Computational Validation of a 3-D Microwave Imaging System for Breast-Cancer Screening

Tonny Rubæk, Oleksiy S. Kim, and Peter Meincke

Abstract—The microwave imaging system currently being developed at the Technical University of Denmark is described and its performance tested on simulated data. The system uses an iterative Newton-based imaging algorithm for reconstructing the images in conjunction with an efficient method-of-moments solution of the associated forward scattering problem. A cylindrical multistatic antenna setup with 32 horizontally oriented antennas is used for collecting the data. It has been found that formulating the imaging algorithm in terms of the logarithm of the amplitude and the unwrapped phase of the measured signals improves its performance when compared to the more commonly used complex phasor formulation. This improvement is illustrated by imaging a simulated hemispherical breast model using both formulations. In addition to this, the importance of using the correct position and orientation of the antennas in the measurement system is shown by imaging the same breast model using a measurement setup in which the antennas are vertically oriented.

Index Terms—Biomedical imaging, cancer, electromagnetic scattering inverse problems, microwave imaging, nonlinear equations.

I. INTRODUCTION

Breast cancer is the most common type of cancer among women [1]–[4], and early detection is one of the most important prerequisites for successful treatment of the cancer [5]. To this end, screening programmes using X-ray mammography is the most widespread approach. X-ray mammography is, however, not perfect, especially when used to screen women under the age of 50 for which sensitivities as low as 53% have been reported[6]. This leaves room for supplementary imaging modalities, such as the well-established magnetic-resonance and ultrasound imaging techniques[7], albeit these are not suitable for screening.

An emerging imaging modality for breast-cancer screening is microwave imaging which is based on the high contrast in the electromagnetic constitutive parameters between healthy and cancerous breast tissue in the microwave frequency range, reported by several authors [8]–[14]. This contrast causes incident electromagnetic fields in the microwave region of the frequency spectrum to be scattered, allowing for detection of the cancerous tissue. Two different approaches are currently being pursued for microwave imaging of the breast. In one, ultrawideband radar techniques are applied [15]–[23], while in the other, nonlinear inverse scattering techniques, also known as microwave tomography, are used [11], [12], [24], [25].

The inverse scattering techniques seek to determine the distribution of the electromagnetic constitutive parameters, permittivity and conductivity, in the breast. When using this approach, the breast domain is illuminated by one antenna at a time and the response is measured on a number of receiving antennas. These responses may then be used as input to the nonlinear inversion algorithm based on Maxwell’s equations. Results for frequency- and time-domain inverse scattering have been reported, both for phantom measurements [25]–[29] and for clinical breast imaging [11], [12], [30] but also for other applications of biomedical imaging [31], [32].

At the Technical University of Denmark (TUD) a microwave imaging system for breast-cancer screening is currently being developed. To reconstruct images of the interior of the breast, frequency-domain nonlinear inverse scattering is applied. The design of the TUD imaging system is inspired by the imaging system currently being used in clinical tests at Dartmouth College. In this system, the breast is imaged using a 2-D measurement setup and reconstructions of the corresponding imaging planes through the breast [11], [28], [30], [33]–[40]. The TUD imaging system, on the other hand, is designed to operate directly on the full 3-D inversion problem, thereby avoiding the inherent errors stemming from applying 2-D algorithms to what is indeed a 3-D problem [41]. The choice of reconstructing the images by solving a full 3-D inverse problem does, however, increase the computational complexity of the problem.

The imaging algorithm is based on a Newton iterative algorithm in which the distribution of the constitutive parameters is updated in each iteration based on a comparison between the measured signals and the signals computed by a forward solver for the current parameter distribution. Since a full 3-D scattering problem must be solved in each iteration of the Newton algorithm, special attention on the computational efficiency of the forward solver is necessary. To this end, a method of moments code, in which the coefficient matrix is reused in each iteration, has been implemented.

During the development of the imaging algorithm it has been found that the widely used complex formulation of the scattering problem, in which complex phasors are used to represent the measured and calculated scattered field, provides suboptimal results. To remedy this, the log-amplitude unwrapped
tenna consists of a coaxial cable from which the outer conductor has been stripped from the outermost 3.5 cm of the antenna, exposing the dielectric. This type of antenna has the advantage of being very simple to manufacture and to include in numerical models. Since the glycerin-water coupling liquid is lossy, the current on the outside of the outer conductor is quickly attenuated and thus, there is no need for a ground plane. Furthermore, when operating in the lossy liquid, the antennas are relatively broadband, allowing for operation in the entire frequency band used by the system. In Fig. 1, the stripped dielectric is represented by the white lines while the outer conductor is represented by the black lines. The 32 antennas are positioned in 4 rows with 8 antennas in each row, with 45° between the antennas and each row rotated 22.5° with respect to the row above. The antennas close to the surface of the liquid, thereby obtaining coverage in the entire imaging domain, including the top part. The importance of this is illustrated in Section IV-B.

The antenna system is positioned in a cylindrical measurement tank which has a radius of 20 cm with each antenna held in place by the coaxial cable. The lossy liquid assures that reflections from the side and bottom of the tank are attenuated so they do not influence the measurements. Therefore, the antenna system may be considered to be positioned in an infinite half space filled with the coupling liquid.

The lid of the measurement tank is made of metal to provide a known boundary toward the chest wall of the patient. Above the 15 cm diameter aperture, through which the breast is suspended, the imaging domain is extended by a 1 cm high cylindrical region. It has been found that, due to the shielding effects of the metallic lid, the influence of objects in the upper halfspace outside of this region on the measured signals is minimal. Hence, it is not necessary to include a larger region of the upper halfspace in the reconstruction.

During a measurement, each antenna in turn transmits while the response is measured on the 31 other antennas. This implies that the total measurement consists of $n_{\text{tested}} = 992$ measurements of the real and imaginary parts of the received signals.

III. IMAGING ALGORITHM

To represent the distribution of constitutive parameters in the imaging domain, the domain is divided into cubic cells. The size of these cells is chosen on the basis of the frequency at...
which the reconstruction is performed and on the expected size of the objects to be imaged. In this paper, the cubic cells are chosen to have a side length of 5 mm, yielding a total of \( n_{\text{cells}} = 7352 \) cubic cells in the imaging domain. In each of these cells the constitutive parameters are assumed to be constant and represented by the squared complex wave number of the cell which, when using the time notation \( e^{j\alpha t} \), is given by

\[
k^2(r) = \frac{\omega^2}{\mu_0} \varepsilon(r) - j\omega\mu_0\sigma(r). \tag{1}
\]

In this expression, \( r \) is a position vector, \( \omega \) is the angular frequency, \( \mu_0 \) is the free-space permeability, \( \varepsilon \) is the permittivity, and \( \sigma \) is the conductivity. Since the constitutive parameters are assumed to be constant within each cell, it holds that

\[
k^2(r) = k^2_l \tag{2a}
\]

for

\[
r \in R_l
\]

where \( R_l \) is the volume covered by cell number \( l = 1, 2, 3, \ldots, n_{\text{cells}} \).

The distribution of the squared complex wave numbers is determined by solving the nonlinear minimization problem

\[
k^2 = \arg\min \left\{ \left\| \mathbf{S}^\text{meas} - \mathbf{S}^\text{calc}(k^2) \right\|_2 \right\}
\]

\[
= \arg\min \left\{ \left\| \mathbf{S}^\text{meas}(k^2) \right\|_2 \right\} \quad \text{subj. to regularization} \tag{3}
\]

using an iterative Newton algorithm. In this expression, the \( 2n_{\text{cells}} \) element vector \( k^2 \) holds the real and imaginary parts of the squared complex wave numbers, the vector \( \mathbf{S}^\text{meas} \) holds the measured signals, while the vector \( \mathbf{S}^\text{calc}(k^2) \) holds the calculated signals for a given distribution of the squared wave numbers. The vector \( \mathbf{S}^\text{res} \) is the residual vector. The nonlinear problem is solved by applying an iterative Newton algorithm, which is initialized with the squared wave numbers in the entire imaging domain set to that of the known coupling liquid, \( k^2_0 \). In each iteration of the Newton algorithm, the distribution of the squared wave numbers is updated using three steps:

1) Compute \( \mathbf{S}^\text{calc}(k^2_{n+1}) \) and the Jacobian \( \mathbf{J}_n^\text{res} \) for the current distribution of squared complex wave numbers.

2) Linearize the problem around the current distribution of constitutive parameters and determine the updates \( \Delta k^2_n \) by solving the linear minimization problem

\[
\Delta k^2_n = \arg\min \left\{ \left\| \mathbf{J}_n^\text{res} \Delta k^2_n - \mathbf{S}^\text{res}_n \right\|_2 \right\} \quad \text{subj. to regularization}. \tag{4}
\]

This problem is ill-posed and underdetermined with a \( 2n_{\text{toms}} \times 2n_{\text{cells}} \) element Jacobian matrix.

3) Update the distribution of the squared wave numbers using

\[
k^2_{n+1} = k^2_n + \alpha_n \Delta k^2_n \tag{5}
\]

where \( \alpha_n \) is the Newton step [46]. Each of the three steps is described in more details below.

### A. Log-Phase Formulation

The complex and log-phase formulations differ in how the data is represented in the vectors \( \mathbf{S}^\text{meas} \) and \( \mathbf{S}^\text{calc}(k^2) \). In the complex formulation, each combination of transmitting antenna \( t \) and receiving antenna \( r \) yields two elements in each vector, resulting in a total of \( 2n_{\text{toms}} \) elements. In \( \mathbf{S}^\text{meas} \), the elements are given by the difference between the measured signals with the object to be examined inserted in the imaging system and the measured signals when the system is empty, i.e.,

\[
S^t_r = \Re \left\{ S^t_r \right\}_{\text{obj}} - S^t_r \left\{ \text{empty} \right\} \tag{6a}
\]

and

\[
S^t_r = \Im \left\{ S^t_r \right\}_{\text{obj}} - S^t_r \left\{ \text{empty} \right\} \tag{6b}
\]

In \( \mathbf{S}^\text{calc} \), the elements are given in the same way, except here the signals are calculated using the forward solver and not measured. In this way, the Jacobian matrix used when solving the problem in its complex formulation has a size of \( 2n_{\text{toms}} \times 2n_{\text{cells}} \) and consists of the derivative of the real and imaginary parts of the calculated fields with respect to the real and imaginary parts of the squared complex wave numbers.

In the log-phase formulation, each measurement is also represented by two elements in the vectors \( \mathbf{S}^\text{meas} \) and \( \mathbf{S}^\text{calc}(k^2) \), both based on the logarithm of the complex signals. By taking the logarithm of the measured or calculated signals, a complex number is obtained

\[
\log S^t_r = \log |S^t_r| + j\angle S^t_r \text{empty} \tag{7}
\]

wherein \( |S^t_r| \) is the amplitude of the signal and \( \angle S^t_r \) is the unwrapped phase of the signal. The \( 2n_{\text{toms}} \) elements of the vectors \( \mathbf{S}^\text{calc} \) and \( \mathbf{S}^\text{meas} \) may now be determined as

\[
S^t_r = \log |S^t_r| - \log |S^t_r|_{\text{empty}} \tag{8a}
\]

and

\[
S^t_r = \angle S^t_r - \angle S^t_r \left\{ \text{empty} \right\} \tag{8b}
\]

The different performances of the reconstruction algorithm when the two formulations are applied can be explained by observing their two major differences. First, the complex formulation deals with absolute changes in the signal level whereas the log-phase formulation deals with relative changes. This implies that, when using the complex formulation, a given
change in the signal level is given the same weight in the reconstruction whether the level of the background signal \( S_{\text{empty}}^{\text{ref}} \) is large or small. When using the log-phase formulation, on the other hand, a given change in the signal level is given more weight if the background signal level is low (and the change relatively large) than if the background signal is large (and the change relatively small). The signals in which the scattered field has the largest influence, that is, the signals where the relative change is large, also hold more information about the scattering object [47]. Hence, the log-phase formulation improves the performance of the algorithm by weighting the measurements with a high information level more than those with a low information level.

The other major difference between the two formulations is the way in which they handle phase changes. Since the unwrapped phase is used in the log-phase formulation, it is capable of reconstructing images even when the phase in the measured signals changes more than \( \pm \pi \), i.e., by using multiple Riemann sheets in the reconstruction. In the complex formulation, on the other hand, the phase information is not retained and all signals will therefore be mapped onto the same Riemann sheet. This implies that if a phase change of more than \( \pm \pi \) is encountered, the algorithm will either not reach convergence or reach an erroneous solution since the solution is constrained to a single Riemann sheet. In terms of computational demands, the two formulations are very similar. The log-phase formulation requires that the Jacobian is expressed in terms of the derivatives of the logarithm of the amplitude and phase with respect to the squared complex wave numbers. This can be done using the chain rule, yielding

\[
\frac{\text{d}(\log|S|)}{\text{d}(k^2)} = \frac{1}{|S|^2} \text{Re} \left\{ S^* \frac{\text{d}S}{\text{d}(k^2)} \right\} \tag{9a}
\]

and

\[
\frac{\text{d}(\angle S)}{\text{d}(k^2)} = \frac{1}{|S|^2} \text{Im} \left\{ S^* \frac{\text{d}S}{\text{d}(k^2)} \right\} \tag{9b}
\]

where \( S^* \) denotes the complex conjugate of \( S \) and \( \text{d}S/\text{d}(k^2) \) is found using (11).

### B. Phase Unwrapping

The phase unwrapping is the one of the most challenging aspects of using the log-phase formulation. Three different methods are applied when unwrapping the phase: Unwrapping in space, unwrapping in frequency, and unwrapping in contrast. When the phase is unwrapped in space, it is assumed that the difference in phase of the signals measured by adjacent antennas is no more than \( \pm \pi \). The spatial unwrapping approach is used for unwrapping the measured signals, especially at the lower frequencies, and can easily be implemented in a preprocessor.

When operating at the higher frequencies, the phase of the measured signals may change more than \( \pm \pi \) between two adjacent antennas. In this case the phase is unwrapped in frequency instead of in space. This implies that the phase is first unwrapped in space at a low frequency where the phase change between the antennas is within the \( \pm \pi \) range. The frequency is then increased in small steps, e.g., 200 MHz, and the signals measured by the individual antennas are assumed to change no more than \( \pm \pi \) in each frequency step. Although the constitutive parameters of both the background and the breast are frequency dependent, unwrapping in frequency is a useful tool as long as the frequency steps are kept small.

During the image reconstruction, the distribution of squared complex wave numbers is changed in steps, with each iteration of the Newton algorithm changing the distribution of the wave numbers in the imaging domain. This allows for the phase to be unwrapped in contrast in the following manner: Assuming that the phase on any given transmit-receive combination of antennas changes no more than \( \pm \pi \) between two successive Newton iteration, the phase of the calculated signals may be unwrapped by comparing the new phase with the phase of the signal in the previous Newton iteration.

When the phase is unwrapped in terms of the contrast it is important that the phase does not change more than \( \pm \pi \) between two Newton iterations, and to this end, the scaling of the calculated update with the Newton step, described below, plays an important role.

### C. Forward Solver

To calculate the forward solution \( \mathbf{S}^{\text{calc}} \), Maxwell’s equations are formulated as volume integral equations (VIE) and solved using a method of moments (MoM) code. Other techniques have also been applied for solving the forward problem in inverse scattering, such as the finite-difference time domain method [26], the finite-difference frequency domain method [48], and the hybrid element method [49]. The choice of using a MoM code in the TUD system is to a large extent based on the fact that the department has built up a considerable expertise within this field during the last 10 years [50]–[52].

Solving the forward scattering problem using VIE and MoM consists of two time consuming tasks; filling the MoM matrix and solving the resulting matrix equation

\[
\mathbf{ZD} = \mathbf{E}^i.
\]

In this expression, \( \mathbf{Z} \) is the MoM coefficient matrix, \( \mathbf{E}^i \) is a vector holding the known incident field, and \( \mathbf{D} \) is a vector holding the unknown dielectric flux density. The most time-consuming task when using MoM for solving the forward problem is the filling of the coefficient matrix. To minimize the impact of this operation on the overall performance of the algorithm, a scheme has been implemented in which the coefficient matrix is calculated only once for a given antenna setup and background medium and then reused in subsequent calls to the forward solver.

In addition to the reuse of the MoM coefficient matrix, the use of higher-order basis functions and the adaptive integral method improves the performance of the algorithm [52]. The benefits of the higher-order basis functions are more pronounced for modeling the relatively large lid of the measurement tank and the long straight antennas while the adaptive integral method assures that the cell size of the imaging domain can be made small.
without causing a prohibitively large, i.e., memory consuming, coefficient matrix.

In a typical setup, filling the coefficient matrix consumes approximately 2 hours while the solution to the forward problem, including calculation of the Jacobian, is obtained in approximately 15 minutes in the subsequent calls to the MoM solver.

When the forward solution has been found in terms of the S-parameters of the 992 combinations of transmitting and receiving antennas, the elements of the Jacobian matrix are found using the expression derived in [53], i.e.,

\[
\frac{dS^k_{\tau \nu}}{dk^2_t} = \frac{Z_{ce} \langle E^k, E^r \rangle_t}{2j\omega \mu_0 V_t V_r^*}.
\]

In this expression, the inner product is taken over the cell \(l\) and \(E^k\) and \(E^r\) are the calculated fields in the cell when the antennas \(t\) and \(r\) are transmitting. The quantities \(V_t\) and \(V_r^*\) are the voltages of the wave incident on the antennas through the coaxial cable, which has characteristic impedance \(Z_{ce}\), when calculating the fields \(E^k\) and \(E^r\), respectively. The inner product is calculated using the flux density \(D\) found when solving the forward problem and the known constitutive parameters of the individual cells.

D. Calculation of Updates

To determine the updates, the under-determined and ill-posed problem (4) is solved using the two-step algorithm described in [54]. This algorithm is based on the conjugated gradient least squares (CGLS) algorithm which is an iterative algorithm that solves the linear inversion problem in five simple matrix-vector operations in each CGLS iteration [55, Sec. 6.3]. The solution of the linear inversion problem (4) obtained after \(m\) CGLS iterations is given by

\[
[\Delta \eta^2_{\tau r}^{(m)}] = \arg\min \|J^{T} \Delta \eta_{\tau r}^{(m)} - \mathbf{S}^{\text{res}}(L^2_{\tau r})\|_2 \quad (12a)
\]

subject to

\[
[\Delta \eta^2_{\tau r}^{(m)}] \in \mathbb{R}_m \{J^{T} I_{m \times m}, J^{T} \mathbf{S}^{\text{res}}(L^2_{\tau r})\} \quad (12b)
\]

Hence, the solution obtained is the least squares solution of the linear inversion problem with the constraint that the solution must lie in the \(m\)-dimensional Krylov subspace \(\mathbb{R}_m\) defined by the Jacobian matrix and the residual vector. The regularizing effect of the CGLS algorithm is obtained because the \(m\)-dimensional Krylov subspace can be seen as an approximation of the subspace spanned by the first \(m\) right-hand singular vectors. Thus, the solution obtained using the CGLS algorithm can be regarded an approximation of the solution obtained using the truncated singular value decomposition with the important difference that it is not necessary to perform a time consuming singular value decomposition of the problem [55]. As the number of iterations with the CGLS algorithm increases, the amount of regularization applied to the problem decreases.

In [54], the algorithm was applied for 2-D microwave imaging but it has been found that the two-step approach is also valid when the algorithm is used for 3-D imaging: In the first few Newton iterations, the number of CGLS iterations used to calculate the updates is kept low. After a number of Newton iterations, the change in the norm of the residual vector between successive Newton iterations will become small. This indicates that the reconstruction algorithm has reconstructed the major features of the image and the number of CGLS iterations used to calculate the updates is now increased to allow the algorithm to reconstruct the finer details of the image.

In the three-dimensional reconstruction algorithm, it has been found that using 2 CGLS iterations in the first part of the reconstruction and 8 in the latter part yields the optimum results. As it was shown in [54], the change between the low and high number of CGLS iterations is most effectively chosen based on the relative change in the normalized norm of the residual vector. The normalized norm \(\eta_{\tau r}\) is introduced as

\[
\eta_{\tau r} = \frac{\|\mathbf{S}^{\text{res}}(L^2_{\tau r})\|_2}{\|\mathbf{S}^{\text{res}}(L^2_{\tau r})\|_2} \quad (13)
\]

wherein \(\mathbf{S}^{\text{res}}(L^2_{\tau r})\) is the residual vector for the system simulated with no object inserted. The change between successive Newton iterations, \(\Delta \eta_{\tau r}\), may now be introduced as

\[
\Delta \eta_{\tau r} = \frac{\eta_{\tau r} - \eta_{\tau r}^{(m-1)}}{\eta_{\tau r}^{(m-1)}} \quad (14)
\]

As the reconstruction algorithm progresses, the norm of the residual vector decreases, implying a negative value of \(\Delta \eta_{\tau r}\). When the value of \(\Delta \eta_{\tau r}\) obtains a value greater than \(-0.1\), the number of CGLS iterations used to calculate the updates is changed from 2 to 8.

The values of \(\eta_{\tau r}\) and \(\Delta \eta_{\tau r}\) are also used to determine when to terminate the algorithm: When \(\eta_{\tau r}\) drops below 0.02 or if \(\Delta \eta_{\tau r}\) becomes greater than \(-0.03\) after the change from 2 to 8 CGLS iterations has been made, the algorithm is terminated. These threshold values are dependent on the noise level in the system and the accuracy of the forward model: If the noise level is decreased or the accuracy of the forward model improved, these value may be set closer to 0, and vice versa.

E. Newton Step

The scaling of the update \(\Delta \eta^2_{\tau r}\) with the Newton step \(\alpha_{\tau r}\) in (5) serves two purposes. First, it serves to assure that the algorithm does not overshoot the actual solution and start to diverge. Second, the Newton step is used to assure that the phases of the calculated signals between two successive Newton iterations do not change too much, thereby ruining the possibility of unwrapping the phase in contrast.

It has been found that the best way to determine the size of the Newton step is by assuming a linearized phase change and calculating the maximum phase change caused by the update \(\Delta \eta^2_{\tau r}\). To estimate the maximum phase change caused by the update vector, a new \(\eta_{\tau r, \text{max}} \times 2\text{reals}\) element matrix \(J^2\) is created from the Jacobian by retaining only those rows that relate to the phase of the calculated signals. The assumed maximum phase change is then determined by multiplying \(J^2\) with the update
vector and finding the maximum absolute value in the resulting vector
\[
\angle_{\text{max}} = \max \left\{ \| \mathbf{y} - \mathbf{A} \mathbf{x} \| \right\}.
\] (15)

If \( \angle_{\text{max}} \) exceeds a given value, e.g., 1 (radian), the Newton step is applied to assure that the phase change is kept at an acceptable level while a value of \( \angle_{\text{max}} \) less than the threshold results in a unity Newton step, i.e.,
\[
\alpha_n = \begin{cases} 
1 & \text{for } \angle_{\text{max}} \leq 1 \\
\frac{1}{\angle_{\text{max}}} & \text{for } \angle_{\text{max}} > 1
\end{cases}.
\] (16)

When the complex formulation is used in the imaging algorithm, the change in phase between two successive Newton iterations is no longer important. In this case, the main purpose of scaling the update by the Newton step is to avoid the reconstruction while it was 8 cm in the reconstructions.

The reconstructed size of the tumor is close to the actual size albeit the reconstructed position is shifted in the negative direction compared to the actual position. The reconstructed permittivity and conductivity of the tumor are considerably lower than the actual values but the fact that a considerable rise in the conductivity is detected implies that the tumor may be distinguished from the fibroglandular inclusion which is seen to give rise to only a minor increase in conductivity. The log-phase variations in the tissue. The tumor was modeled with a relative permittivity of 56.0 and a conductivity of 3.0 S/m. The coupling liquid was assigned a relative permittivity of 19.6 and a conductivity of 1.2, corresponding to a 85–15 glycerin-water mixture.

To avoid the “inverse crime”, the meshes used to model the breast, lid, and antennas in the simulation were different and finer than those used in the reconstructions. A total of 8908 cells were used to model the 5 cm radius breast, including the tumor and the fibroglandular inclusion. The antennas were modeled in full in both the simulations and in the reconstructions. The outer conductor was modelled as a thin metal cylinder (radius 1.5 mm) and the 3.5 cm stripped inner conductor modelled as a thinner metal cylinder (radius 0.46 mm) surrounded by a cylinder of Teflon with the same radius as the outer conductor and a relative permittivity of 2 and zero conductivity. The length of the cylinder modelling the outer conductor was 12 cm in the simulation while it was 8 cm in the reconstructions.

Finally, Gaussian noise mimicking a noise floor 110 dB below the transmitted power has been added to the simulated signals.

A. Log-Phase Versus Complex Formulation

The reconstructed images of the heterogeneously dense breast model obtained using the log-phase formulation are shown in Fig. 4 and the images obtained using the complex formulation are shown in Fig. 5.

When the log-phase formulation is used, both the breast, the tumor, and the fibroglandular inclusion are easily identified in the resulting images. The effects of the added noise are, however, clearly visible, especially in the permittivity images where the contours of all three objects are somewhat irregular and artifacts are visible both inside and outside of the breast.

The reconstructed size of the tumor is close to the actual size albeit the reconstructed position is shifted in the negative z direction compared to the actual position. The reconstructed permittivity and conductivity of the tumor are considerably lower than the actual values but the fact that a considerable rise in the conductivity is detected implies that the tumor may be distinguished from the fibroglandular inclusion which is seen to give rise to only a minor increase in conductivity. The log-phase variations in the tissue. The tumor was modeled with a relative permittivity of 56.0 and a conductivity of 3.0 S/m. The coupling liquid was assigned a relative permittivity of 19.6 and a conductivity of 1.2, corresponding to a 85–15 glycerin-water mixture.

To avoid the “inverse crime”, the meshes used to model the breast, lid, and antennas in the simulation were different and finer than those used in the reconstructions. A total of 8908 cells were used to model the 5 cm radius breast, including the tumor and the fibroglandular inclusion. The antennas were modeled in full in both the simulations and in the reconstructions. The outer conductor was modelled as a thin metal cylinder (radius 1.5 mm) and the 3.5 cm stripped inner conductor modelled as a thinner metal cylinder (radius 0.46 mm) surrounded by a cylinder of Teflon with the same radius as the outer conductor and a relative permittivity of 2 and zero conductivity. The length of the cylinder modelling the outer conductor was 12 cm in the simulation while it was 8 cm in the reconstructions.

Finally, Gaussian noise mimicking a noise floor 110 dB below the transmitted power has been added to the simulated signals.

A. Log-Phase Versus Complex Formulation

The reconstructed images of the heterogeneously dense breast model obtained using the log-phase formulation are shown in Fig. 4 and the images obtained using the complex formulation are shown in Fig. 5.

When the log-phase formulation is used, both the breast, the tumor, and the fibroglandular inclusion are easily identified in the resulting images. The effects of the added noise are, however, clearly visible, especially in the permittivity images where the contours of all three objects are somewhat irregular and artifacts are visible both inside and outside of the breast.

The reconstructed size of the tumor is close to the actual size albeit the reconstructed position is shifted in the negative z direction compared to the actual position. The reconstructed permittivity and conductivity of the tumor are considerably lower than the actual values but the fact that a considerable rise in the conductivity is detected implies that the tumor may be distinguished from the fibroglandular inclusion which is seen to give rise to only a minor increase in conductivity. The log-phase variations in the tissue. The tumor was modeled with a relative permittivity of 56.0 and a conductivity of 3.0 S/m. The coupling liquid was assigned a relative permittivity of 19.6 and a conductivity of 1.2, corresponding to a 85–15 glycerin-water mixture.

To avoid the “inverse crime”, the meshes used to model the breast, lid, and antennas in the simulation were different and finer than those used in the reconstructions. A total of 8908 cells were used to model the 5 cm radius breast, including the tumor and the fibroglandular inclusion. The antennas were modeled in full in both the simulations and in the reconstructions. The outer conductor was modelled as a thin metal cylinder (radius 1.5 mm) and the 3.5 cm stripped inner conductor modelled as a thinner metal cylinder (radius 0.46 mm) surrounded by a cylinder of Teflon with the same radius as the outer conductor and a relative permittivity of 2 and zero conductivity. The length of the cylinder modelling the outer conductor was 12 cm in the simulation while it was 8 cm in the reconstructions.

Finally, Gaussian noise mimicking a noise floor 110 dB below the transmitted power has been added to the simulated signals.

A. Log-Phase Versus Complex Formulation

The reconstructed images of the heterogeneously dense breast model obtained using the log-phase formulation are shown in Fig. 4 and the images obtained using the complex formulation are shown in Fig. 5.

When the log-phase formulation is used, both the breast, the tumor, and the fibroglandular inclusion are easily identified in the resulting images. The effects of the added noise are, however, clearly visible, especially in the permittivity images where the contours of all three objects are somewhat irregular and artifacts are visible both inside and outside of the breast.

The reconstructed size of the tumor is close to the actual size albeit the reconstructed position is shifted in the negative z direction compared to the actual position. The reconstructed permittivity and conductivity of the tumor are considerably lower than the actual values but the fact that a considerable rise in the conductivity is detected implies that the tumor may be distinguished from the fibroglandular inclusion which is seen to give rise to only a minor increase in conductivity. The log-phase variations in the tissue. The tumor was modeled with a relative permittivity of 56.0 and a conductivity of 3.0 S/m. The coupling liquid was assigned a relative permittivity of 19.6 and a conductivity of 1.2, corresponding to a 85–15 glycerin-water mixture.

To avoid the “inverse crime”, the meshes used to model the breast, lid, and antennas in the simulation were different and finer than those used in the reconstructions. A total of 8908 cells were used to model the 5 cm radius breast, including the tumor and the fibroglandular inclusion. The antennas were modeled in full in both the simulations and in the reconstructions. The outer conductor was modelled as a thin metal cylinder (radius 1.5 mm) and the 3.5 cm stripped inner conductor modelled as a thinner metal cylinder (radius 0.46 mm) surrounded by a cylinder of Teflon with the same radius as the outer conductor and a relative permittivity of 2 and zero conductivity. The length of the cylinder modelling the outer conductor was 12 cm in the simulation while it was 8 cm in the reconstructions.

Finally, Gaussian noise mimicking a noise floor 110 dB below the transmitted power has been added to the simulated signals.
algorithm changes from 2 to 8 iterations in the CGLS algorithm after 7 Newton iterations and reaches convergence after 10 Newton iterations.

In the images reconstructed using the complex formulation, both the breast, fibroglandular inclusion and tumor are reconstructed poorly. This is mainly due to the large phase changes observed in the simulated signals. For neighboring antennas the phase changes are relatively low, but for signals measured with receivers on the opposite side of the breast from the transmitter phase changes of more than $1.5\pi$ are encountered. This causes problems since the reconstruction is limited to a single Riemann sheet when the complex formulation is applied. The greatest phase changes are obtained when an antenna from the top row is used either as transmitter or receiver, and as a result of this, the top of the breast, including the tumor, is not properly reconstructed. The reconstruction of the bottom of the breast is more successful and an increase in the permittivity at the position of the fibroglandular inclusion is observed, although the circular shape of the inclusion is not reconstructed correctly.

When using the complex formulation, the algorithm changes from the low to the high number of CGLS iterations in the update algorithm after Newton iteration number 13. The algorithm converges after 19 iterations, and thus uses considerably more time to converge than when the log-phase formulation is applied.

The skin is not visible in either set of images. This is because the reconstructed distributions are low-pass representations of the actual distribution. This implies that the contrast between the high-valued coupling liquid on one side of the skin and the low-valued breast tissue on the other side of the skin results in images where the skin is not visible.

**B. Influence of Antenna Configuration**

To illustrate the importance of choosing the optimum antenna configuration, the performance of an antenna configuration with 4 rows of 8 vertically oriented antennas, shown in Fig. 6, has been tested. The antennas were organized in a cylindrical setup with a radius of 8 cm with the top row of antennas positioned with the tips of the antennas at $z = -1$ mm, the second row with the tips of the antennas at $z = -19$ mm, the third row with the tips of the antennas at $z = -37$ mm, and the bottom row positioned with the tips of the antennas at $z = -55$ mm.

The images obtained when applying this antenna configuration for imaging the heterogeneously dense breast are shown in Fig. 7. The most important thing to notice in these images is how the system is less capable of reconstructing the top part of the imaging domain and both the tumor and the contour of the breast are less well-defined than when the horizontal antenna configuration is applied. Meanwhile, the bottom part of the breast as
Fig. 6. Schematic of antenna system with vertically oriented antennas. The exposed dielectric of the antennas are represented by the white lines while the outer conductor of the coaxial lines are represented by the black lines.

Fig. 7. Images obtained using the vertically oriented antennas and the log-phase formulation. The system is not capable of imaging the top part of the imaging domain, thereby missing the tumor. The dashed lines indicate the positions of the breast, the tumor, and the fibroglandular inclusion.

well as the fibroglandular inclusion are reconstructed with permittivity values close to the actual values.

To understand why the system is not capable of reconstructing the upper part of the imaging domain when using the vertically oriented antennas it is useful to observe the spatial distribution of the elements in the Jacobian matrix. This is a measure of how sensitive the measured signals are to changes in the constitutive parameters of the imaging domain. The spatial distribution of the Jacobians for two antennas in the top rows of the vertical and horizontal setups are shown in Fig. 8. In both cases, the transmitting antenna is located to the right while the receiving antenna is to the left, on the opposite side of the imaging system. For the vertically oriented antennas, the normalized amplitude of the elements of the Jacobian matrix is seen to be at a maximum in an approximately 3 cm tall region across the imaging domain ranging from $z \approx -2 \text{ cm}$ to $z \approx -5 \text{ cm}$. Below and, more importantly, above this region, the amplitude of the elements of the Jacobian is seen to be significantly lower than inside the region. This implies that the system is much more sensitive to changes in the constitutive parameters within the 3 cm tall region than to changes outside. And while the part of the imaging domain which is located below the region is covered by other combinations of transmit- and receive antennas, no other antenna combination covers the upper part of the imaging domain better than the one showed here. Hence, any scattering objects in the lower part of the imaging domain will have a greater impact on the measured signals and thus be given more weight in the reconstruction algorithm than scatterers in the top part. This explains why the algorithm is not capable of accurately reconstructing the upper part of the imaging domain containing the tumor.

For the horizontally oriented antennas, on the other hand, the Jacobian for the two antennas is seen to have good coverage in the top part of the imaging domain while the amplitude of the elements of the Jacobian decreases towards the bottom part of the imaging domain. Similar to the setup using vertically oriented antennas, the bottom of the imaging domain is covered by other antenna combinations. This implies that the sensitivity of the system is more evenly distributed throughout the imaging domain and as a result, the algorithm is capable of reconstructing both the upper and the lower part of the imaging domain.

In both configurations, the maximum amplitude of the elements of the Jacobian are seen to occur close to the end of the outer conductor of the coaxial antennas, i.e., at the center of the antennas. This implies that the added noise in the simulated signals is likely to cause artifacts at these positions, as can be observed in all of the reconstructed images in Figs. 4, 5 and 7.

As a final observation regarding the antenna configuration, the effects of the added noise should be noted. The noise is seen to have less impact, i.e., resulting in fewer artifacts, on the images obtained using the vertically oriented antennas than on the images obtained using the horizontally oriented antennas. This is due to the fact that the coupling between the antennas is better when all of the antennas are $\phi$ polarized than when they $\phi$-directed as in the horizontal setup. Hence, the simulated noise floor 110 dB below the transmitted power has less effect on the reconstruction using the vertically oriented antenna setup.
The simulation setup presented here is chosen to illustrate the performance of the TUD imaging system in what is considered to be a worst-case scenario. First, because of the large difference in constitutive parameters between the coupling liquid and the breast, the scattered field created by this contrast dominates the measurements. In clinical trials a 90:10 glycerin-water coupling liquid with a relative permittivity of approximately 14 and a conductivity of approximately 0.9 S/m will be used as the standard coupling liquid. The parameters of this liquid are close to the average of the values reported in [11] for the breast tissue and will thus allow for more energy to be coupled to the interior of the breast. Another approach is to image each patient with two or three different liquids to better cover the large range of permittivity and conductivity values reported. This will, however, increase the examination time.

Second, the tumor is positioned close to the top of the imaging domain. This implies that only the measurements involving the top row of antennas have a notable contribution from the tumor while in the vast majority of the measurements, the tumor response is insignificant. The effects of this are further enhanced by the presence of the fibroglandular inclusion in the center of the breast. In most of the measurements, the response from this inclusion is far greater than the tumor response. Improvements may also be obtained by using a priori knowledge about the chest wall. As seen in the images obtained with the horizontally oriented antennas in Fig. 4, the chest wall is not reconstructed properly and this gives rise to additional artifacts in the images. If in clinical trials it is found that the chest wall is similar from patient to patient, either a fixed-valued chest wall can be applied in the algorithm, or the region above the lid may be assigned initial constitutive parameters in the reconstruction algorithm which are close to those of the chest wall.

Finally, the reconstruction is performed at the rather low frequency 1.3 GHz, because the values in [11] were given at this frequency. By increasing the frequency, a better resolution may be obtained and smaller objects imaged.

V. Conclusion

The TUD microwave imaging system for breast-cancer screening was presented. The imaging system consists of 32 antennas in a cylindrical setup and is designed to operate at a single frequency in the range from 300 MHz to 3 GHz. The large frequency range allows for choosing the optimum frequency at which to do the image reconstruction.

The reconstruction algorithm is based on an iterative Newton scheme in which the measured data is represented using the log-phase formulation. This has been shown to improve the performance of the imaging algorithm with a minimum of additional computation time. The updates in the Newton algorithm are calculated using a CGLS algorithm and the number of CGLS iterations is increased as the algorithm approaches convergence, corresponding to a reduction in the regularization of the solution of the linear update problems. The Newton algorithm requires the calculation of the scattered field in each iteration. To this end, a method of moment (MoM) solver has been implemented in which the time consuming operation of filling the coefficient matrix needs only to be done once after which the matrix may be stored and reused in the following Newton iterations. Furthermore, the MoM code has been augmented using the adaptive integral method which drastically reduces the memory consumption.

To illustrate the performance of the system, a model of a heterogeneous dense breast with a large fibroglandular inclusion and a smaller tumor was used. In the images of this simulated data set reconstructed using the log-phase formulation, the breast, tumor, and fibroglandular inclusions were all visible. Although the tumor in this reconstruction was not reconstructed with the actual values of permittivity and conductivity, the fact that the tumor was reconstructed with the correct size and only a small error in the position, along with a raised conductivity indicating a tumor, shows that the imaging system is capable of detecting tumors in less-than-ideal imaging conditions.

When using the complex formulation for the reconstruction, the algorithm failed to reconstruct the distribution of the constitutive parameters because of the inability of the complex formulation to handle phase changes greater than $\pm \pi$.

In addition to a comparison of the log-phase and complex formulations of the imaging problem, the effects of changing the antenna setup were investigated. Here, it was found that it is of great importance to organize the antennas of the imaging system in a suitable way to make sure the entire imaging domain is covered by the antennas.

In this paper, the system has been simulated at the frequency 1.3 GHz since average values for the normal and fibroglandular breast tissue were available for this frequency. The system is, however, capable of working at frequencies up to 3 GHz, thereby providing better resolution. At the time of writing, research is being focused on completing the microwave circuitry for the imaging system. When phantom measurements are done, more accurate estimates of the resolution of the system will be available. Furthermore, it will be investigated whether using multiple frequency measurements improves the performance of the system.
