Abstract—A prediction-error-method tailored for model based predictive control is presented. The prediction-error method studied are based on predictions using the Kalman filter and Kalman predictors for a linear discrete-time stochastic state space model. The linear discrete-time stochastic state space model is realized from a continuous-discrete-time linear stochastic system specified using transfer functions with time-delays. It is argued that the prediction-error criterion should be selected such that it is compatible with the objective function of the predictive controller in which the model is to be applied. The suitability of the proposed prediction error-method for predictive control is demonstrated for dual composition control of a simulated binary distillation column.

I. INTRODUCTION

Predictive control computes the controls based on a prediction of the outputs. The predictions are based on a model of the system. Original model predictive control algorithms developed for the process industries such as Dynamic Matrix Control [1] and Model Predictive Heuristic Control [2] are based on step and impulse response models for the output predictions and introduce feedback by updating a bias term representing an output disturbance. In contrast to the approach applied by the process industries, the academic system identification community developed predictive controllers based on ARMAX (ARIMAX, CARIMA) models [3]–[5]. Generalized Predictive Control [4] is the most famous implementation of this class of predictive controllers that use an ARMAX model for the filter in generating the feedback as well as for the output predictions. The success of these model based control algorithms and their applications is to a large extent due to existence of efficient methods for generation of the models needed by these controllers.

Modern predictive control is discussed in terms of state space models [6]–[8]. These algorithms are based on a discrete-time linear stochastic state space model. They apply a Kalman filter to compute the current state based on the measurements, and a Kalman predictor for predicting the outputs [9]. State space based model predictive controllers may be derived by realization of input-output models (i.e. FIR, ARX, ARMAX models) in state space form. Subspace identification may be regarded as state space realization of ARX models. However, no advice has been given regarding direct construction of a linear state space model suitable for predictive control. Therefore, better identification methods for state space based predictive control are requested [10]–[14].

This paper addresses construction of stochastic linear state space models using the prediction-error-method and a continuous-discrete time linear stochastic transfer function parametrization [15]–[17]. In particular, we argue that for predictive control the parameters in the model should be based on the multi-step prediction error compatible with the predictive controller in which the predictor is to be used. Shah and coworkers [18]–[20] apply a similar multi-step approach based on impulse response models and a least-squares criterion. The approach presented in this paper distinguishes itself by being general for linear systems, by applying a maximum likelihood criteria for the prediction errors in the estimator, and in particular by providing models that are tuned for state space model based predictive control in its modern implementation.

II. PREDICTIVE CONTROL

The predictive controller considered assumes that the system, $\mathcal{S}$, can be described by a linear stochastic discrete-time difference equation of the form

$$x_{k+1} = A(\theta)x_k + B(\theta)u_k + w_k$$
$$y_k = C(\theta)x_k + v_k$$

in which

$$\begin{bmatrix} \omega_k \\ \nu_k \end{bmatrix} \sim \mathcal{N}_{iid} \left( \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{bmatrix} R_{w\omega}(\theta) & R_{w\nu}(\theta) \\ R_{v\omega}(\theta)' & R_{v\nu}(\theta) \end{bmatrix} \right)$$

and

$$x_0 \sim \mathcal{N}(x_{0|-1}(\theta), P_{0|-1}(\theta))$$

The system matrices, $(A = A(\theta), B = B(\theta), C = C(\theta))$, are parameterized in terms of the parameter vector, $\theta$. This parameter vector is also used to specify the distribution of the exogenous stochastic variables, i.e. to specify the covariance matrices, $(R_{w\omega} = R_{w\omega}(\theta), R_{w\nu} = R_{w\nu}(\theta), R_{v\omega} = R_{v\omega}(\theta), R_{v\nu} = R_{v\nu}(\theta))$, of the noise terms as well as to specify the initial condition, $\hat{x}_{0|-1} = \hat{x}_{0|-1}(\theta)$, and its covariance $P_{0|-1} = P_{0|-1}(\theta)$. The states, $x_k$, the process noise, $\omega_k$, the measurement noise, $\nu_k$, and the outputs, $y_k$, are stochastic vectors. As $x_0$, $\omega_k$, and $\nu_k$ are normally distributed and the system is linear, the states, $x_k$, and the outputs, $y_k$, are also normally distributed. The inputs, $u_k$, are assumed to be deterministic and in particular assumed to be uncorrelated with the process.
measurements, \( y_k \). This assumption implies that the IO-data, \( \{y_k, u_k\}_{k=0}^{N-1} \), are collected for a system that operates in open-loop.

Assume that the system matrices, noise covariance matrices, and distribution of the model, \( M \), and the true system, \( S \), are identical. Then prediction uncertainties and errors are due to the stochastic nature of the initial state, the process noise, and the measurement noise, but not due to any systematic trend as a consequence of an incorrect model. In this case, the optimal filter and predictor is the Kalman filter and predictor [9]. Under the same assumptions the separation principle is valid, and the optimal controller for the system can be split into an estimator and a certainty equivalence regulator. Obviously, the true system and the model are never identical. The separation principle does not hold either, as the system is constrained. Nevertheless, predictive control uses the Kalman filter feedback, the Kalman predictor for the output predictions, and separates the controller into an estimator and a regulator. To guarantee offset free control in the case of model-plant mismatch as well as unknown disturbances, the model must be augmented with integrators [21], [22]. For ARMAX models this is achieved by differencing the inputs and outputs [4]. In the face of these approximations and deliberate model modifications introduced to obtain steady-state offset-free control, it is clear that the structure of the estimated model, \( M \), in general will be different from the structure of true system, \( S \). Therefore, it seems most reasonable to view the parameter-estimation purpose to obtain good predictors for the predictive controller rather than accurate parameters in the true unknown model [16].

A. Filter and Predictor

The filter and predictor used in the predictive controller for the system (1) is the Kalman filter and predictor. The recursions defining the Kalman filter and predictor along with their covariances are stated in this subsection. The filter and predictors are the conditional states, \( x_{k+j|I_k} \), and the conditional outputs, \( y_{k+j|I_k} \), given the information vector \( I_k \) defined recursively as \( I_k = \{I_{k-1}, y_k, u_{k-1}\}, I_0 = \{y_0\} \), and \( I_{-1} = \emptyset \). As all states, \( x_k \), and outputs, \( y_k \), are normally distributed, the conditional states, \( x_{k+j|I_k} \), and the conditional outputs, \( y_{k+j|I_k} \), are also normally distributed. Normally distributed stochastic variables are completely characterized by their mean and covariance.

The Kalman filter and predictor algorithm stated next is the measurement-time updated Kalman filter and predictor [9]. As new information, \( y_k \), becomes available, the gains, \( K_{f,x,k} \) and \( K_{f,w,k} \), and one-step prediction error, \( e_k \), of the filter are updated according to

\[
\begin{align*}
\hat{y}_{k|k-1} &= C\hat{x}_{k|k-1} \\
e_k &= y_k - \hat{y}_{k|k-1} \\
R_{e,k} &= CP_{k|k-1}C' + R_{vv} \\
K_{f,x,k} &= P_{k|k-1}C'R_{e,k}^{-1} \\
K_{f,w,k} &= R_{vw}R_{e,k}^{-1}
\end{align*}
\]

The filtered state and filtered process disturbance are normally distributed, i.e. \( x_k|I_k \sim \mathcal{N}(\hat{x}_{k|k}, P_{k|k}) \) and \( w_k|I_k \sim \mathcal{N}(\hat{w}_{k|k}, Q_{k|k}) \). The expressions for the filtered conditional means are

\[
\begin{align*}
\hat{x}_{k|k} &= \hat{x}_{k|k-1} + K_{f,x,k}e_k \\
\hat{w}_{k|k} &= K_{f,w,k}e_k
\end{align*}
\]

and the expressions for the filtered conditional covariances are

\[
\begin{align*}
P_{k|k} &= P_{k|k-1} - K_{f,x,k}R_{e,k}K_{f,x,k}' \\
Q_{k|k} &= R_{wv} - K_{f,w,k}R_{e,k}K_{f,w,k}'
\end{align*}
\]

The one-step-ahead prediction of the state, \( x_{k+1|I_k} \sim \mathcal{N}(\hat{x}_{k+1|k}, P_{k+1|k}) \), and the measured output, \( y_{k+1|I_k} \sim \mathcal{N}(\hat{y}_{k+1|k}, R_{k+1|k}) \), are also normally distributed. The one-step-ahead prediction conditional means are

\[
\begin{align*}
\hat{x}_{k+1|k} &= A\hat{x}_{k|k} + Bu_{k|k} + \hat{w}_{k|k} \\
\hat{y}_{k+1|k} &= C\hat{x}_{k+1|k}
\end{align*}
\]

and the associated covariances are computed by

\[
\begin{align*}
P_{k+1|k} &= AP_{k|k}A' + Q_k - AK_{f,x,k}R_{wv} - R_{wv}K_{f,x,k}A' \\
R_{k+1|k} &= CP_{k+1|k}C' + R_{vv}
\end{align*}
\]

Similarly, the \( j \)-step-ahead predictions (\( j > 1 \)) of the states, \( x_{k+j|I_k} \sim \mathcal{N}(\hat{x}_{k+j|k}, P_{k+j|k}) \), and the outputs, \( y_{k+j|I_k} \sim \mathcal{N}(\hat{y}_{k+j|k}, R_{k+j|k}) \), are normally distributed. The \( j \)-step-ahead prediction conditional means are

\[
\begin{align*}
\hat{x}_{k+j|k} &= A\hat{x}_{k+j-1|k} + Bu_{k+j-1|k} \\
\hat{y}_{k+j|k} &= C\hat{x}_{k+j|k}
\end{align*}
\]

and the associated conditional covariances are computed by

\[
\begin{align*}
P_{k+j|k} &= AP_{k+j-1|k}A' + R_{wv} \\
R_{k+j|k} &= CP_{k+j|k}C' + R_{vv}
\end{align*}
\]

The recursions (2)-(8) specifies the Kalman filter and predictor equations used by the predictive controller completely. Often the \( j \)-step-ahead (\( j > 1 \)) conditional covariance equations (8) are not used directly in the predictive controller. Equations (2) and (3) are used in the estimator part for forming the filtered states and filtered process disturbances. Equations (4), (5a), and (6a) are used in the estimator part for updating the Kalman filter.

The described Kalman filter and predictor is implemented numerically robust using the array algorithm [9].

B. Regulator

Given the conditional mean of the filtered state, \( \hat{x}_{k|k} \), and the conditional mean of the filtered process disturbance, \( \hat{w}_{k|k} \), the certainty equivalence predictive regulator applies
equations (5) and (7) for predicting the mean of the conditional outputs, \( \hat{y}_{k+j|k} \), in the regulator objective function

\[
\phi_k = \frac{1}{2} \sum_{j=1}^{N_p} (\hat{y}_{k+j|k} - r_{k+j|k})^T Q (\hat{y}_{k+j|k} - r_{k+j|k}) + \frac{1}{2} \sum_{j=0}^{N_c} \Delta \hat{u}_{k+j|k}^T S \Delta \hat{u}_{k+j|k}
\]  

(9)

The objective, \( \phi_k \), has a finite prediction horizon, \( N_p \), and computes the optimal predicted inputs, \( \{ \hat{u}_{k+j|k} \}_{j=0}^{N_p-1} = \{ \hat{u}_{k+j|k} \}_{j=0}^{N_p-1} \cup \{ \hat{u}_{k+j|k} \}_{j=N_p+1}^{N_{c}} \) by solving

\[
\begin{align*}
\min_{\{ \hat{u}_{k+j|k} \}_{j=0}^{N_p-1}} & \phi_k \\
\text{s.t.} & \quad (5), (7) \\
& \quad \hat{u}_{k+j|k} \in U(\hat{x}_{k|k}, \hat{w}_{k|k}) \\
& \quad \hat{y}_{k+j|k} \in Y(\hat{x}_{k|k}, \hat{w}_{k|k})
\end{align*}
\]

(10)

and using some parametrization of the tail inputs, \( \{ \hat{u}_{k+j|k} \}_{j=N_p+1} \), [6], [8], [22]–[25]. The sets \( U(\cdot, \cdot) \) and \( Y(\cdot, \cdot) \) denote input constraints, rate of movement input constraints, and output constraints. (10) is a quadratic program with special structure for which efficient solution algorithms exist [26]. Predictive control is implemented in a moving horizon manner, which means that the first optimal control, \( \hat{u}_{k|k} \), of the optimal control sequence obtained by solving (10), \( \{ \hat{u}_{k+j|k} \}_{j=0}^{N_p-1} \), is implemented on the process, i.e. \( u_k = \hat{u}_{k|k} \). In some implementations, the setup is modified slightly to accommodate the duration of computation and the implemented process input is \( u_k = \hat{u}_{k|k-1} \).

The implemented process input, \( u_k = \hat{u}_{k|k} \), is an implicit function of the output predictions. The objective function in the regulator of the model predictive controller requires multi-step output prediction, i.e. \( \hat{y}_{k+j|k} \) for \( j = 1, 2, \ldots, N_p \). Hence, intuitively it seems natural to estimate the model parameters based on multi-step prediction capabilities compatible with the regulator objective [18]–[20], [27], [28]. This is in contrast to the usual approach in which the parameters are determined based on their single-step one-step-ahead prediction capabilities. In yet another alternative, \( N_p \) different models are identified, i.e. one model for each single-step \( j \)-step-ahead output prediction, \( \hat{y}_{k+j|k} \) for \( j = 1, 2, \ldots, N_p \). This implies that instead of using \( \hat{y}_{k+j|k}(\theta) \) for \( j = 1, 2, \ldots, N_p \), the predictors \( \hat{y}_{k+j|k}(\theta_j) \) for \( j = 1, 2, \ldots, N_p \) are proposed. This multi-model approach has been applied for ARX models [29], [30] and is also adopted in the MUSMAR (multi-step multi-variable adaptive regulator) algorithm for predictive control [31], [32].

C. Parametrization and Realization

A parsimonious parametrization of the state space model (1) is obtained using a multivariate stochastic transfer function specification

\[
Z(s) = G(s; \theta) U(s) + H(s; \theta) E(s)
\]  

(11a)

\[
y(t_k) = z(t_k) + v(t_k)
\]  

(11b)

in which \( U(s) \) is the process input vector, \( E(s) \) is a vector with white noise components, \( Z(s) \) is the process output vector, \( v(t_k) \) is the measurement noise vector and \( y(t_k) \) is the measured process output vector at time \( t_k \).

\[
g_{ij}(s) = \frac{b_{ij}(s; \theta)}{a_{ij}(s; \theta)} \exp(-\tau_{ij}(s))
\]  

(12a)

\[
h_{ij}(s) = \frac{d_{ij}(s; \theta)}{c_{ij}(s; \theta)} \exp(-\lambda_{ij}(s))
\]  

(12b)

(11) is converted to a linear system of delayed stochastic differential equations using an observer-canonical realization. This system is converted to a stochastic discrete-time state space model using a zero-order-hold input representation and the theory for linear stochastic differential equations. Finally, a minimal stochastic discrete-time state space model (1) is obtained by model reduction using the Hankel-norm.

This realization process is conducted numerically by computation of the discrete-time Markov parameters for each SISO system. The resulting minimal discrete-time state space system is realized from the Hankel matrix with all Markov parameters.

D. Maximum Likelihood Prediction-Error Identification

The \( N_p \) multi-step maximum-likelihood multi-step prediction error estimate is compatible with the model predictive controller with a prediction horizon of \( N_p \). This multi-step maximum likelihood prediction error estimate is

\[
\hat{\theta} = \arg \min_{\theta \in \Theta} V_{ML}(\theta)
\]  

(13)

in which the likelihood function is

\[
V_{ML}(\theta) = \frac{N_y f}{2} \ln(2\pi) + \frac{1}{2} \sum_{k=1}^{N-2} \ln(\det \hat{R}_k) + \epsilon_k R_k^{-1} \epsilon_k
\]  

(14)

\[
f = N_p [N - \frac{1}{2} (N_p - 1)], \quad \epsilon_k = Y_k - \hat{Y}_k(\theta), \quad R_k = \langle \epsilon_k, \epsilon_k \rangle
\]

(15)

\[
\{ (\hat{y}_{k|k}, u_k) \}_{k=0}^{N_p-1}
\]

is the input-output data for which the estimation is performed. Based on these data, \( Y_k \) and \( \epsilon_k = Y_k - \hat{Y}_k(\theta) \). \( R_k \) has a special structure that should be utilized in the efficient solution of this multi-step maximum-likelihood estimation problem.

III. WOOD AND BERRY DISTILLATION EXAMPLE

In this section we demonstrate the proposed multi-step prediction-error identification procedure for the Wood and Berry distillation column separating methanol and water [33], [34]. The Wood and Berry distillation column model is

\[
Y(s) = G(s) U(s) + G_d(s) D(s)
\]  

(16)
The variables in the model are: $y_1$ is the overhead methanol mole fraction, $y_2$ is the bottom product methanol mole fraction, $u_1$ is the overhead reflux flow rate, $u_2$ is the bottoms steam flow rate, and $d$ is the column feed flow rate.

The output data for the Wood and Berry distillation column is generated using the stochastic model

$$Z(t) = G(s)U(s) + G_d(s)(D(s) + \sigma E(s))$$

(18a)

$$y(t_k) = z(t_k) + v(t_k)$$

(18b)

with $E(s)$ being white noise and $\sigma = 1$. The measurement noise is

$$v(t_k) \sim N_{iid} \left( \begin{bmatrix} 0 \\ 0 \\ r_1^2 \\ 0 \\ r_2^2 \end{bmatrix} \right)$$

(19)

in which $r_1 = r_2 = 1.0$. The sampling time of the system is $T_s = 1.0$. In the identification experiment $u$ is a pseudo random binary sequence and the systematic feed flow rate deviation, $d$, is set to zero.

The IO-data generated for this system and used for identification is plotted in figure 1. It is apparent that outputs are highly co-linear, i.e. the system is ill-conditioned. This is a well known phenomenon for distillation columns and may in many cases require closed-loop identification or specially designed perturbations suitable for the directionality of the plant [35]-[37].

A. Identification of a Control Relevant Model

In the following the generated open-loop data will be used for estimation of a process model, $\hat{G}(s)$, and a disturbance model, $\hat{H}(s)$. The application of this model for predictive control is demonstrated.

The estimated model is of the form

$$\hat{Z}(s) = \hat{G}(s)U(s) + \hat{H}(s)\hat{E}(s)$$

(20a)

$$y(t_k) = \hat{z}(t_k) + \hat{v}(t_k)$$

(20b)

in which $\hat{G}(s)$ is a transfer function with the same structure as $G(s)$. The disturbance model, $\hat{H}(s)$, has the structure

$$H(s) = \begin{bmatrix} h_{11}(s) & 0 \\ 0 & h_{22}(s) \end{bmatrix}$$

(21)

with

$$h_{ii}(s) = \frac{1}{s} \frac{\sigma_{ii}}{\gamma_{ii}s + 1}$$

(22)

Note that the disturbance model is equipped with integrators in order to ensure steady-state offset-free control when the model is applied in a predictive controller [21], [22]. Using the multi-step maximum likelihood criterion, the estimated model transfer functions are

$$\hat{G}(s) = \begin{bmatrix} 13.21e^{-0.84s} + 1.72e^{-0.55s} + 10.03e^{-1} \\ -18.52e^{-3.34s} - 18.20e^{-1} - 1.29e^{-3.97s} \end{bmatrix}$$

(23a)

$$\hat{H}(s) = \begin{bmatrix} \frac{1}{s} \frac{0.18}{0.16s + 1} & 0 \\ 0 & \frac{1}{s} \frac{0.27}{0.16s + 1} \end{bmatrix}$$

(23b)

and the estimated covariance of the measurement noise is

$$\hat{R}_{vv} = \begin{bmatrix} 1.03^2 & 0 \\ 0 & 1.04^2 \end{bmatrix}$$

(23c)

In this particular disturbance model, we have not utilized that the impact of the actual disturbance on the outputs are correlated even though this is evident from the estimated disturbance model. This implies that the estimated model is essentially two MISO models.

The step responses of the estimated transfer function, $\hat{G}(s)$, and the true transfer function, $G(s)$, are shown in Fig. 2. Phase plane plot of the output data of the Wood and Berry distillation column simulated using the model defined by (18) with the transfer functions (17), $\sigma = 1$ and $r_1 = r_2 = 1.0$. The inputs, $\{u(t)\}$, are PRBS with bandwidth $[0 0.01]$ and levels $[-0.5 0.5]$. The figure shows that the output data are highly co-linear.
**B. Model Predictive Control**

The suitability of the proposed identification method for predictive control is validated by application of the identified model (23) for the design of a constrained multivariable predictive controller. This controller is tested in a simulation using (18) as the plant. The transfer functions are defined by (17), $\sigma = 1$ and the measurement noise covariance is defined by (19). At time $t = 150$ a deterministic feed flow step disturbance, $d = 1$, occurs. This disturbance is unknown to the controller. At time $t = 400$, the disturbance disappears again.

The performance of the model predictive controller is shown in figure 5. In the upper plots the noise free outputs, $z_1$ and $z_2$, as well as the measurements, $y_1$ and $y_2$, are shown. The measurement noise is significant. Its effect on the measured output is of the same order of magnitude as the effect of the process noise. This corresponds to the common industrial plant using low resolution sensors contaminated with noise.

**Fig. 3.** Step responses for the deterministic part of the Wood and Berry distillation column model. Solid line: Estimated model. Dashed line: True model.

**Fig. 4.** Low and high gain plots for the true model (dashed line) and the estimated model (solid line) of the Wood and Berry distillation column. It is evident that the error of the estimated model is almost entirely in the low gain direction, while the gain in the high gain direction is estimated accurately.

**Fig. 5.** The Wood and Berry distillation column controlled by a predictive controller. Top: Outputs ($z$, solid line) and measured outputs ($y$, dotted line). Bottom: Controlled process inputs, $u$.

**Fig. 6.** The process outputs, $z$, for the Wood and Berry distillation column controlled by a predictive controller (solid line) and the identical scenario without control (dotted line).
with a high level of measurement noise. In this situation, no control system can completely eliminate the effect of the process noise on the outputs. However, as is evident by figure 6 which compares the open-loop outputs, (\(z_1\) and \(z_2\), dotted line), to the closed-loop outputs, (\(z_1\) and \(z_2\), solid line), the controller rejects the disturbance and performs marginally better than the no-control (open-loop) case in the situation with only white process noise. This closed-loop performance of the constrained predictive controller indicates that the proposed prediction-error methodology is suitable and feasible for identification of models that can be used by a predictive controller. For the performance of the controller in the situation with model-plant mismatch as well as unmeasured disturbance, it is important that the noise model is equipped with integrators. In addition identification of parameters in stochastic transfer functions with delays have proven feasible and very useful for specification of predictive controllers.

IV. CONCLUSION

A constructive method for estimation of parameters in continuous-discrete-time stochastic systems parameterized by transfer functions with time delays has been described. The method applies a multi-step maximum-likelihood prediction-error criterion. The predictions are generated using the Kalman filter and Kalman predictor for a stochastic linear discrete-time state space model, which is a realization of a continuous-discrete-time stochastic transfer function model with time delays. The multi-step prediction-error criteria may be selected such that it is compatible with the optimization criterion in the intended predictive control application. The feasibility of the suggested approach for predictive control is demonstrated using the Wood and Berry [33] distillation example. In particular, the design of predictive controllers using continuous-discrete-time stochastic models specified by transfer functions with delays has proven very convenient.
