Using infrared spectroscopy and low electron energy diffraction, we have investigated the adsorption of N\textsubscript{2}, at 30 K, on the Pt(111) and the Pt(111)(1×1)\textsubscript{H} surfaces. At monolayer coverage, N\textsubscript{2} orders in commensurate (3×3) structures on both surfaces, and we propose that the unit cells contain four molecules in each case. The infrared spectra reveal that N\textsubscript{2} exclusively physisorbs on the Pt(111)(1×1)\textsubscript{H} surface, while both physisorbed and chemisorbed N\textsubscript{2} is detected on the Pt(111) surface. Physisorbed N\textsubscript{2} is the majority species in the latter case, and the two adsorption states show an almost identical uptake behavior, which indicates that they are intrinsic constituents of the growing (3×3) N\textsubscript{2} islands. An analysis of the infrared absorbance data, based on a simple scaling concept suggested by density functional theory calculations, supports a model in which the (3×3) unit cell contains one chemisorbed molecule in end-on atop configuration and three physisorbed molecules. We note that a classic “pinwheel” structure on a hexagonal lattice, with the end-on chemisorbed N\textsubscript{2} molecules acting as “pins,” is compatible with this composition. © 2007 American Institute of Physics. I. INTRODUCTION

Experimental and theoretical studies show that N\textsubscript{2} interacts weakly with Pt surfaces. Recent infrared spectroscopic measurements have revealed that N\textsubscript{2} does not adsorb at 90 K on the defect-free Pt(111) surface\textsuperscript{1} or on the terraces of the stepped Pt(779) and Pt(335) surfaces.\textsuperscript{2} However, N\textsubscript{2} chemisorbs readily at the step sites of the stepped crystals\textsuperscript{2} and at similar defects on the Pt(111) surface\textsuperscript{1,2} with a characteristic spectroscopic signature, an infrared absorption peak around 2230 cm\textsuperscript{-1}, i.e., ~100 cm\textsuperscript{-1} lower than the gas phase N\textsubscript{2} internal vibration at 2331 cm\textsuperscript{-1}. These observations are supported by density functional theory (DFT) calculations,\textsuperscript{2} which identify an end-on atop chemisorbed N\textsubscript{2} configuration at the Pt surface step sites. The N\textsubscript{2}–Pt binding energy is ~0.5 eV. The calculations also show that N\textsubscript{2} may chemisorb very weakly (~0.15 eV binding energy, end-on atop configuration) at the Pt(111) terrace sites, but this adsorption state may also be nonexisting depending on the calculational approach and conditions. This raises an obvious experimental question regarding whether a weakly chemisorbed N\textsubscript{2} state may be populated at lower temperatures.

At a surface temperature below 45 K, N\textsubscript{2} physisorbs readily on Pt(111), as shown by x-ray photoemission spectroscopy (XPS) measurements.\textsuperscript{3} He-diffraction experiments\textsuperscript{3} reveal the formation of a commensurate (4×4)N\textsubscript{2} overlayer at 40 K and a commensurate (3×3)N\textsubscript{2} overlayer at 30 K and below. Both these investigations observe, below 30 K, a two-dimensional (2D) gas phase N\textsubscript{2} adsorbate at low coverage, which at a critical density nucleates to form condensed 2D islands. For larger N\textsubscript{2} exposures, the He-diffraction experiments show that additional molecules are incorporated in the growing (3×3) N\textsubscript{2} islands, and according to the XPS measurements,\textsuperscript{3} physisorbed N\textsubscript{2} is the majority species in the full monolayer at a surface coverage Θ≈0.4. The physisorbed N\textsubscript{2} was not detected in the concomitant infrared spectroscopic measurements.\textsuperscript{3} However, N\textsubscript{2} chemisorbed at steplike surface defects was readily detected, and the highly mobile N\textsubscript{2} molecules were found to saturate the steps at very small gas exposures. Most interesting though is the observation at low temperature of a new chemisorbed N\textsubscript{2} state with a vibrational frequency of 2266 cm\textsuperscript{-1}. The population of this state increases linearly with increasing N\textsubscript{2} coverage up to saturation of the N\textsubscript{2} monolayer, i.e., an entirely different behavior from that observed for N\textsubscript{2} chemisorbed at the steplike defects. Consequently, this new N\textsubscript{2} chemisorption state, with a binding energy around 0.15 eV, was assigned to correspond to N\textsubscript{2} chemisorbed at the terraces of the Pt(111) surface in an end-on atop configuration.\textsuperscript{3} A nagging point in this context is the lack of a distinct XPS signal. Are these molecules simply very few, and if so why? Can only sufficiently energetic molecules enter this state or is a peculiar defect related mechanism involved? A possible explanation is that the N\textsubscript{1}s XPS line of this weakly chemisorbed state is so little shifted relative to the physisorption signal that only a single slightly distorted XPS peak results.

Here, we report measurements using infrared reflection absorption spectroscopy (IRAS) and low-energy electron diffraction (LEED) of N₂ adsorption at 30 K on the Pt(111) surface and the hydrogen saturated Pt(111)(1 × 1)H surface. Our LEED observations show that the adsorbed N₂ monolayers form ordered commensurate (3 × 3) structures on both surfaces. The infrared spectra reveal that only physisorbed N₂ populates the Pt(111)(1 × 1)H surface characterized by a narrow infrared absorption peak at 2324 cm⁻¹. A physisorbed N₂ state also populates the Pt(111) surface, characterized by a sharp peak at 2322 cm⁻¹. Most notable though is the observation of a weakly chemisorbed N₂ state at 2265 cm⁻¹, i.e., identical to the state reported in Ref. 3 and discussed above. Our measured integrated infrared absorbance of this N₂ state is also in good agreement with these data. This close correspondence between the observations from two different experiments strongly supports the proposal that this N₂ chemisorption state is characteristic of the Pt(111) terraces. N₂ adsorption at defects behaves differently and reflects the status of the specific substrate surface investigated. For N₂ chemisorbed at the Pt(111) step sites, we observe an infrared absorption peak at 2232 cm⁻¹, which is more than an order of magnitude weaker than the corresponding signal at 2234 cm⁻¹ reported in Ref. 3.

The infrared spectra show that the physisorbed N₂ state is the majority species on Pt(111). This state and the terrace chemisorbed state have an almost identical uptake behavior, which indicates that both species are intrinsic constituents of the growing (3 × 3) N₂ islands. An analysis of the infrared absorbance data, based on a simple scaling concept suggested by DFT calculations, supports a model in which the (3 × 3) unit cell contains one chemisorbed molecule in an end-on atop configuration and three physisorbed molecules. We note that a classic “pinwheel” structure on a hexagonal lattice is compatible with this composition. Every end-on bonded chemisorbed N₂ “pin” would then be surrounded by six physisorbed N₂ each attached to two pin molecules.

II. EXPERIMENTAL

The IRAS measurements were performed with the use of an evacuated Bruker IFS 120 HR Fourier transform infrared spectrometer connected to an ion pumped ultrahigh vacuum (UHV) chamber with a base pressure in the 10⁻¹⁰ Torr range. The UHV chamber was equipped with LEED optics and a quadrupole mass spectrometer. In order to obtain optimal sensitivity in the spectral range of interest, 2100–2500 cm⁻¹, a spectrometer setup with a globar light source, a potassium bromide beam splitter, and an indium antimonide (InSb) detector was used. A more detailed description of the apparatus is presented in Ref. 5.

The Pt(111) single crystal, oriented to within 0.3° of the (111) face by Laue backreflection, was mounted on a manipulator equipped for resistive heating, LN₂ or LH₂ cooling, and temperature measurements using a platinum thermocouple clamped to the crystal surface. The specimen was measured in situ by heating at 1150 K for 15 min followed by oxidation at 1000 K for 1 h and subsequently sputtered with Ar ions (250 eV, 1 μA/cm²) at room temperature, and finally annealed at 1000 K.

The crystal was exposed to gases from the background via a manifold system with leak valves. All gas exposures were measured in langmuirs (1 L=1×10⁻⁶ Torr s) based on the ionization gauge pressure readings. Before IRAS measurements, the hydrogen and nitrogen adsorptions were monitored by work function measurements. The N₂ adsorption and the IRAS measurements were performed at 30 K. The surface was cleaned between consecutive measurements by flash heating to 1000 K. In the Pt(111)(1 × 1)H experiments, the hydrogen exposure was performed before the background spectrum was recorded. IR absorbance spectra were obtained by taking the ratio of consecutive normalized background and sample spectra. All IRAS data were collected with 2 cm⁻¹ resolution, Blackman-Harris three-term apodization function, and zero filling factor of 4. LEED observations of ordered structure formation were performed after IRAS measurements and also in separate experiments with a low primary current in order to avoid possible electron-beam-induced effects in the N₂ overlayer.

The DFT calculations are performed using DACapo, employing ultrasoft pseudopotentials to represent the ionic cores. For the exchange and correlation functional, the RPBE functional was used. The Brillouin zone was sampled using a Monkhorst-Pack scheme with a temperature smearing of the Fermi surface. An energy cutoff of 26 Ry was employed. The Pt(111) surface was represented using a periodically repeated four layer slab of platinum atoms in a 2 × 2 surface symmetry with a PRBE lattice constant of 4.02 Å. The slabs were separated by 12 Å of vacuum. The two topmost layers were allowed to relax, while the lower layers were kept fixed at the bulk positions. The N₂ molecule was adsorbed in an end-on atop configuration.

III. RESULTS AND DISCUSSION

Here, we present and discuss IRAS and LEED observations of molecular nitrogen adsorption on the clean Pt(111) surface and the Pt(111)(1 × 1)H surface at low temperatures.

A. N₂ adsorption: Vibrational spectra

Figure 1 shows IRAS spectra recorded for several different N₂ exposures, ranging from 0.6 to 8 L, of the Pt(111) surface at 30 K. Three infrared absorption peaks related to the intramolecular stretch vibration of adsorbed N₂ are observed at 2232, 2265, and 2322 cm⁻¹, respectively.

The sharp peak at 2322 cm⁻¹ is only marginally downshifted, Δν=9 cm⁻¹, relative to the gas phase value, 2231 cm⁻¹, of the internal N₂ vibration, and the observed linewidth, ~3 cm⁻¹, is essentially given by the instrumental resolution of 2 cm⁻¹. Both features are characteristic signs of the weak electronic interaction between the adsorbate and the substrate for a physisorbed molecular state. However, the physisorption interaction is responsible for the observed dipole activity of the N₂ stretch vibration. This mode is not dipole active for the homonuclear N₂ molecule, but the physisorption interaction induces a dipole moment in the ad-
sorbed molecule, which depends on the molecular polarizability and hence varies with the internuclear distance. The vibrating molecule will accordingly be associated with a dynamic dipole moment, and the \( n=0 \rightarrow 1 \) transition will be dipole active. We have discussed this process in more detail elsewhere\(^1\) and only remark here that the physisorption induced dynamic dipole moment is weak compared to the moments associated with chemisorbed molecules. We note that this physisorbed \( \text{N}_2 \) state on Pt\(^{111} \) around 30 K has previously been identified with x-ray photoelectron spectroscopy.\(^3\)

The relatively intense infrared absorption peak located at about 2265 cm\(^{-1}\) is significantly downshifted from the \( \text{N}_2 \) gas phase frequency, \( \Delta \nu = 66 \text{ cm}^{-1} \), with an enhanced line-width around 5 cm\(^{-1} \), i.e., properties characteristic of a chemisorbed molecular state. This \( \text{N}_2 \) state was observed previously in IRAS measurements\(^3\) and was tentatively assigned to \( \text{N}_2 \) weakly chemisorbed at the terrace sites of the Pt\((111)\) surface. We will make a more detailed comparison below. The physisorbed and the weakly chemisorbed \( \text{N}_2 \) states experience similar adsorption energies, and both desorb around 45 K.\(^3,4\) Our IRAS data in Fig. 1 reveal that the \( \text{N}_2 \) vibration frequency of these two adsorption states is essentially independent of the \( \text{N}_2 \) exposure below 4 L.

![FIG. 1. IRAS spectra recorded for different nitrogen exposures, ranging from 0.6 to 8 L, of the Pt(111) surface at 30 K. The amplitude in the interval 2300–2400 cm\(^{-1}\) has been magnified with a factor of 10.](Image)

![FIG. 2. The integrated absorbance vs nitrogen exposure of Pt(111) at 30 K for (a) the 2322 cm\(^{-1}\) physisorbed state, (b) the 2265 cm\(^{-1}\) chemisorbed state, and (c) the 2232 cm\(^{-1}\) defect site state.](Image)

The weak infrared peak at about 2232 cm\(^{-1}\) in Fig. 1 is within the interval 2230–2245 cm\(^{-1}\), which is characteristic of \( \text{N}_2 \) chemisorption at defect/step sites on Pt\((111)\) at temperatures below 90 K.\(^1,3\) The integrated absorbance varies with surface preparation, as expected for species chemisorbed at such sites. In our measurements, the defect site adsorption is weak and completed already for our lowest \( \text{N}_2 \) exposure.

Figure 2 shows integrated absorbance data versus \( \text{N}_2 \) exposure at 30 K obtained from the spectra shown in Fig. 1. Panels (a), (b), and (c) display such data for the 2322 cm\(^{-1}\) physisorbed state, the 2265 cm\(^{-1}\) chemisorbed terrace state, and the 2232 cm\(^{-1}\) defect/step site state, respectively. A striking observation in Fig. 2 is the similar evolution of the \( \text{N}_2 \) uptake in the physisorbed and chemisorbed states, which increases rapidly up to the formation of an ordered \((3 \times 3)\) \( \text{N}_2 \) overlayer at an exposure around 3 L. The subsequent compression and saturation of the overlayer proceeds slowly. Helium-diffraction experiments\(^4\) show that \( \text{N}_2 \) initially adsorbs in a 2D gas phase, which nucleates to form 2D islands at an exposure of \( \sim 0.15 \) L. Additional \( \text{N}_2 \) molecules contribute to the island growth. Hence, a natural explanation of the similar uptake is that the physisorbed and chemisorbed \( \text{N}_2 \) states are intrinsic constituents of the ordered 2D islands.
of the condensing N₂ overlayer. The weak coverage dependence of the vibrational frequencies of the two terrace adsorption states is compatible with this idea since molecules incorporated in an ordered structure experience an equivalent local environment.

Our spectroscopic data strongly support the tentative proposal of Ref. 3 that the weakly adsorbed 2265 cm⁻¹ N₂ species corresponds to a terrace chemisorbed state. It is instructive to compare the integrated absorbance data in Fig. 2 with the corresponding data in Ref. 3. The integrated absorbance is given by

\[ I = \int d\omega \Delta(\omega) = \frac{16\pi^2}{\hbar c} n_s(\mu_s^2)^2 \Omega G(\alpha), \]

where \( n_s \) is the number of adsorbed molecules per unit area, \( \mu_s^2 \) is the vibrational dipole matrix element at this coverage, and \( \Omega \) is the frequency of the internal stretch vibration. The factor \( G(\alpha) \) is determined by the optical incidence conditions and the dielectric properties of the metal substrate. \( G(\alpha) \) may differ slightly between different setups due to different incidence conditions [\( G(\alpha)=11.5 \) in our case]. Apart from that, we expect that well-defined adsorption states should give equal values of \( I \) in different experiments performed at otherwise equal experimental conditions, while defect related adsorption states may give completely different signals depending on surface preparation. The IRAS data in the two investigations reflect these aspects well. (i) The defect related N₂ chemisorption state saturates at low N₂ exposure but give very different \( I \) values of \( \sim 0.1 \times 10^{-3} \) cm⁻¹ in our case and \( \sim 3 \times 10^{-5} \) cm⁻¹ in Ref. 3. (ii) The terrace chemisorbed N₂ signal increases smoothly up to a coverage around 0.4 corresponding approximately to the \((3 \times 3)\) N₂ structure. The observed infrared absorbances are very similar \( I \sim 2.5 \times 10^{-3} \) cm⁻¹ in our work and \( I \sim 3.5 \times 10^{-3} \) cm⁻¹ in Ref. 3. A marginal difference which may be related to different \( G(\alpha) \) values.

We have found that the chemisorbed N₂ states are completely eliminated if the Pt(111) surface is precoated with a Pt(111)H overlayer. This was formed by an 80 L H₂ dose at 90 K prior to N₂ adsorption at 30 K. The spectra shown in Fig. 3 were recorded subsequent to a 3 L nitrogen exposure of the clean Pt(111) surface and the hydrogen saturated Pt(111)(1×1)H surface resulting in a \((3 \times 3)\) N₂ overlayer in both cases. On the Pt(111)(1×1)H surface, the nitrogen chemisorption peaks are extinct and the internal vibration of the physisorbed molecule is upshifted to 2324 cm⁻¹. These observations agree well with our previous findings regarding O₂ adsorption on Pt(111)(1×1)H: blocked chemisorption and a slightly upshifted internal vibration frequency of the physisorbed O₂ state. The physisorbed nitrogen molecules desorb at about 45 K. The infrared absorbance of the physisorption peaks at 2322 and 2324 cm⁻¹ in Fig. 3 is \( \sim 0.5 \times 10^{-3} \) cm⁻¹ in both cases, which indicates, as we discussed already, that the physisorbed molecules are majority species in the Pt(111)(3×3)N₂ structure.

\[ \text{FIG. 3. Spectra recorded for a 3 L N₂ exposure at 30 K of the clean Pt(111) and the Pt(111)(1×1)H surface.} \]

B. N₂ Adsorption: Structure

Our LEED observations show that nitrogen adsorption on Pt(111) at 30 K results in an adsorbed commensurate \((3 \times 3)\) N₂ overlayer, which for nitrogen exposures larger than 3 L distorts rotationally when the overlayer density is increased. These observations agree well with the results from a previous helium scattering experiment. As discussed above, we also observe the formation of a \((3 \times 3)\) N₂ overlayer for a 3 L N₂ exposure of the Pt(111)(1×1)H surface at 30 K. This structure contains only physisorbed N₂ molecules, and we note that also monolayers of Ar and O₂ adsorbed on Pt(111)(1×1)H at 30 K grow azimuthally aligned \((3 \times 3)\) structures. In the Ar case, the simplest interpretation of this structure is a commensurate overlayer with two Ar unit lengths matching three Pt(111)(1×1)H unit lengths and with four adparticles in each \((3 \times 3)\) unit cell. We propose the same structure model for the Pt(111)(1×1)H(3×3)N₂ system. The coverage of physisorbed N₂ is then \( \Theta=0.44 \), and the adsorbate density is \( 6.7 \times 10^{14} \) molecules/cm². This structure model is compatible with the \((3 \times 3)\) structure of a physisorbed N₂ monolayer on the Pt(111) surface found in molecular dynamics simulations, and the molecules exhibit in this case an in-plane herringbone orientational order.

The experimental information regarding the Pt(111)(3×3)N₂ structure suggests a more complicated situation. The IRAS data discussed above indicate that the unit cell involves both physisorbed and chemisorbed N₂ molecules and that physisorbed N₂ constitutes the majority species, observations corroborated by previous XPS and IRAS measurements. A structure model similar to the Pt(111)(1×1)H(3×3)N₂ system, discussed above, but with one chemisorbed and three physisorbed N₂ molecules, as shown in Fig. 4, is compatible with the experimental observations. The chemisorbed N₂ molecules is assumed to occupy an end-on configuration on top of a Pt atom, which is reasonable considering the relatively small downshift, 66 cm⁻¹, of the N–N vibrational frequency and also in accordance with
observations for N$_2$ adsorbed on stepped Pt surfaces.\textsuperscript{2} The physisorbed N$_2$ molecules are simply placed in symmetry positions in the unit cell. The N$_2$ coverage in this structure is $\Theta=0.44$, which agrees well with the reported saturation coverage 0.41±0.04 of N$_2$ on Pt(111) below 40 K.\textsuperscript{3} An interesting feature of the model in Fig. 4 is the adsorbate arrangement with an end-on chemisorbed N$_2$ molecule surrounded by six physisorbed N$_2$ molecules at a distance of 4.16, as seen in the center of Fig. 4. This is a well known pinwheel configuration,\textsuperscript{16} with four molecules in the unit cell and each wheel molecule linked to two pin molecules. A different kind of pinwheel arrangement has been reported for N$_2$ physisorbed on the Cu(110) surface.\textsuperscript{10} In this case, every wheel molecule belongs to a single pin molecule.

The structure model in Fig. 4 is compatible with the infrared spectroscopic data, the uptake behavior of chemisorbed and physisorbed molecules, the N$_2$ coverage, and the LEED observations. However, precise data regarding the relative abundance of chemisorbed and physisorbed N$_2$ would be most valuable. Neither the thermal desorption nor the XPS data of Ref. 3 reveal distinct separate signals from the two species. We have investigated the possibility to obtain quantitative information about the surface density of chemisorbed N$_2$ from the infrared data.

As mentioned in the Introduction, DFT calculations show that the chemisorption bond for N$_2$ in the end-on atop configuration on Pt(111) is weak, ~0.1 eV, or absent. Considering an accuracy of ~0.1 eV in the calculations, this picture agrees with the measured small adsorption energy of 0.15 eV.\textsuperscript{3,4} Frequency shifts of the internal N–N stretch vibration and induced dipole moments can also be obtained from the DFT calculations. The frequency shift is accurately measured in the experiment, and we decided to tune the calculation to the measured shift by varying the Pt–N$_2$ distance over a suitable range in order to obtain a theoretical estimate of the induced dynamic dipole and the related N$_2$ density. The calculated data for the shift $\Delta \nu$ and the dynamic dipole $\mu'$ versus the Pt–N$_2$ distance are shown in Fig. 5. The dashed and solid lines are linear fits to the calculated data points and give $\mu'=0$ and $\Delta \nu=0$ at about the same Pt–N$_2$ distance, 3.1 and 3.2 Å, respectively, in fact close to the estimated distance of 3.1 Å for physisorbed N$_2$. The adsorption energy is small, ±0.1 eV, over the distance range. The measured frequency shift is $\Delta \nu=66$ cm$^{-1}$, which, from the linear fits in Fig. 5, corresponds to a Pt–N$_2$ distance of 2.78 Å and a dynamic dipole moment $\mu'=0.15e$ at this distance.

We can now estimate the surface density of chemisorbed N$_2$ molecules from Eq. (1) using the measured integrated infrared absorbance $I=25 \times 10^{-4}$ cm$^{-1}$, the measured vibrational frequency $\Omega=2265$ cm$^{-1}$, and the calculated dipole matrix element $\mu_1$, given by

$$\mu_1 = \mu' \sqrt{\langle r^2 \rangle}.$$  

Here, $\sqrt{\langle r^2 \rangle}=\sqrt{\hbar/(2m\Omega)}$ is the rms displacement of the internal molecular bond in the harmonic oscillator approximation, where $m$ is the reduced mass of the oscillator, which gives $\mu_1=0.023$ D. $G(\alpha)=11.5$ at our optical conditions, and we obtain $3.6 \times 10^{13}$ chemisorbed N$_2$/cm$^2$. This is ~5% of the total density $6.7 \times 10^{14}$ N$_2$/cm$^2$ in the (3×3)N$_2$ overlayer, which indicates that chemisorbed N$_2$ is a characteristic adsorption state of the N$_2$ overlayer and not just a small contamination ~0.05% like the N$_2$ molecules chemisorbed at the step edges of our Pt(111) crystal.

Arguing along the lines presented above, we may obtain estimates of the physisorbed and chemisorbed N$_2$ densities in the Pt(111)(3×3)N$_2$ structure using the Pt(111)(1×1)H(3×3)N$_2$ system as a gauge. The latter structure contains only physisorbed N$_2$; the adsorption energy is ~0.15 eV, i.e., the same as for physisorbed and chemisorbed N$_2$ on Pt(111)\textsuperscript{3,4} The N$_2$ vibrational frequency is 2324 cm$^{-1}$, downshifted $\Delta \nu=7$ cm$^{-1}$ relative to the gas phase; the infrared absorbance is 0.45×10$^{-4}$ cm$^{-1}$, the surface density is $6.7 \times 10^{14}$ physisorbed N$_2$ molecules/cm$^2$, as proposed above, and the corresponding dipole matrix element is $7.0 \times 10^{-3}$ D. The XPS data\textsuperscript{3} and our IRAS data show that physisorbed N$_2$ is the majority species on Pt(111), which means that dipole screening will be similar for the physisorbed molecules in the two systems. The vibrational frequency shift and dynamic dipole
moment are zero for the free N₂ molecule, and we simply use a linear scaling of the vibrational frequency shifts and the dynamic dipole moment to obtain the dipole matrix element and density of physisorbed N₂ on Pt(111). In this case, the vibrational frequency is 2322 cm⁻¹, i.e., Δν=9 cm⁻¹, and the dynamic dipole moment is, accordingly, 9/7 times the value for our gauge system. From Eq. (2), we then obtain the dipole matrix element μ₁=9.0×10⁻⁴ D, which from the integrated absorbance and Eq. (1) gives a surface density of 4.6×10¹⁴ physisorbed N₂ molecules/cm² in the (3×3)N₂ structure on Pt(111). This is about 70% of the N₂ surface coverage of 6.7×10¹⁴/cm², close to 75%, which corresponds to three physisorbed N₂ molecules in the (3×3) unit cell of Fig. 4.

We have also used this scaling idea to obtain an estimate of the surface density of chemisorbed N₂ on Pt(111). This is the minority species, and dipole screening should be weak; we have used the screening corrected value of 1.0×10⁻³ D (Ref. 13) for the Pt(111)(1×1)H(3×3)N₂ reference system. The vibrational frequency for the chemisorbed N₂ is 2265 cm⁻¹, i.e., Δν=66 cm⁻¹, and the infrared absorbance is 25×10⁻⁴ cm⁻¹. The dynamical dipole is, accordingly, 66/7 times larger than for the N₂ reference. From Eq. (2) and the reference dipole matrix element, 1.0×10⁻³ D, we obtain for chemisorbed N₂ the dipole matrix element μ₁=9.5×10⁻³ D, which from the integrated absorbance and Eq. (1) gives a surface density of 2.1×10¹⁴ chemisorbed N₂ molecules/cm² in the Pt(111)(3×3)N₂ structure. This density is ~30% of the total N₂ surface density and is also in this case close to the expected 25% corresponding to one chemisorbed N₂ molecule in the (3×3) unit cell.

Our simple analysis of the measured infrared data evidently gives support for the (3×3)N₂ structure model in Fig. 4. The idea of scaling the vibrational frequency shifts and the dynamic dipole moments derives empirically from the DFT calculations. The N₂ adsorption states of concern have low adsorption energies reflected in small values of Δν and μ’ corresponding to small perturbations of the adsorbed molecules. It is conceivable that a linear scaling of Δν and μ’ in this limit is a reasonable approximation.

IV. CONCLUSION

Our LEED and IRAS measurements show that N₂ adsorption at 30 K on the Pt(111) and Pt(111)(1×1)H surface results in commensurate (3×3) overlayers. We propose that the unit cell contains four N₂ molecules in both cases, at a surface coverage of Θ=0.44, with the distinction that only physisorbed N₂ populates the hydrogen covered Pt surface, while both physisorbed and chemisorbed molecules appear on the bare surface. In the latter case, the two species show a similar uptake behavior at constant vibrational frequencies, which suggest that both adsorption states are intrinsic constituents of the growing (3×3)N₂ islands. The IRAS intensities show that physisorbed N₂ is the majority species, and estimated surface densities of adsorbed N₂ suggest that the unit cell contains three physisorbed and one chemisorbed molecules. The small vibrational frequency shift of the chemisorbed N₂ relative to the gas phase indicates, in accordance with N₂ chemisorption on stepped Pt surfaces, that the molecule is bonded in an end-on atop configuration. We propose a simple structure model for this system with each chemisorbed molecule acting as a pin surrounded in a symmetric arrangement by six physisorbed wheel molecules each (shared by two pin molecules). This is a well-known pin-wheel configuration and is compatible with the experimental information available.
