ABSTRACT

The system LiCl-KCl-KF-1 mole percent K$_2$NbF$_7$ (molar ration F~ Nb = 8) has been investigated in the temperature range 370 to 725°C by cyclic and square wave voltammetry. In the temperature range from 370 to 520°C Nb(V) was reduced to Nb(III) in two reversible steps: Nb(V) $\rightarrow$ Nb(IV) $\rightarrow$ Nb(III). At these temperatures subvalent halides of niobium were formed at more negative potentials. At temperatures above 660°C metallic niobium was formed during reduction. When oxide (molar ratio O~/Nb = 1.1) was introduced in the melt at 725°C only minor changes were observed in the voltammograms. It is suggested that oxide addition mainly leads to precipitation of oxide containing compounds.

Introduction

LiCl-KCl melts are possible alternatives to fluoride melts as molten salt baths for electrochemical pitting of corrosion resistant layers of niobium metal. Although all fluoride melts, e.g., LiF-NaF-KF eutectic melts (FLINAK), seem to fulfill most of the technical demands to produce high quality surface layers of niobium, subvalent halides of niobium metal have been obtained from such melts. Although NaCl-KCl is the cheapest choice of solvent, the rather high melting point (approximately 700°C) of these mixtures may be a disadvantage. LiCl-KCl offers a wider range of liquidus temperatures, e.g., the melting point of the eutectic mixture is as low as 354°C.

At high temperatures (> approximately 600°C) the reduction of Nb(V) is reported to proceed according to

$$\text{Nb(V)} + 5e^- \rightarrow \text{Nb(IV)} + 4e^- \rightarrow \text{Nb(metal)}$$

both in mixed chloride-fluoride melts and in fluoride melts. This conclusion has mainly been drawn from experiments performed by cyclic voltammetry (CV). At lower temperatures most work has been performed on all chloride systems such as chloroaluminate and LiCl-KCl melts. The situation seems to be rather complicated and a number of different reduction paths for Nb(V) have been proposed. Only a few publications deal with the influence of oxide or fluoride at low temperatures. No work seems to have been performed on the niobium redox chemistry in LiCl-KCl melts with fluoride or oxide additions at temperatures above 550°C.

Experimental

The solvent (anhydrous eutectic LiCl-KCl mixture) was prepared in the following way: analytical grade LiCl and KCl from Merck were previously dried at 140°C for 2 days. Subsequently the salts were weighed, mixed, and placed in the dehydration apparatus described in details elsewhere. Gaseous hydrogen chloride (Gerling Holz; 99.995%) was passed through the salts for approximately 45 min, while they were heated to a temperature approximately 25°C beyond the melting point. The gas flow was retained 15 min after the salts were melted. Then nitrogen (Air Liquide, 99.8%) was led through the melt for 18 min to remove dissolved HCl. Both gasses were dried in columns filled with P$_2$O$_5$ before entering the dehydration apparatus. The melt was subsequently filtered and allowed to solidify in a quartz ampul, which was sealed under vacuum. Alternatively the salts were dehydrated directly in the setup used for the electrochemical experiments according to the following procedure: the salts were mixed in a vitreous carbon crucible which was then evacuated overnight at 130°C. The salts were then treated with chlorine (Air Liquide N27) during heating to the melting point and thereafter for 15 min in the molten state.

The alkali metal fluorides (Merck, analytical grade) were purified by recrystallization from molten state under argon atmosphere followed by mechanical separation as described previously. K$_2$NbF$_7$ was prepared by mixing hot solutions of KF (Merck, analytical grade) and Na$_2$O (Cerac, 99.95%). The product (precipitate) was then recrystallized in 40% hydrofluoric acid. Na$_2$O was formed by heating Na$_2$O$_2$ under vacuum as earlier reported. All handling and weighing of the chemicals were carried out in a glove box with a dry argon atmosphere (dew point approximately 45°C).

The voltammograms were generated by the means of a potentiostat (EG&G Princeton Applied Research Model 273 or Tacussel PRT 20-10X). The square wave voltammograms were obtained with a symmetrical square wave form (i.e., the forward and reverse pulses were of equal duration) and the current was measured just before switching the signal. These voltammograms could be resolved with a computer program (PeakFit™ from Jandel Scientific) that fitted the experimental curves according to a Gaussian procedure. All the experiments were conducted under argon atmosphere (≥99.99%) either by flow or a gauge pressure of 0.2 bar. The furnaces and experimental procedures have been described in detail elsewhere.

Electrode setup: either a platinum wire (quasi-reference electrode) or a Ni$^{2+}$/Ni reference electrode were used in the experiments. The Ni$^{2+}$/Ni reference electrode consisted of a nickel wire immersed in an inert melt bath with 1 mole percent (m/o) KF and 1 m/o NiCl$_2$ added. The inner
Results and Discussion

As mentioned in the experimental section both a Ni\textsuperscript{2+}/Ni-electrode and platinum metal have been applied as reference electrodes in our experiments. To simplify the discussion all potentials are referred vs. the Ni\textsuperscript{2+}/Ni reference electrode.

Cyclic voltammetry.—Figure 1 shows a typical voltammogram obtained at 725°C of an eutectic LiCl-KCl melt with K\textsubscript{3}NbF\textsubscript{7} and KF (molar ratio F/Nb = 7.9) added. The anodic limit is due to oxidation of the indicator electrode (platinum). Two reduction waves R\textsubscript{1} (0.24 V) and R\textsubscript{2} (—0.3 V) followed by a strong reduction wave R\textsubscript{3} (—0.45 V) appear in the voltammogram. R\textsubscript{1} is accompanied by an oxidation wave Ox\textsubscript{1} at —0.3 V. The reduction waves R\textsubscript{2} and R\textsubscript{3} are not very obvious in Fig. 1 but appear distinctly in Fig. 2 where the ordinate scale (current) has been magnified. On this figure it can be seen that R\textsubscript{1} and R\textsubscript{3} are coupled to the oxidation waves Ox\textsubscript{1} (0.4 V) and Ox\textsubscript{3} (0.2 V), respectively.

R\textsubscript{1}/Ox\textsubscript{1}.—In the scan range 0.5 to 20 V/s the peak potential of R\textsubscript{1} remained constant, and the peak current was proportional to the square root of the scan rate. Obviously R\textsubscript{1}/Ox\textsubscript{1} is due to a reversible process. The difference between the peak and half-peak potential (E\textsubscript{p} — E\textsubscript{1/2}) of R\textsubscript{1} was 0.17 V. When the equation

\[
|E_p - E_{1/2}| = 2.2RT/nF
\]

that is valid for reversible reactions\textsuperscript{22} is applied, an n value of 1.1 is obtained.

As can be seen from Fig. 1 and 2 the oxidation wave Ox\textsubscript{1} is overlapped by Ox\textsubscript{2} and the current due to oxidation of the Pt working electrode. Therefore exact values of the peak potential of Ox\textsubscript{1} could not be obtained at high temperatures (>600°C). However at lower temperatures (in the range from 370 to 520°C) Ox\textsubscript{1} is to a lesser extent overlapped by other waves, as can be seen in Fig. 3A-C. From these voltammograms the number of electrons involved was calculated by the equation\textsuperscript{22}

\[
E_p - E_{1/2} = 2.2RT/nF
\]

Compared to H\textsubscript{1} the current involved in H\textsubscript{3} is considerably more negative than R\textsubscript{2}. A platinum substrate was used as cathode. A gray deposit, which was insoluble in water was formed. A scanning electron microscope (SEM) investigation showed that the plate was covered by a thin surface layer. An electron dispersive x-ray analysis (EDX) of the layer gave signals from platinum and niobium. The average niobium to platinum atomic ratio was measured to be 0.3. These results suggest formation of a Nb-Pt alloy.

R\textsubscript{1}/Ox\textsubscript{1}.—R\textsubscript{1} is the strongest reduction wave in Fig. 1. Compared to R\textsubscript{2} the current involved in R\textsubscript{1} is considerably higher, indicating that more than one electron takes part in the process. Ox\textsubscript{1} has the shape of a stripping peak, suggesting that a solid product is formed at the working electrode during reduction. The observed pattern with a steep reduction wave (R\textsubscript{1}) situated at a potential approximately 0.7 V more negative than the Nb\textsubscript{3+} reduction (R\textsubscript{3}) is similar to observations at temperatures near 700°C in both FLINAK and NaCl-KCl melts with K\textsubscript{3}NbF\textsubscript{7} added.\textsuperscript{7,21} In both cases the reduction product was identified to be metallic niobium. To investigate whether this is the case also in LiCl-KCl, electrolysis was performed at a constant potential corresponding to that of R\textsubscript{1}. Molybdenum was chosen as cathode material since it does not form alloys.

\[
\text{Nb}(V) + e^- \rightarrow \text{Nb}(IV)
\]

This redox process has previously been reported to take place in all chloride,\textsuperscript{2,4,6,10,17,23} all fluoride,\textsuperscript{15,21} and mixed chloride fluoride\textsuperscript{3,5,14,19} melts.

Fig. 1. Cyclic voltammogram at 725°C of K\textsubscript{3}NbF\textsubscript{7} (1.1 m/o) dissolved in eutectic LiCl-KCl melt with KF (1.0 m/o) added. Scan rate: 0.5 V/s. Platinum working (0.024 cm\textsuperscript{2}), counter- and reference electrodes.

Fig. 2. Cyclic voltammogram at 725°C of K\textsubscript{3}NbF\textsubscript{7} (1.1 m/o) dissolved in eutectic LiCl-KCl melt with KF (1.0 m/o) added. Scan rate: 0.5 V/s. Platinum working (0.024 cm\textsuperscript{2}), counter- and reference electrodes.

These results suggest formation of a Nb-Pt alloy.
Influence of the temperature.—Figure 3 shows how the voltammograms change as a function of temperature in the range 370 to 660°C. Both the cathodic and anodic wave of \( R_5/Ox_5 \) are slightly displaced toward more negative values, when the temperature is lowered. The standard potential \( E^0 \) of a reversible reaction can be calculated from the equation:

\[
E^0 = 0.5 \left( E^0_{Ox} - E^0_{Red} \right)
\]  

As a result the following equation describes the temperature dependence of the \( \text{Nb}(V)/\text{Nb}(IV) \) redox couple:

\[
E^0_{\text{redox}} = (0.26 + 2.3 \cdot 10^{-4} \cdot T/°C) \ V
\]

in the temperature region from 370 to 520°C.

Furthermore two strong reduction waves (\( R_5 \) and \( R_6 \)) are observed in Fig. 3A-C. The peak potential of \( R_6 \) (–0.4 V) is almost independent of the temperature where-as \( R_5 \) shifts toward positive potentials with increasing temperature, e.g., from a wave potential of –0.9 V at 370°C (Fig. 3A) to –0.5 V at 520°C (Fig. 3C). As the temperature reaches 660°C (Fig. 3D) \( R_5 \) and \( R_6 \) merge into one wave, \( R_1 \). Thus the voltammogram is now very similar to the one previously recorded at 725°C (Fig. 1). Besides the more obvious reductions described above, it can further be seen that a supplementary reduction \( R_1 \) occurs in the region –0.1 to –0.35 V. Two strong oxidation waves in the region 0 to –0.25 V are apparent in Fig. 3. The one at the most positive potential is seen as a shoulder at the lowest temperature (370°C) and seems to grow with increasing temperature.

In order to clarify the correspondence between oxidation and reduction waves, experiments with changing cathodic reverse potential were performed. The resulting voltammograms can be seen in Fig. 4. It appears that \( R_5 \) is accompanied by a weak oxidation wave \( Ox_5 \) around –0.2 V. This wave is obviously not a stripping peak, which implies that the reduction product of \( R_5 \) is soluble. The correspondence between \( R_5 \) (–0.8 V) and the stripping peak \( Ox_5 \) (–0.3 V) appears clearly from the voltammogram where the potential is reversed at a potential slightly more negative than \( R_5 \) (dotted line). For even more negative reverse potentials a second stripping wave \( Ox_5' \) (approximately –0.1 V) shows up.

Fig. 3. Cyclic voltammograms at different temperatures of \( K_2\text{NbF}_7 \) (1.0 m/o) dissolved in eutectic LiCl-KCl melts with KF (1.0 m/o) added. Scan rate: 0.5 V/s. Platinum working electrode (0.047 cm²), vitreous carbon counterelectrode, and \( \text{NiCl}_2(1 \text{ m/o})/\text{Ni} \) reference electrode. Temperatures: A, 370°C; B, 450°C; C, 520°C; D, 660°C.

with niobium. A powdery gray layer covered by a black crust, was obtained. We have not been able to identify the nature of the black crust. However it could be dissolved in ethanol, resulting in a yellow-green solution. It is known that subvalent niobium species have dark colors and that some of these can be dissolved in ethanol to form olive solutions. The gray layer beneath consisted of nodules that were insoluble both in water and alcohol. Electrolytically deposited niobium metal from FLINAK melts has been reported to have a very similar morphology as we observe. Further an EDX analysis of the nodules showed signals from niobium. Consequently we conclude that metallic niobium is formed during the \( R_5 \) reduction. However it seems that the deposit also involves subvalent halides.

Fig. 4. Cyclic voltammograms at 450°C with different cathodic reverse potentials of \( K_2\text{NbF}_7 \) (1.0 m/o) dissolved in eutectic LiCl-KCl melts with KF (1.0 m/o) added. Platinum working electrode (0.047 cm²), vitreous carbon counterelectrode, and \( \text{NiCl}_2(1 \text{ m/o})/\text{Ni} \) reference electrode. Scan rate: 0.5 V/s.
At the scan rate applied in Fig. 4 (0.5 V/s) it was difficult to obtain specific information about $R_5$, since the wave was partly overlapped by the following reduction wave ($R_4$). However, it was possible to separate $R_4$ and $R_5$ when the scan rate exceeded 1 V/s, since $R_5$ shifted in negative direction. $R_4$ now appeared as a distinct wave (Fig. 5). For scan rates between 1 and 20 V/s $R_4$ and Ox$_4$ was situated at constant potentials of $-0.30$ and $-0.16$ V, respectively. Thus the redox couple R$_4$/Ox$_4$ seems to be due to a reversible reaction. It appears that the difference in the wave potentials ($E^{\bullet}_{\text{p}} - E^{\bullet}_{\text{n}}$) is $140$ mV. If Eq. 3 is applied an $n$ value of 1.1 can be calculated. Probably one electron is involved in the process R$_4$/Ox$_4$. Since we, from what previously has been said, can assume that Nb(V) has been reduced to Nb(IV) in a step previous to the R$_4$ reduction, it is most likely that $R_4$ is due to a reversible reduction of Nb(IV) to Nb(III) according to the equation

$$\text{Nb(IV)} + e^- \rightarrow \text{Nb(III)} \quad [7]$$

As we shall see in a later paragraph this hypothesis is supported by our square wave experiments. At 450°C the standard potential for the Nb(IV)/Nb(III) reaction was calculated from Eq. 5 to $-0.23$ V. To judge from the voltammogram recorded at 660°C (Fig. 3D) and 725°C (Fig. 1) $R_5$ may still be present as a prewave to $R_4$ even at high temperatures.

The Nb(IV)/Nb(III) reduction is known to take place over a wide temperature range in all chloride melts such as LiCl-KCl, NaCl-KCl and CsCl-NaCl melts. In addition previous work also showed the presence of the Nb(IV)/Nb(III) redox pair in a LiCl-KCl melt at 450°C with fluoride added (F'/Nb up to 8).

$R_5$.—We have further investigated the influence of the scan rate on the voltammogram at 450°C with cathodic reverse potential just beyond the one of $R_5$. The peak potential of $R_5$ vs. the logarithm of the scan rate is shown in Fig. 6. The curves appear. At low scan rates (between 5 and 50 mV/s) the peak potential is constant ($-0.41$ V) indicating a reversible reaction. For scan rates between 50 mV/s and 1 V/s a nonlinear change is observed. At scan rates above 1 V/s the curve again becomes linear suggesting that we now deal with an irreversible reduction. In the latter case the number of electrons taking part in the reaction can be estimated from the following equation

$$E^{\bullet}_{\text{p}} = K - (2.3 \, RT)/(2anF) \log \nu \quad [8]$$

where $K$ is a constant, $\alpha$ the transfer coefficient, and $\nu$ is the scan rate. From Eq. 8 and the slope of the curve a value of $an = 1.6$ can be calculated. In the case of redox reactions proceeding in solution it is normally safe to assume, that $\alpha$ has a value between 0.4 and 0.6. Under this assumption we obtain an $n$ value of approximately 3 for $R_5$.

As previously mentioned Eq. 3 can be used to estimate the number of electrons when the reaction is reversible. However, $R_5$ overlaps $R_4$ in the range $-0.2$ to $-0.3$ V implying that a reliable value of the half-wave potential of $R_5$ cannot be obtained from the voltammograms in Fig. 3 or 4.

A technique where a constant potential slightly below the peak potential of the prewave is applied for a period may overcome this problem. In this way the current due to the preceding reduction is minimized as it appears from the Cottrell equation. Thus an initial potential of $-0.30$ V was applied for 10 s before the voltammograms were recorded. The result can be seen in Fig. 7 (dotted line). By comparison with the voltammogram under normal condition (full line) it is obvious that the current due to $R_5$ is eliminated to a reasonable extent. We can now estimate $E^{\bullet}_{\text{p}} - E^{\bullet}_{\text{n}}$ for $R_5$ to be $60$ mV. This corresponds to an $n$ value of 2.3. Thus considering this result and the $n$ value (approximately 3) obtained from Fig. 6 (irreversible conditions) it seems like two or three electrons are involved in the process R$_4$/Ox$_4$. Further the standard potential $E^{\bullet}_{\text{p}}$ was calculated from the voltammograms in the reversible region (Eq. 5) to $-0.35 \pm 0.02$ V.

Since Ox$_4$ is not a stripping peak it is likely that R$_4$/Ox$_4$ only involves soluble species. A number of lower valent niobates are reported in the literature. Among them clusters containing Nb$_3^{x+}$ are known to exist in soluble form in chloride media. In two or three electron step

$$3n \, \text{Nb}^{x+} + n^e \rightarrow n \, \text{Nb}^{3+x} \quad (n = 2 \text{ or } 3) \quad [9]$$

In previous work on the redox behavior of niobium in LiCl-KCl melts (without fluoride added) no wave corresponding to $R_5$ was observed. An attempt to investigate melts with fluoride added at potentials corresponding to our $R_5$ region was impeded by passivation of the vitreous carbon working electrode. Thus no definite conclusion could be made. $R_5$.—In Fig. 4 a reduction wave $R_5$ is observed near the cathodic limit of the voltammograms ($-0.8$ V). This wave seems to correspond to two oxidation waves Ox$_3$ and Ox$_4$.

These have the shapes of stripping waves indicating that
two solid products are formed in the potential region near R3. It thus appears that the R1 wave could be due to two overlapping waves. An electrolysis at constant potential (−0.7 V) was subsequently performed in an attempt to identify the reduction products formed at 450°C. A gray deposit was obtained. However, it was not possible to identify the nature of the products by X-ray diffraction. It was observed that the diffractogram changed with time when the sample was exposed to the atmosphere (probably due to reaction with water vapor). The deposit was partly soluble in alcohol. This solution was olive-brown.

The pattern with a broad reduction wave and two corresponding oxidation peaks is very similar to previous observations in LiCl-KCl melts at 450°C. In this case electrolysis at potentials slightly more positive than the peak potential of the reduction wave resulted in formation of subvalent niobium species. Further metallic niobium was formed when the deposition potential was displaced toward potentials more negative than the peak potential. Thus it seems likely insoluble subvalent niobates are also formed during reduction when fluoride is present in the melt.

Square wave voltammetry (SWV).—SWV has proved to be a useful method to investigate redox reactions with overlapping waves. In the case of reversible processes the peaks are Gaussian shaped and the peak potentials are equal to the half-potentials (E1/2) of the redox processes. In our case we found it especially interesting to apply this method to the redox couples R4/Ox4 and R5/Ox5, since overlapping of the reduction waves occurred in the cyclic voltammograms. It was possible to resolve the obtained voltammogram into individual Gaussian curves (P1, P4, and P5) by a peak separation computer software as it appears in Fig. 8. Obviously P1 and P4 and P5 correspond to the redox couples R1/Ox1, R2/Ox2, and R3/Ox3, respectively, which have been previously observed by cyclic voltammetry (Fig. 4). P1 and P4 have similar shapes and heights whereas P5 are slimmer and two to three times more intensive than P1 and P4. The wave characteristics of the simulated waves are seen in Table I. A rough estimate of the number of electrons involved can be obtained from the half-peak widths (W1/2) of the peaks calculated from the square wave voltammogram at 450°C (Fig. 8).

Influence of oxide.—In Fig. 9 voltammograms of melts without and with Na2O added are compared. In the voltammogram with oxide added (Fig. 9B) a small additional reduction wave R7 appears approximately 0.1 V more negative than R5. The changes in the shape of the voltammograms when oxide is added are less pronounced than in FLINAK or NaCl-KCl melts containing K2NbF7. In those solvents the
wave corresponding to R₁ has disappeared and is replaced by a wave more negative (0.2 V) \(2,13\) Raman spectroscopic investigations on those melts show a nearly quantitative formation of \(\text{oxo complexes when oxide is added to the melts},^1\text{ i.e., the equilibrium}

\[
\text{NbF}_7^{2-} + \text{O}^2- \rightleftharpoons \text{NbO}_4^{2-} + (7 - \eta)\text{F}^- \quad [10]
\]

is shifted to the right. In our case where LiCl-KCl-KF is used as the solvent the effect of the oxide addition is expressed to a lesser extent since we still observe R₂ at an O/Nb molar ratio slightly above one (1.1). The reason for this could be precipitation of a Nb(V) oxo compound.

Thermodynamic calculations \(^1\) on niobium dissolved in LiCl-KCl-KF support this view since LiNbO₃ obviously forms at low \(p\text{O}^2-\) (i.e., high oxide content). In the voltammmogram in Fig. 9B a further oxidation wave Oₓ appears besides the wave due to oxidation of niobium metal (Oₓ). Obviously a second deposit is formed at the electrode during reduction. One could suggest that a subvalent oxide-containing compound is formed. However, this wave is very weak and the amount of material deposited is small, which makes it difficult to identify the reduction product.

**Conclusion**

The redox chemistry of \(\text{K}_2\text{NbF}_5\) dissolved in LiCl-KCl-KF melts (molar fluoride to niobium ratio \(\text{F}/\text{Nb} = 7.9\)) has been investigated in the temperature range 370 to 725°C. At low temperatures (370 to 520°C) cyclic voltammetry and square wave voltammetry show that Nb(V) is reduced to Nb(III) in two reversible steps

\[
\text{NbF}_5^{2-} + \text{e}^- \rightleftharpoons \text{NbO}_4^{2-} + (7 - \eta)\text{F}^- \quad [11]
\]

The standard potential \(E_{\text{red}}\) was found to vary linearly with the temperature according to \((0.26 - 2.3 \times 10^{-4} T/\text{°C})\) V [vs. Ni²⁺ (1 m/o NiCl₂/Ni)]. At moderate scan rates (less than 1 V/s) the reduction of Nb(V) to Nb(III) appeared as a pre-wave in the voltammograms in the region \(-0.2\) to \(-0.3\) V. The standard potential \(E_{\text{red}}\) was \(-0.23\) V at 450°C. The wave due to formation of Nb(III) is less pronounced at higher temperatures. A two-step reduction of Nb(V) to Nb(III) has also been observed in chloride melts without fluoride additions in a wide temperature range.\(^5,23\) It would be interesting to compare our results with electrochemical experiments in all fluoride melts, a situation where only fluoride complexes can be formed, at low temperatures (i.e., below 800°C). However only investigations at higher temperatures on such melts appear in the literature.\(^1,13\)

In the temperature range from 370 to 520°C two strong reduction waves appear at more negative potentials than the Nb(IV)/Nb(III) reduction wave. The first (around \(-0.4\) V) is due to formation of a soluble product. We suggest formation of Nb₁⁺ as a possible alternative. The second wave (around \(-0.8\) V) involves formation of two solid products (probably a subvalent niobium cluster compound and niobium metal). When the temperature exceeded 660°C the two reduction waves merged into one wave due to niobium metal formation.

Knowledge about the formation of niobium complexes could be a key for understanding the different redox behavior at low and high temperatures. Unfortunately the electrochemical measurements applied in our work are not suitable for clarifying the complex formation. So the question whether we deal with fluoro, mixed fluoro/chloro, or chloro complexes at low temperatures remains open. The problem may be solved by spectroscopic measurements, which have previously \(^3\) been shown to be useful for clarifying the situation in mixed chloride/fluoride media at high temperatures.

Only small changes were observed in the voltammograms when oxide was added to the melt at 725°C. The wave due to metal deposition from niobium halide complexes was still the strongest wave after oxide had been introduced in an amount equal to \(\text{O}/\text{Nb} = 1.1\). Consequently the formation of soluble oxo complexes in LiCl-KCl melt is less pronounced than in FLINAK and NaCl-KCl melts with \(\text{K}_2\text{NbF}_5\) added. Precipitation of niobates, e.g., LiNbO₃ may take place upon oxide addition to niobium(V) containing LiCl-KCl melts.

ABSTRACT

The mechanism of Zn-Ni alloy deposition in acidic sulfate electrolytes is analyzed essentially from polarization curves and impedance plots, using a rotating disk electrode. The anomalous deposition of the zinc-rich phases γ and δ occurs at high cathodic polarizations, nickel deposition being inhibited and zinc deposition being stimulated. At low polarizations, nickel-rich deposits are formed, on which the diffusion-controlled hydrogen evolution predominates, at pH 1.5. The transition is shown to be related both an increase in the interfacial pH and the presence of sulfur in the deposit. Impedance data reveal the reversibility of the charge-transfer reactions involved in hydrogen evolution and in anomalous deposition. They also show the existence of four relaxation processes: one inductive process due to zinc deposition, and three capacitive processes associated to nickel deposition and hydrogen evolution on a nickel-rich surface. They also reflect the anion adsorption.

Introduction

In recent years, great interest has been shown in the possibilities offered by the electrodeposition of alloys, mainly in the automotive industry. In particular it is known that the mechanical properties (hardness, stamping) of zinc electrodeposits can be improved by alloying zinc with nickel. Using Zn-Ni alloy deposits on iron sheets also increases their corrosion resistance. The electrodeposition of Zn-Ni alloys is generally anomalous. However under certain conditions (low current density), it is possible to produce normal deposition where nickel is deposited preferentially to zinc. Then a transition current density, and it hardly explains how a transition (upd) of zinc on nickel-rich zinc alloys or on nickel nuclei. This approach does not predict the existence of a transition current density, and it hardly explains how a high zinc content in thick alloy deposits can be generated by the upd of zinc monolayers. It can be admitted that both zinc hydroxide precipitation and zinc upd take place on the electrode surface, but these two phenomena do not suffice to account for the presence of four time-constants in the faradaic impedance of Zn-Ni alloys deposition in sulfate electrolytes, as recently reported. Electrochemical impedance measurements have already given new informations on the reaction mechanism of Zn-Ni alloys deposition in chloride electrolytes: a reaction model has been proposed, involving several adsorbed intermediates, and where the presence of a mixed surface compound (ZnNi) permits the deposition of zinc-rich alloys. This compound, which acts as a catalyst for nickel deposition, is incorporated in the alloy deposit with increasing polarization, thus allowing zinc deposition to predominate. The aim of this work was to investigate the mechanism of Zn-Ni alloy deposition in sulfate electrolytes. The results of the experimental approach, based essentially on efficiency is much higher, close to 98% and (ii) the nickel content in the alloy raises with increasing pH.

1. The second theory is based on the underpotential deposition (upd) of zinc on nickel-rich zinc alloys or on nickel nuclei. This approach does not predict the existence of a transition current density, and it hardly explains how a high zinc content in thick alloy deposits can be generated by the upd of zinc monolayers.

2. It can be admitted that both zinc hydroxide precipitation and zinc upd take place on the electrode surface, but these two phenomena do not suffice to account for the presence of four time-constants in the faradaic impedance of Zn-Ni alloys deposition in sulfate electrolytes, as recently reported. Electrochemical impedance measurements have already given new informations on the reaction mechanism of Zn-Ni alloys deposition in chloride electrolytes: a reaction model has been proposed, involving several adsorbed intermediates, and where the presence of a mixed surface compound (ZnNi) permits the deposition of zinc-rich alloys. This compound, which acts as a catalyst for nickel deposition, is incorporated in the alloy deposit with increasing polarization, thus allowing zinc deposition to predominate.
