ABSTRACT: Plasmon hot carriers are interesting for photoredox chemical synthesis but their direct utilization is limited by their ultrafast thermalization. Therefore, they are often transferred to suitable accepting materials that expedite their lifetime. Solid-state photocatalysts are technologically more suitable than their molecular counterparts, but their photophysical processes are harder to follow due to the absence of clear optical fingerprints. Herein, the journey of hot electrons in a solid-state multimetallic photocatalyst is revealed by a combination of ultrafast visible and infrared spectroscopy. Dynamics showed that electrons formed upon silver plasmonic excitation reach the gold catalytic site within 700 fs and the electron flow could also be reversed. Gold is the preferred site until saturation of its 5d band occurs. Silver-plasmon hot electrons increased the rate of nitrophenol reduction 16-fold, confirming the preponderant role of hot electrons in the overall catalytic activity and the importance to follow hot carriers' journeys in solid-state photosystems.

KEYWORDS: Plasmon, hot-electron, photocatalysis, multimetallic system, ultrafast dynamics

Light is used in a multitude of processes, from energy and chemical production to therapy. The development of energy efficient lighting devices and sunlight abundance have made light a versatile and cost-effective reagent. Plasmonic materials have optical absorptions that exceed 10-fold their cross-section, making them uniquely suitable light converters into electric carriers. Optical excitation of the localized surface plasmon resonance (LSPR) creates hot carriers^{1,2} that can be used in chemical transformations^{3–8} and photovoltaics.^{9–11} Their relaxation liberates thermal energy that can be used in photothermal processes, such as catalysis,^{12,13} desalination,^{14,15} cancer therapy,¹⁶ and sensing.¹⁷

Plasmon hot carriers with energy up to the absorbed photon energy¹⁸ multiply rapidly, decreasing their average thermal energy.¹⁹ This ultrafast charge relaxation process limits their direct utilization.^{18,20} Their transference to a suitable acceptor, such as semiconductor, can extend their lifetime^{2,11,21,22} as well as proton-coupled electron transfer events.²³ Semiconductors have characteristically low surface reactivity; therefore, the hot carriers are subsequently transferred to a catalytic site, e.g., metallic nanoparticles (NPs).^{4,5}

Solid-state systems are stabler and better for application in photocatalysis than their molecular counterparts. Understanding energy and hot carrier flow in plasmonic solid-state nanostructures is essential to exploit their potential. Aslam et al.^{24,25} were able to control the energy flow on a multimetallic nanostructure composed of silver nanocubes and platinum. However, the hot carriers' journeys in solid-state systems remain elusive because their photophysical processes are noticeably harder to follow, due to the absence of clear optical

fingerprints. Charge transfer to the catalyst is often deduced by signal quenching.⁵

Herein, we report an ultrafast spectroscopic study of plasmon-created hot electron flow in a multimetallic nanostructure consisting of Ag-TiO₂-Au, where silver, TiO₂, and gold act as a photosensitizer, electron relay, and catalyst, respectively. Dynamics showed that plasmon-formed hot electrons on silver take 700 fs to reach the catalytic site through the electron relay. The catalyst is the favoured site until the saturation of the gold 5d band. The plasmon-mediated process increases 16-fold the rate of nitrophenol reduction, confirming the presence of accumulative charge separation²⁶ necessary to fulfil the requirements on multi-charge photoredox processes. Gold is considered the noblest of the metals,²⁷ but Haruta et al.²⁸ demonstrated that gold at sub-10 nm is active due to depopulation of the 5d band caused by hybridization with the 6sp band.²⁹ Since then, gold has been found active in several reactions, e.g., nitrogen³⁰ and alkane activation,³¹ carbonylations,³² acetylene hydrochlorination,³³ and selective CO₂ reduction catalyst in aqueous media.^{7,34}

The complete multimetallic system consisted of gold NPs sandwiched between TiO₂ layers. The sandwich structure was

immersed in an aqueous colloidal solution to attach silver NPs. A schematic overview of the system, as well as the associated absorption spectra of the system, can be found in Figure 1c and 1d, respectively. Further preparation and characterization can be found in the Supporting Information (SI).

Silver NPs were prepared via a modified version of the polyol process³⁵ that yields spherical NPs with a mean diameter of 22 nm (TEM analysis, Figure 1a). DLS measurements (Figure S3) showed larger particle size because the hydrodynamic radius is sensitive to the PVP capping layer, undetectable by TEM. The PVP layer avoids Fermi level pinning upon charge injection to passivate the TiO₂ surface.³⁶ The silver NPs exhibited a single LSPR peak at 404 nm (Figure S4). Gold NPs were formed by evaporation and subsequent annealing of a 1 nm gold layer. The procedure yielded uniform gold NPs with an average diameter of 5 nm (TEM analysis, Figure 1b), thus within gold active range.²⁸ Upon assembling, the Ag NPs LSPR red-shifted by 16 nm (Figure 1d) due to the change in the dielectric environment.³⁷ The ratio between silver and gold was determined by SEM EDS (Table S1), using 10 randomly selected sample spots. The average silver/gold ratio was found to be 8.4 ± 1.1 , indicating a uniform distribution of silver and gold on the prepared films and excess of photosensitizer silver NPs.

Transient absorption spectroscopy was used to gain an insight into the charge carrier dynamics. An excitation wavelength of 435 nm was chosen as the best comprise

between exciting silver near its LSPR and having a low response resulting from gold interband transitions,³⁸ which occur in the same spectral region (Figure S12). The studies were performed using the same photon density (200 μ W and fixed aperture), enabling a direct comparison of the samples. The selected wavelength also avoids any signal related to the excitation of the TiO₂ bandgap or trap states (see Figures S14 and S15).

The plasmonic response of silver NPs in the visible regime was studied in the complete system (Figure 2c) and without gold catalyst (Ag-TiO₂; Figure 2b). An additional sample comprised of silver NPs on ZrO₂ was used as a noninjectable reference¹¹ (Figure 2a). For both silver and gold NPs, light excitation resulted in a change in the internal electronic structure of the NPs that broadens the plasmon resonance, resulting in the characteristic transient signal comprised of a bleach around the NPs LSPR surrounded by two positive winglets. The signal decay is known to be dominated by electron-phonon scattering (e-ph),³⁹ the dominant cooling pathway for hot electrons following ultrafast electron-electron scattering.³⁹ Figure 2e shows the kinetics at 470 nm (where the silver transient bleach occurs) for Ag-ZrO₂, Ag-TiO₂, and the full multimetallic system. Signal fitting was performed using the instrument response function (IRF) convoluted with a monoexponential decay and an infinite lifetime when TiO₂ is present, as signals did not decay to zero. The rising-edge region at 470 nm is assigned to electron-electron scattering

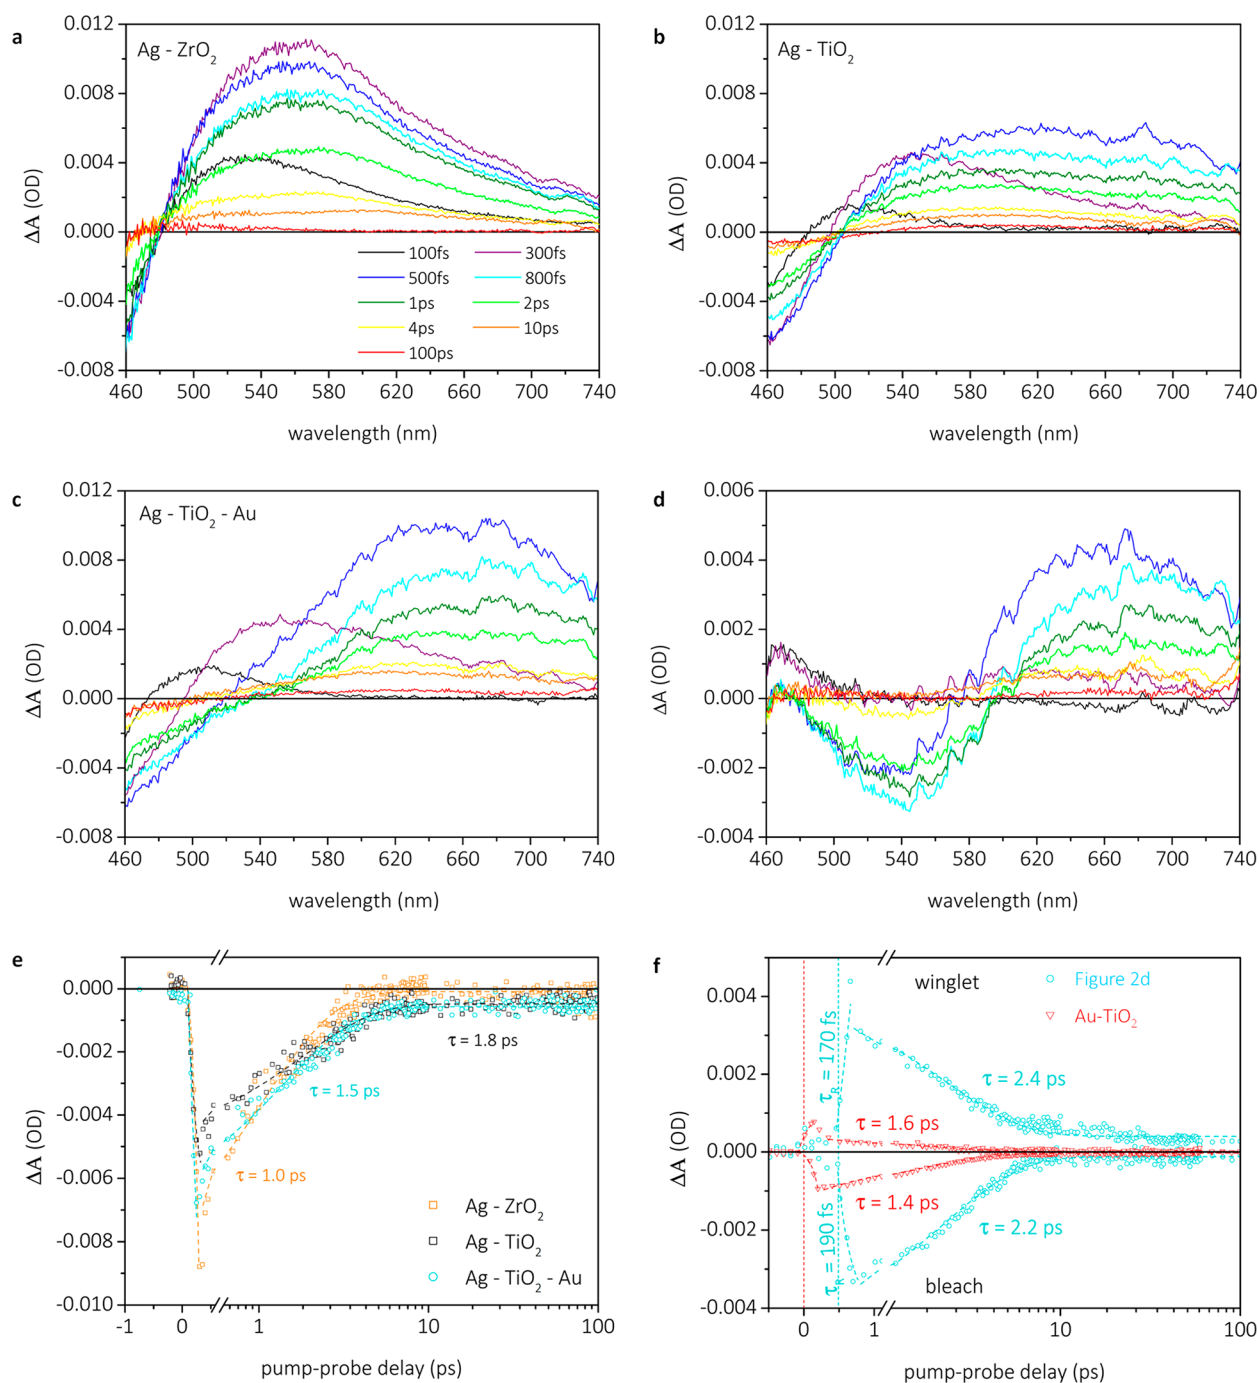

Figure 2. Transient absorption spectra of Ag-ZrO₂ (a), Ag-TiO₂ (b), and Ag-TiO₂-Au (c). Resulting transient absorption spectra after subtracting the data of panel b from c (d). events,^{11,23} but in the present case the determined time constant was below the instrumental resolution (ca. 150 fs); thus, one can only state that those events happen in less than 150 fs, as expected.¹ Kinetic analysis of the decay part revealed a faster decay component for Ag-ZrO₂, corresponding to e-ph scattering, of 1.1 ps, in comparison to Ag-TiO₂ and Ag-TiO₂-Au, of 1.7 and 1.5 ps, respectively. The reduced e-ph scattering time observed on ZrO₂ is attributed to the blue-shift of the silver LSPR on ZrO₂ caused by the difference in dielectric constant between ZrO₂ and TiO₂,⁴⁰ resulting in excitation taking place further away from the LSPR and consequently giving rise to lower electron temperature and faster cooling.

Furthermore, the kinetic traces not decaying to zero for Ag-TiO₂ and Ag-TiO₂-Au within the experimental delay line (ca. 5 ns) indicates the presence of a residual amount of unrecombined holes in silver, suggesting electron injection taking place from silver into TiO₂. This explanation is further supported by the appearance of a broad signal from 620 to 740 nm for the Ag-TiO₂ and Ag-TiO₂-Au samples (Figure 2b and 2c), attributed to electrons in the TiO₂ conduction band,²¹ as confirmed by measuring the transient response of bare TiO₂ when pumped above the bandgap at 330 nm (Figure S13).

The injection is apparent from the responses of the multimetallic system in the visible regime but is considerably

overlapped with the other signals. Therefore, we opted to perform similar experiments but probing in the mid-infrared regime, where free charge carriers in the conduction band of TiO_2 yield a characteristic, strong, featureless absorption,⁴¹ enabling us to study electron injection into TiO_2 without overlaps (Figure 3a). Kinetic traces extracted at 5200 nm can

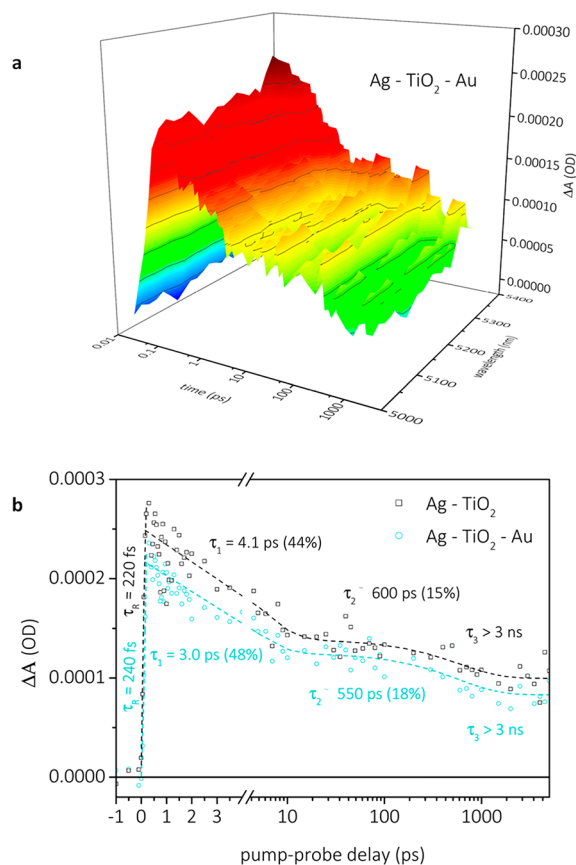

Figure 3. Transient infrared absorption spectra of $\text{Ag-TiO}_2\text{-Au}$ (a). Kinetic traces at 5200 nm extracted from TIRAS spectra (b).

be found in Figure 3b. A time of approximately 220 fs associated with charge injection from silver into the TiO_2 conduction band was found by the fitting of the rising edge with a monoexponential growth function. This time was virtually unaffected by the addition of gold NPs (ca. 240 fs), signifying that electrons are indeed relayed via TiO_2 . The lower signal magnitude for the full system suggests rapid transference of some electrons from TiO_2 to gold NPs. The measured decay of the sample with and without gold was fitted using two-exponential decay functions and an infinite lifetime component. Addition of gold resulted in a decrease of both time components from 4.1 to 3.0 ps and from 600 to 550 ps, respectively, and most importantly a significant decrease in the ΔA values. In the absence of gold, the measured decay is attributed to recombination processes across the $\text{TiO}_2\text{-Ag}$ interface. The difference in decay kinetics and signal amplitude upon gold addition indicates the appearance of a new channel that competes for the hot electrons in the TiO_2 conduction band, which was intuitively assigned to electrons being transferred from TiO_2 to gold. This is somewhat probable considering the energetics of the complete system, with the Fermi level of gold located at energies below the silver Fermi level and TiO_2 conduction band edge position.

Note that the observed TIRAS signal for electrons in the TiO_2 conduction band does not establish their origin, which can come from several processes, namely, (i) enhancement by the near-field of the silver NPs; (ii) enhancement by the near-field of the gold NPs; (iii) plasmon-induced resonant energy transfer (PIRET), and (iv) hot carriers generated directly in the silver NPs. We observed experimentally (SI; section on Reverse electron flow, pages 21–25) that the electron flow could be reversed by exciting the system at 550 nm (gold LSPR resonance). The signal trends were similar to what was observed when silver was excited, suggesting that electrons come from plasmon excitation. Additionally, and as aforementioned, the residual signal associated with unrecombined holes in the plasmonic structure that was excited is only consistent with a plasmon-mediated electron transfer mechanism.

While decreases in lifetimes of electrons on a semiconductor relay (TiO_2 here) have been reported before upon addition of a catalytic site that electrons can preferentially move to,^{5,6} the process has remained elusive and without direct proof. The use of gold here, however, allows for direct observations of changes in gold's electronic structure reflected by its transient absorption response following silver excitation. Figure 2d shows the difference spectrum between the full multimetallic system and Ag-TiO_2 pumped at identical fluences, and the associated kinetics extracted at the bleach and high-wavelength winglet of this difference spectrum is presented in Figure 2f. The corresponding transient absorption spectrum of Au-TiO_2 pumped at 435 nm and kinetic analyses can be found in Figures S16 and S17, respectively, for comparison. Three important differences between these spectra are to be noted. First, the signal amplitude in the difference spectrum extracted from $\text{Ag-TiO}_2\text{-Au}$ is significantly higher than the one observed when pumping Au-TiO_2 pumped at 435 nm, indicating a larger hot carrier population. Second, the monoexponential fitting of the signal decay that provides information about the e-ph scattering time³⁹ revealed a significantly increased e-ph cooling time, from 1.4 to 1.6 ps on Au-TiO_2 pumped at 435 nm (Figure S17) to 2.2–2.4 ps (Figure 2f) for the full system. The changes were rationalized as that higher electron density on gold in the full system will result in slower cooling, similar to the electron–phonon bottleneck reported for other systems.^{42,43} Third, and possibly the most important of all, there is a clear time lag (ca. 450–500 fs) in the rising edge component of the complete system, which is not present on the signal of Au-TiO_2 when pumped at 435 nm, that shows the expected edge rising at time zero with a time constant outside our instrument time resolution. The time lag in the ΔA signal was assigned to the travel time of hot electrons originated from the silver-plasmon to reach the $\text{TiO}_2\text{-Au}$ interface. Once at the $\text{TiO}_2\text{-Au}$ interface, the electrons take roughly 190 fs to move from TiO_2 to gold, indicating that most hot electrons initially created at the plasmonic silver site reach the gold catalytic site in 650–700 fs. It is recognized here that this time is extremely fast, and assuming a 1 μm TiO_2 thickness, which roughly corresponds to the minimal thickness for screen-printed TiO_2 films, an electron travelling velocity in the order of 10^6 m s^{-1} is required. Thermal velocities in the order of 10^5 m s^{-1} of electrons at room temperature in bulk semiconductors have been reported.⁴⁴ The electrons having larger energies than just thermal energy could explain the higher velocity. We speculate, however, that the presence of silver NPs in the mesoporous TiO_2 channels is more likely to cause this rapid

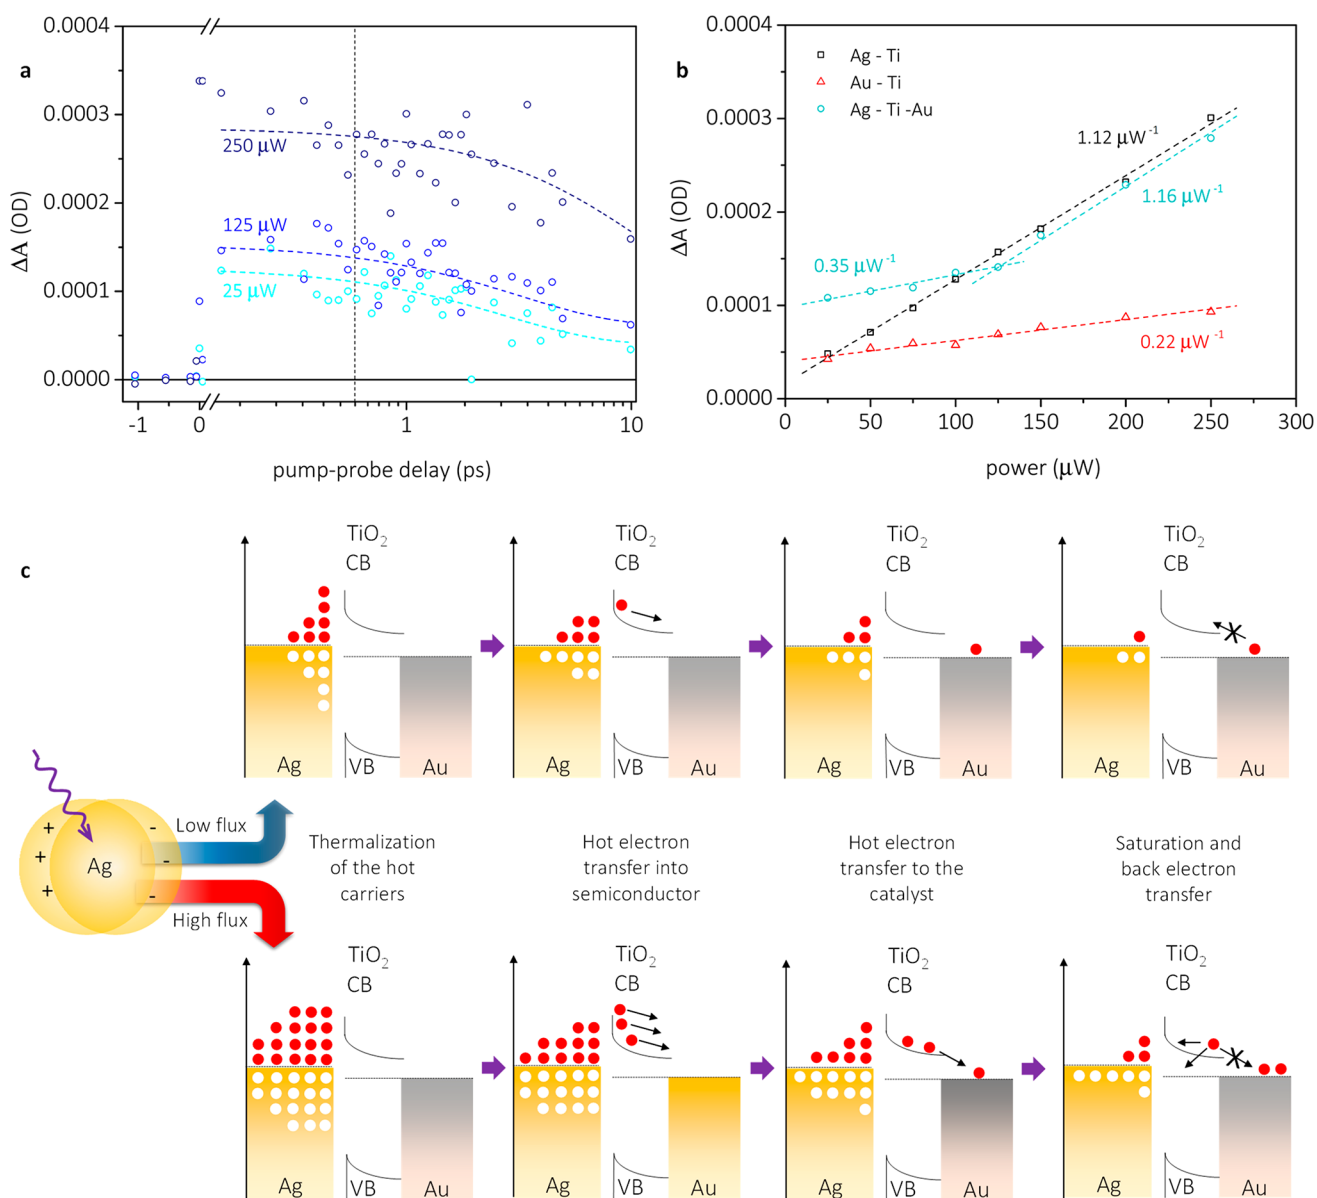

Figure 4. Kinetic traces at three different pump-powers, extracted at 5200 nm for the Ag-TiO₂-Au system (a), power dependence measurements, kinetics extracted at 5200 nm (b), and proposed model to account for the observed results in the power dependence measurements (c). The gap between silver and TiO₂ in (c) represents the PVP layer that prevents Fermi level pinning upon charge injection.

electron transfer, as this could significantly decrease the Ag-Au distance, which would subsequently also result in lower required electron velocities.

The dependence of the ΔA signal in the mid-infrared regime, attributed to free charge carriers on TiO₂,^{41,45} on the pump fluence is presented in Figure 4a. Since electrons reach gold on ultrafast time scales (< 1 ps), these measurements were performed only up until a 10 ps pump-probe delay. Twenty measurements at each power were performed, and the obtained average decay was fitted with a monoexponential function on the time scale of the measurement. The ΔA signal at 0.6 ps was extracted as the transient absorption measurements had shown the maximum amplitude of the gold plasmonic response to occur at this time (Figure 2d and 2f). As shown in Figure 4b, a clear linear increase in signal intensity for Ag-TiO₂ and Au-TiO₂ is observed upon increasing the pump fluence. As expected, the increase observed for Ag-TiO₂ is significantly steeper than for Au-TiO₂, i.e., at $1.12 \mu\text{W}^{-1}$

versus $0.22 \mu\text{W}^{-1}$, since the LSPR of silver is excited at 435 nm, resulting in a larger formation of hot, injectable electrons than in case of gold, where direct interband transitions are primarily excited at 435 nm.³⁸ Interestingly, extrapolating the fitted line for Au-TiO₂ to a theoretical zero power value yields a nonzero ΔA value. We speculate that this is a result of plasmon-induced interfacial charge transfer⁴⁶ or direct interfacial charge transfer.⁴⁷ Both processes happen within 10s of fs and are beyond the time resolution we can achieve. The fact that this is observed only when gold is present is likely due to the direct contact between gold and TiO₂ and the absence of capping ligands, which, as observed for the Ag-TiO₂ sample, seem to inhibit these processes.

An evaluation of the response obtained for the full multimetallic system shows the presence of two distinguishable regimes, i.e., a low power regime, in which an increase of the pump fluence results in an increase of the ΔA signal of $0.35 \mu\text{W}^{-1}$, and a high-power regime, where a $1.16 \mu\text{W}^{-1}$ increase in

Figure 5. Proposed reaction scheme for the reduction of 4-nitrophenol under light irradiation of the prepared multimetallic system (a) and the setup used to carry out the catalytic measurements (b). the ΔA signal is observed. We attribute this sudden change in slope around 125 μW to the saturation of the partly unfilled 5d states of gold.²⁹ Gold is considered the noblest of the metals due to its largely filled 5d band,²⁷ which reduces its ability to adsorb molecules and accept an electrical charge.^{48–50} The detected saturation point does not necessarily equate to the point at which the gold 5d band is filled; rather, it suggests that after this point it is hard to transfer more charge to gold nanoparticles. Further substantiation for this assignment is that the saturation point is sensitive to the gold concentration, shifting to higher pulse energies with an increase of gold concentration. Once at gold, hot electrons should remain there for a significant time since the electronic barrier between the TiO₂ conduction band and gold is ca. 0.8 eV and thus not thermally accessible to enable fast back electron transfer.^{51,52} After the saturation point, transference to gold is largely suppressed, and thus, the injected electrons originated from silver-plasmons remain in TiO₂. The small increase in slope at pump powers below the saturation point indicates that while it is energetically favourable for electrons to move to gold (ca. 0.8 eV), not all injected electrons reach the gold NPs. The nearly identical slopes obtained after the saturation point illustrate that further injected electrons remain on TiO₂ until recombination occurs.

The overall process is summarized in Figure 4c. Upon light absorption by silver NPs, plasmons were created and relaxed into hot carriers, omitted from the scheme due to space constraints. The thermalized hot electrons were injected into TiO₂ in 220–240 fs through the PVP layer,³⁶ used to prevent

Fermi level pinning. The PVP layer is expected to affect electron transfer,⁵³ but assessing its influence is outside the scope of this work. The injected hot electrons were subsequently transferred to the catalytic gold site within ca. 450–500 fs after their injection into TiO₂. The process was continued until saturation of the gold electronic structure occurred.

The multimetallic system photocatalytic activity was evaluated using the 6e⁻ reduction reaction between 4-nitrophenol (4-NP) and NaBH₄ (Figure 5a).^{54,55} Since silver and gold NPs have both been reported to catalyze this reaction in the absence of light, the reaction is ideal to assess any changes in catalytic activity upon excitation of the silver LSPR. Figure 5b shows the setup used in these experiments.⁵⁶ Tests were performed in dark and with light and using 100-fold excess of NaBH₄, to extract the apparent reaction rate from the pseudo-first-order rate kinetics (SI, page 5).⁵⁴ As is evident, in the case of Au-TiO₂, the apparent rate is increased by a factor of 1.35, whereas in the case of Ag-TiO₂, an increase of 4.3 times was observed upon laser excitation, which is in line with the laser excitation being performed closer to the silver LSPR (Figure 5c, top panel, and Figures S32–S34). We attribute these rate enhancements to an increase in electron density on the NPs due to the holes on the metal NPs being regenerated by the hydride source, while injected electrons also return to the NP, resulting in an overall larger number of electrons. The slower increase observed for gold is in good agreement with the results presented in Figure 4, showing a significantly lower

electron injection for Au-TiO₂ than for Ag-TiO₂, as expected based on the relative LSPR peaks of gold and silver.

Upon testing the full system (Figure 5c bottom panel), a 16-fold rate increase was observed when illumination at 445 nm is applied, and an apparent rate constant of $1.85 \times 10^{-3} \text{ s}^{-1}$ is found, surpassing by one order of magnitude the combined reactivity of the two individual systems. The results obtained here are in good quantitative agreement with those obtained by Hajfathalian et al.⁵⁷ on AuCu bimetallic structures. This study, however, adds an active support, TiO₂, which acts as an electron relay, to the complete system, thereby resembling more closely the design of nature's photosynthetic system.⁵⁸ The role of gold as a catalytic site and as a means to increase the electron lifetime can be inferred from these and the ultrafast transient absorption results. Note that in all cases the only product detected was 4-aminophenol,^{54,55} as confirmed by the appearance of the peak at around 300 nm and an isosbestic point at ca. 320 nm (Figures S35–S42). It should be mentioned that due to experimental limitations concerning CW laser power output, it was not possible to reach electronic saturation of gold and observe reduced kinetics. However, even if that were possible, we speculate that reduced kinetics would be observed before gold saturation due to mass transfer limitations.

In summary, the journey of a hot electron in a solid-state photocatalyst was followed in real-time. Ultrafast studies revealed that plasmon-generated hot electron transfer from the photosensitizer (silver NPs) to the catalytic site (gold NPs) via a semiconductor relay (TiO₂) takes roughly 700 fs. The presence of gold was shown to enhance charge separation, contributing to a 16-fold increase in photocatalytic activity in the studied model reaction. The studies also revealed gold NP electronic saturation, confirming effective electron transport to the catalytic site and limited capacity of the gold 5d band. The observations revealed that multimetallic photoredox systems containing plasmonic materials are highly effective in generating and utilizing hot carriers, and thus, we forecast their widespread utilization in photocatalysis and photovoltaics.
