottom was covered with 10 cm of gravel (5–10 mm diameter). Intervals of 5 cm were marked on the cylinder from the water surface to the gravel for behavioural observations. Water was added to the cylinder to ensure 100 cm of water above the gravel bottom. A 40 W bulb provided light 40 cm above the water surface, and water temperature was kept at 12.1±0.6°C.

_Acipenser fulvescens_ were sampled randomly from the treatment tanks (control, low, medium and high calcium; N=42 per treatment) and released individually at the water surface of the cylinder. Water chemistry in the cylinder reflected the corresponding calcium treatment. All larvae started sprinting towards the bottom immediately after release and swimming performance was recorded. Specifically, travel speed (mm s⁻¹) was recorded by dividing 1000 mm (i.e. cylinder length) by the time interval (to the nearest 0.1 s) it took the larvae to move from the water surface to the bottom of the cylinder. In addition, observations were carried out to record the distance swum (to nearest 5 cm) from the water surface until cessation of active swimming movements (i.e. absence of tail beats). These observations were included because many larvae ceased to actively swim before reaching the bottom of the cylinder. After ceasing tail beat, larvae would sink passively towards the bottom. Due to significant image distortion of the circular cylinder and because larvae were difficult to retrieve from the gravel after testing, kinematic (i.e. tail beat frequency, tail beat amplitude) and morphological (i.e. body length, body mass and yolk sac volume) metrics were not quantified in these fish; instead, such variables were assessed from fish utilised in the horizontal sprint swimming trials as outlined below.

### Horizontal sprint swimming trials

Individual _A. fulvescens_ were sampled randomly from the treatment tanks (control, low, medium and high calcium; N=20–25 per treatment) and transferred to a circular arena (4×35 cm; depth×diameter) for high-speed video recordings. Tested larvae differed from those used in the vertical swim trials. A high-speed camera (HiSpec1 (125 Hz), Fastec Imaging, San Diego, CA, USA) was positioned above the arena for dorsal recordings of fish swimming. Similar to Shepherd et al. (2000), water depth in the arena was set at 4 cm, and a dim light underneath the arena was used to enhance image contrast. A 10 mm×10 mm grid was placed in the field of view to calibrate distances. Sprint swimming was elicited by touching the caudal region of the larva with a thin needle, similar to previous studies on larval fish (Batty and Blaxter, 1992). All larvae responded to the stimuli by rapid undulations of the tail and swimming near the bottom of the circular arena to escape the stimuli placed on the tail region. A total of one to six video swimming sequences were recorded per individual larva. Each sequence included at least two complete tail beats.

Analysis of the video recordings was restricted to sequences in which larvae swam in a steady and linear fashion (Fuiman and Batty, 1997) and at least 2 cm away from the sides of the arena (Fish et al., 1991; Svendsen et al., 2003) to minimise any wall effects (Webb, 1993). The software Tracker (version 4.82; available from http://www.cabrillo.edu/~dbrown/tracker/) was employed to track the tip of the tail and the centre of the yolk sac. The latter was assumed to approximate the centre of mass (COM) of the larva. Video sequences were analysed frame by frame and provided three biomechanical variables: (1) swimming speed, (2) tail beat frequency and (3) tail beat amplitude.

Swimming speed (mm s⁻¹) was calculated as the total accumulated distance (mm) covered by the COM divided by the duration (s). The distance (d) between two pairs of x, y coordinates was calculated using:

\[
d = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2},
\]

where \(x_1\) and \(x_2\) and \(y_1\) and \(y_2\) indicate the coordinates of two sequential positions. Tail beat frequency was defined as a full oscillation of the tail (i.e. a complete cycle of left and right lateral displacement; Hunter and Zweifel, 1971; Svendsen et al., 2010). Tail beat amplitude was calculated as the perpendicular distance (mm) between the trajectory of COM and the most lateral x, y coordinates of the tip of the tail.

Measurements of COM and tail tip were synchronised and the COM trajectory was extrapolated posteriorly in a linear fashion to the tail tip coordinates to estimate amplitude. A full tail oscillation around the COM trajectory was used as the measure of amplitude. Each analysed video sequence included at least two consecutive tail beats (Fuiman and Batty, 1997) and provided one measure of speed, tail beat frequency and tail beat amplitude. The latter two variables were estimated as the average of consecutive tail beats.

Body mass, body length and yolk sac volume were quantified after each sprint swim trial. Individual larvae were removed from the circular arena using a wide mouth pipette (Shepherd et al., 2000) and transferred to 25 ml vials, where larvae were euthanised with ~250 p.p.m. tricaine methanesulfonate (MS-222; Syndel Laboratories, Nanaimo, BC, Canada) following previous studies (Hale, 1999). Vials contained a limited volume (2–3 ml) of treatment water to prevent dehydration and were kept on ice immediately after finishing the high-speed video recordings. Next, larvae were carefully blotted dry using a soft paper towel and transferred to a microscope (Nikon, YS100) connected to a digital camera (Sony 3CCD colour camera) to take lateral (dexter; i.e. right side) and dorsal images of each larva. Vials were kept on ice for no more than 6 h prior to taking the images. Image pixels were converted to millimetres using a 10 mm×10 mm grid included in the field of view. Wet larva body mass (M, g) was determined (to the nearest 0.0001 g) using a Mettler AE163 analytical balance (Mettler-Toledo, Columbus, OH, USA).
Images were analysed using the software Vernier Logger Pro (version 3.6; Vernier Software & Technology, Beaverton, OR, USA). The analysis provided a measure of total body length in addition to yolk sac length, height and width (all in mm) for each larva. The yolk sac was assumed to be an ellipsoid (Kamler, 2008) with the volume calculated as:

\[ V = \frac{4}{3} \pi \frac{h}{2} \times \frac{l}{2} \times \frac{w}{2}, \]

where \( V \) is yolk sac volume (mm\(^3\)), and \( l, h \) and \( w \) represent yolk sac length, height and width (mm), respectively. By assuming that the yolk specific gravity is 1 (Kamler, 2008), the proportion (\( P \), %) of the total body mass allocated to yolk sac was calculated as:

\[ P = \frac{V}{(M \times 1000)} \times 100. \]

**Statistical analyses**

Effects of environmental calcium on travel speeds (mm s\(^{-1}\)) tested in the vertical cylinder were analysed using a one-way ANOVA. The same analysis was applied to examine effects of environmental calcium on the distance swim (cm) before swimming cessation. Standard transformations of data [e.g. \( \ln(x+1) \)] prior to statistical analysis were employed to meet assumptions of normal distribution of data and homogeneity of variance. If assumptions were met, the tests were followed by Holm–Šídák pairwise multiple comparison procedures. If data transformations did not permit the use of parametric testing, an ANOVA on ranks was employed, followed by pairwise multiple comparisons procedures involving the Student–Newman–Keuls method.

To test the effects of environmental calcium and yolk sac volume on sprint swimming speed in the circular arena, a linear mixed-effects model (LMM) approach was applied following Zuur et al. (2009). Larva identity (ID) was included as a random effect, thereby inducing a compound correlation structure to accommodate the repeated measures on each larva (up to six measures on individual larva). Yolk sac volume, total body length and calcium treatment of individual larvae, as well as tail beat frequency and amplitude, were included as covariates in the model to account for potential effects of these variables. Body mass was not included as a covariate in the model as it is highly correlated with total body length. The initial full model was written as:

\[ \text{Speed}_j = \alpha + V_j + L_j + Ca^{2+}_j + f_j + A_j + a_j + e_{ij}, \]

\[ a_j \sim N(0, \sigma_a^2), e_{ij} \sim N(0, \sigma^2), \]

in which the swimming speed of individual \( j \) in sequence \( i \) is a function of a common intercept (\( \alpha \)), yolk sac volume (\( V \)), body length (\( L \)) and calcium treatment (\( Ca^{2+} \)) of individual \( j \), tail beat frequency (\( f \)) and amplitude (\( A \)) of individual \( j \) measured in sequence \( i \), all two-way interactions including yolk sac volume of individual \( j \), a random intercept (\( a_j \)) and residual variation (\( e_{ij} \)). The model assumed that \( a_j \) was normally distributed with mean zero and variance \( \sigma_a^2 \), and \( e_{ij} \) was normally distributed with mean zero and variance \( \sigma^2 \).

Significance of model terms were evaluated using likelihood ratio tests comparing nested models fitted using maximum likelihood estimation. Non-significant (\( P>0.05 \)) interactions were removed to obtain a final model including all significant main effects. Parameter estimates of the final model were obtained using restricted maximum likelihood estimation. The final model was validated using Q–Q plots of model residuals and by plotting model residuals as functions of fitted values and all explanatory variables. There were no indications that model assumptions of normality and variance homogeneity were violated. The model output was correlated with the empirical data using least squares linear regression to assess the predictive ability of the developed model.

The free statistical software R (http://www.r-project.org/) and SigmaPlot 11.0 (Systat Software, Erkrath, Germany) were used for statistical analyses and graphing. The R package nlme (Pinheiro et al., 2017) was used to fit models. Results were considered significant at \( P<0.05 \). All values are reported as means±s.e.m. unless otherwise stated.

**RESULTS**

**Vertical swimming performance**

All tested larvae began swimming towards the bottom immediately after transfer to the vertical cylinder. The results revealed that travel speed was reduced significantly (\( P<0.05 \)) by 19% in the low calcium treatment compared with the other treatments. Travel speeds in the control, medium and high calcium treatments were similar; fish travelled at speeds ranging between 62.4 and 66.7 mm s\(^{-1}\).

Although all larvae started swimming downwards after release into the cylinder, not all larvae reached the bottom while actively swimming. Instead, active swimming frequently stopped before the larvae reached the bottom. Results showed that larvae conditioned in low calcium environments ceased swimming after a significantly (\( P<0.05 \)) shorter distance compared with the other treatments (Fig. 1). Following cessation, larvae sank passively towards the bottom, which decreased the average travel speed. This observation indicated that the slower travel speeds associated with fish reared in the low calcium environments were a product of early swimming cessation in the vertical cylinder rather than slower swimming speeds per se.

![Fig. 1. Vertical swimming behaviour of larval lake sturgeon Acipenser fulvescens is affected by environmental calcium. Larvae were tested in four different calcium treatments: control, low, medium and high environmental calcium. Using a vertical distance of 100 cm, the figure shows the distance swum actively (i.e. beating the tail) before swimming cessation in A. fulvescens. Larval A. fulvescens reared in low calcium swam a significantly shorter distance before swimming cessation compared with the other treatments (\( N=42 \) per treatment). This result shows that the low calcium environment was associated with reduced volitional swimming performance. Different letters indicate significant (\( P<0.05 \)) differences between treatments. Values are means±s.e.m.](https://example.com/fig1.png)
Horizontal sprint swimming trials
A total of 250 high-speed video sequences were analysed for sprint swimming speed (mm s$^{-1}$) using 92 different larvae with an average total length of 13.1±0.1 mm (total length) and wet body mass of 0.0174±0.0001 g. The average yolk sac volume was 7.4±0.1 mm$^3$ (range 5.4–10.3 mm$^3$). The percentage of the total larval body mass allocated to the yolk sac was 42.6±0.5% (range 30.6–53.5%), as calculated using Eqn 3. Using a LMM analysis, there was no evidence that the calcium treatments influenced the sprint swimming speed ($P>0.05$). Thus this covariate was removed, and the LMM approach continued to test for effects of body length, body kinematics (i.e. tail beat frequency and tail beat amplitude) as well as yolk sac volume on the sprint swimming speed. This test provided evidence ($P<0.05$) that sprint swimming speed correlates positively with body length (A), tail beat frequency (B) and tail beat amplitude (C), and negatively with yolk sac volume (D) ($N=20–25$ per treatment). Note that each regression line is conditional on the other covariates being at their respective mean values.

DISCUSSION
Examining locomotor performances in larval A. fulvescens, this study revealed (1) that low environmental calcium concentrations ($\leq$4 mg l$^{-1}$ [Ca$^{2+}$]) reduce volitional swimming performance, and (2) that elevated maternal allocation, as indicated by a large yolk sac volume, is associated with reduced sprint swimming speed. These findings are important because variation in locomotor performance may have fitness implications. For example, swimming performance predicts survival in tadpoles of the Pacific tree frog (Pseudacris regilla) (Watkins, 1996) and the Trinidadian guppy (Poecilia reticulata) (Walker et al., 2005) as well as foraging efficiency in larval Atlantic cod (Gadus morhua) (Hunt von Herbing and Gallager, 2000). Moreover, swimming performance was a function of a common intercept ($\alpha$), yolk sac volume ($V$), body length ($L$), tail beat frequency ($f$) and tail beat amplitude ($A$). $\sigma^2_a$ and $\sigma^2$ represent the variance associated with the random intercept and the residuals, respectively. n.a., not applicable.

Swimming speed of individuals was a function of a common intercept ($\alpha$), yolk sac volume ($V$), body length ($L$), tail beat frequency ($f$) and tail beat amplitude ($A$). $\sigma^2_a$ and $\sigma^2$ represent the variance associated with the random intercept and the residuals, respectively. n.a., not applicable.
we employed two different swimming tests: (1) vertical swimming (Faillettaz et al., 2018). To date, no study has examined the effects of vertical swimming performance on larval fish, despite reports of widespread declining environmental calcium concentration (Jezierski et al., 2008; Jezierski and Smol, 2016) and field-based relationships between environmental calcium concentration and fish production (Jonsson et al., 2011). The present study examined the effects of discrete calcium environments on the swimming performance of larval A. fulvescens. To this end, we employed two different swimming tests: (1) vertical swimming was used to investigate the effects of calcium concentration on travel speed and time to swimming cessation, while (2) horizontal swimming was used to investigate the interactive effects of calcium concentration, body kinematics and morphology (e.g. yolk sac volume) on sprint swimming speed. Except for the low calcium concentration treatment, average larvae covered 92–96% of the vertical cylinder prior to swimming cessation. This differed significantly from the low calcium concentration treatment where larvae only covered about 80% of the vertical cylinder prior to swimming cessation. Importantly, the effects of the low calcium concentration treatment where larvae stopped swimming during the test. Data revealed no effects of calcium concentration on the horizontal swimming test where the full swimming duration was not quantified. Thus, we found no evidence that calcium concentration affects swimming speed during ongoing locomotion, but low calcium concentration reduced the time that A. fulvescens larvae were capable of swimming actively. These findings indicate that low calcium concentration affects swimming towards the end of a continuous swimming bout. The fact that low calcium concentration larvae stopped swimming, or perhaps were fatigued faster than the other calcium concentration treatments may indicate that the low calcium concentration modulated fatigue resistance. Although we use the term fatigue here, we acknowledge the limitations of our data, and we recommend further physiological and behavioural studies to investigate if voluntarily swimming larvae are truly fatigued when they cease swimming in a vertical cylinder test. Approaching physiological fatigue commonly involves decreasing levels of intracellular pH (Lurman et al., 2007) and muscle glycogen (Peake and Farrell, 2004) and increasing levels of lactate (Martinez et al., 2004; Peake and Farrell, 2004), inorganic phosphate (Lurman et al., 2007) and excess post-exercise oxygen consumption (Svendsen et al., 2010, 2015). Studies of such variables are required before the vertical cylinder test can be recognised as a tool to examine fatigue resistance in aquatic locomotion. Likewise, it would be relevant to examine whether data from vertical cylinder tests are repeatable within individual fish (Svendsen et al., 2014; Killen et al., 2016; Merrick and Koprowski, 2017). Tests of repeatability reveal if a measure is consistent across time and context within individuals. Several studies have reported that tests of aerobic and anaerobic swimming performances are repeatable within individual fish (Kolok, 1992; Kolok et al., 1998; Reidy et al., 2000; Claireaux et al., 2007; Outiero and Garland, 2009; Handelsman et al., 2010; Marras et al., 2010), hinting that the swimming performance revealed by the vertical cylinder test could be repeatable as well, but the hypothesis remains to be tested.

Larvae from the low calcium environment could be more prone to disruption of the mechanisms regulating calcium homeostasis. Internal calcium is involved in many important physiological processes and will probably be influenced by available environmental calcium. For example, the fundamental mechanism of excitation–secretion coupling involves calcium triggering synaptic vesicle exocytosis, thereby releasing neurotransmitters contained in the vesicles and initiating synaptic transmission and neuronal connectivity (Mintz et al., 1995; Štufhol, 2012; Petersen and Verkhratsky, 2016). Moreover, calcium handling by the sarcoplasmic reticulum (SR) mediates the muscle excitation–contraction–relaxation coupling and determines contraction and relaxation rates (Seebacher and Walter, 2012). Specifically, calcium is released from the SR and resorbed as resting levels, the force declines and relaxation occurs (Berchtold et al., 2000). The discrete steps of calcium release and resequestration as well as the availability of ATP may all constrain muscle function and swimming performance (Seebacher and Walter, 2012). In the present study, larvae from the low calcium environment were therefore hypothesised to exhibit reduced swimming performance. Surprisingly, the volitional vertical cylinder test showed that the low calcium concentration larvae stopped swimming after a shorter distance than the larvae exposed to higher calcium concentrations. Studies have uncovered several mechanisms regulating locomotion cessation or more specifically fatigue to calcium release and resequestration (Allen et al., 2008; Hostrup and Bangsbø, 2017). The SR can accumulate substantial amounts of additional calcium without evident effect, whereas reduction of the amount of releasable calcium in the SR adversely affects calcium release and force production (Allen et al., 2008). Indeed, recent studies have linked muscle fatigue and calcium release from the SR (Ortenblad et al., 2013; Nielsen et al., 2014). The present study did not include any internal or flux calcium measurements needed to identify the exact mechanism; however, on a whole-animal scale, A. fulvescens at this developmental stage has been shown to increase overall calcium influx in low calcium environments, suggesting an increased demand (Genz et al., 2014), although the distribution of absorbed calcium and the exact nature of the presumed demand remains unknown. However, we speculate that the low calcium concentration environment might constrain calcium handling, or perhaps the myosin binding, such that the low calcium concentration larvae stopped swimming after covering a relatively shorter distance.

Body morphology also affects swimming performance of larval fishes. For example, propulsive area (Fisher et al., 2000), fineness ratio (Fisher et al., 2005) and caudal peduncle depth (Fisher and Hogan, 2007) may influence larval swimming performance. To
date, few studies have examined the influence of yolk sac size on swimming performance, leading researchers to encourage further areas of study (Louhi et al., 2011; Kopf et al., 2014). The studies so far have provided inconsistent results (Shepherd et al., 2000; Kekäläinen et al., 2010), perhaps because morphological measurements were limited to two-dimensional (2D) measurements of the yolk sac. Specifically, Kekäläinen et al. (2010) estimated yolk sac volume from yolk sac length and height (i.e. no width) and reported a weak negative correlation between yolk sac volume and swimming performance. In contrast, Shepherd et al. (2000) reported a positive correlation between yolk sac area (i.e. 2D) and swimming performance. To our knowledge, the present study is the first to relate swimming performance to yolk sac volume estimated using measures of yolk sac length, height and width (i.e. 3D; Eqn 2). Our data revealed a significant negative correlation between yolk sac volume and sprint swimming speed, indicating that elevated yolk sac volume constrains sprint swimming performance in larval A. fulvescens. Thus, elevated maternal allocation (i.e. more yolk) was associated with reduced swimming performance. This is because a larger yolk sac volume will probably increase the cross-sectional area of the organism, leading to an increase in drag forces and faster energy loss (Vogel, 1996) compared with larvae of similar sizes but with smaller yolk sacs. For example, in many coral reef fishes, the maximum swimming speed is reduced by isopod ectoparasites, because the ectoparasites increase drag coefficients (Östlund-Nilsson et al., 2005; Binning et al., 2013). Similarly, heavily pregnant Trinidadian guppies (P. reticulata) often exhibit reduced sprint swimming speeds, presumably because of increased drag associated with pregnancy (Banet et al., 2016; Ghalambor et al., 2004). Although these organisms are much larger than the larvae tested in the present study, we suggest that the reduced swimming speed, observed in larval A. fulvescens carrying a large yolk sac, is induced by elevated drag forces experienced while swimming. It is unknown if larvae with large yolk sacs, and reduced swimming performance, modify behaviours (e.g. elevated shelter use) to offset the locomotor constraints associated with increased maternal allocation. In teleosts, heavily pregnant individuals may modify behaviours (i.e. elevated use of slow current habitats) to offset the locomotor constraints associated with pregnancy (Banet et al., 2016).

An evolutionary compromise or trade-off (Stearns, 1989; Elgar, 1990; Ghalambor et al., 2004) may be at play in A. fulvescens, where the benefits of maternal investment in elevated offspring body condition (i.e. more yolk) are partly countered by the cost of reduced swimming performance. In a similar example, Outiero et al. (2012) suggested that a superior physiological condition in sword tails (Xiphophorus hellerii) with an unusually long sword compensates for the negative effect of the sword on swimming performance. Resource allocation trade-offs play an important role in life history theory (Stearns, 1989; Zera and Harshman, 2001), such that fish with a larger yolk sac could spend a longer period of time prior to emergence (i.e. longer yolk absorption period), thus resulting in a bigger body size at emergence. This, in turn, might increase the probability of survival as smaller individuals are often selected against (Rosenberg and Haugen, 1982; Einum and Fleming, 2000). However, in more harsh environments (Fischer et al., 2011; Segers and Taborsky, 2011), where conditions in the substrate might deteriorate and larvae are forced to leave (Louhi et al., 2011), a large yolk sac may decrease swimming performance and perhaps elevate mortality until favourable substrate is located.

How the interaction between large yolk sac and low calcium environments might influence A. fulvescens, or any other fish species, is currently unknown. More studies are needed to understand the phenotypic plasticity of early ontogeny under inherent biological attributes and induced environmental changes because different phenotypes could influence the demographics of various populations and species. This remains particularly important to understand for imperilled species, including many members of the Acipenseridae family.
