44 **Abstract**

45
46 Landfills receiving a mix of waste, including organics, have developed dramatically over the
47 last 3-4 decades; from open dumps to engineered facilities with extensive controls on leachate
48 and gas. The conventional municipal landfill will in most climates produce a highly contaminated
49 leachate and a significant amount of landfill gas. Leachate controls may include bottom liners and
50 leachate collection systems as well as leachate treatment prior to discharge to surface water. Gas
51 controls may include oxidizing top covers, gas collection systems with flares or gas utilization
52 systems for production of electricity and heat.

53 The importance of leachate and gas control measures in reducing the overall environmental
54 impact from a conventional landfill was assessed by life-cycle-assessment (LCA). The direct cost
55 for the measures were also estimated providing a basis for assessing which measures are the most
56 cost-effective in reducing the impact from a conventional landfill. This was done by modeling
57 landfills ranging from a simple open dump to highly engineered conventional landfills with
58 energy recovery in form of heat or electricity. The modeling was done in the waste LCA model
59 EASEWASTE. The results showed drastic improvements for most impact categories. Global
60 warming went from an impact of 0.1 person equivalent (PE) for the dump to -0.05 PE for the best
61 design. These correspond to a load of 870 kg CO₂-equivalents per tonne of waste landfilled (on a
62 wet weight basis) to a saving of -435 kg CO₂-equivalents per tonne of waste landfilled,
63 respectively. Similar improvements were found for photochemical ozone formation (0.02 PE to
64 0.002 PE) and stratospheric ozone formation (0.04 PE to 0.001 PE).

65 For the toxic and spoiled groundwater impact categories the trend is not as clear. The reason
66 for this was that the load to the environment shifted as more technologies were used. For the
67 dump landfill the main impacts were impacts for spoiled groundwater due to lack of leachate
68 collection, 2.3 PE down to 0.4 PE when leachate is collected. However, at the same time,
69 leachate collection causes a slight increase in eco-toxicity and human toxicity via water (0.007E
70 to 0.013PE and 0.002 to 0.003 PE respectively). The reason for this is that even if the leachate is
71 treated, slight amounts of contaminants are released through emissions of treated wastewater to
72 surface waters. The drop in the impact from potentially spoiled groundwater, due to increased
73 collection of leachate, is offset by a rise in increased human and eco-toxicity via water, due to
74 contaminants in the larger amount of treated waste water.

75 The largest environmental improvement with regard to the direct cost of the landfill was the
76 capping and leachate treatment system. The capping, though very cheap to establish, gave a huge
77 benefit in lowered impacts, the leachate collection system though expensive gave large benefits
78 as well. The other gas measures were found to give further improvements, for a minor increase in
79 cost.

80

81 **Keywords:** EASEWASTE, LCA, landfill, leachate and gas collection

82

83 1 Introduction

84 Landfills have developed dramatically over the last 3-4 decades; from open dumps to
85 engineered facilities with extensive controls on leachate and gas. Albeit many countries have
86 detailed guidelines on how to plan, design and operate landfills, landfills will also in the future on
87 a global scale encompass a wide range of technologies with various potential impacts on the
88 environment. Due to regulations conventional landfills as presented here are being outpaced in a
89 European context as organic waste is being treated with other technologies, but it is still the
90 dominant technology worldwide both in industrialized and developing countries.

91 The conventional municipal landfill will in most climates produce a highly contaminated
92 leachate and a significant amount of landfill gas. Leachate controls may include bottom liners and
93 leachate collection systems as well as leachate treatment prior to discharge to surface water. Gas
94 controls may include oxidizing top covers, gas collection systems, flares and also gas utilization
95 in terms of electricity and heat production. These technical controls have also increased the direct
96 cost of landfilling, which in some cases may be as high as 150 Euro per tonne (Hogg, 2002).

97 The purpose of this paper is to assess by life-cycle-assessment (LCA) how important leachate
98 and gas control measures are in reducing the overall environmental impact from a conventional
99 landfill. The direct cost for the measures are also estimated providing a basis for assessing which
100 measures are the most cost-effective in reducing the impact from a conventional landfill. The
101 environmental benefits of introducing new landfill technologies such as the bioreactor, the
102 flushing bioreactor and the semi-aerobic landfill technology are not addressed here but in a paper
103 by Manfredi & Christensen (2009).

104

105 2 Life-Cycle-Assessment: Approach and model

106 LCA provides a consistent framework for assessing potential environmental impacts for a
107 specified system including any related up-stream and down-stream processes. We have chosen to
108 use the EASEWASTE model (Kirkeby et al., 2006) for modeling the environmental impacts from
109 landfilling. The EASEWASTE landfill module is described in detail by Kirkeby et al. (2007).

110 The functional unit for the study is 1 tonne of wet household waste deposited in a landfill with
111 an average depth of 12.5 m and a compacted density of 800 kg/m³; all the environmental aspects
112 are accounted for in a time horizon of 100 years after disposal. The depth and density is used to
113 calculate the amount of leachate generation based on the surface associated with this 1 tonne in
114 the overall landfill design. These numbers are used to calculate the amounts of gas and leachate
115 as explained later.

116 Table 1 presents the impact categories that EASEWASTE uses for aggregating all the
117 quantified emissions to air, soil, surface water and groundwater. Most of the impact categories
118 are based on the EDIP 97 method (Wenzel *et al.*, 1997). Table 1 also presents the normalization
119 references used to convert the individual potential impacts into person equivalents (PE), which is
120 an average value for the yearly contribution to a given impact category by all the activities and
121 consumptions relative to one person. In the article the potential impacts are divided into 3 groups:
122 standard, toxicity related and spoiled groundwater (i.e. groundwater polluted above the drinking
123 water criteria).

124 2.1 Standard potential impacts

125 The standard potential impacts include Global Warming (GW), Photo-chemical Ozone Formation
126 (POF), Ozone Depletion (OD), Acidification (AC) and Nutrient Enrichment (NE). The

127 methodologies utilized for the assessment of these environmental impacts are well-
128 acknowledged, although different units may appear in different models. The degree of certainty
129 of the potential impacts can be considered high. In the case of global warming, emissions of CO₂
130 of biological origin are considered neutral as discussed in Christensen *et al.* (2009). This means
131 that the CO₂ being emitted from the landfill as well as methane that is oxidized into CO₂ are
132 counted as neutral and not contributing to GW since it originates from organic matter generated
133 by an equivalent uptake of CO₂ during the plant growth. Emissions of CO₂ originating from fossil
134 sources will be counted as contributing to GW, since this release of carbon is not balanced by a
135 recent, equivalent uptake of carbon. The EASEWASTE model also counts the amount of
136 biogenic carbon entering the landfill and left after the time horizon of the study (as default in
137 EASEWASTE set to 100 years). This carbon is considered sequestered in the landfill and will
138 therefore be counted as a saving and thereby decreasing the potential GW impact. The amount of
139 biogenic CO₂ released from the landfill is being calculated in the EASEWASTE inventory, it is
140 only in the characterization that it is counted as neutral. It is important to note that the neutrality
141 associated with biogenic CO₂ is only methodologically correct when factoring in carbon
142 sequestration as discussed in Christensen *et al.* (2009). Alternatively the biogenic CO₂ could have
143 been included with an impact, but in this case carbon sequestration should not have been included
144 in order to be methodologically consistent.

145 2.2 Toxicity-related potential impacts

146 Toxicity-related potential impacts include Human Toxicity in soil (HTs), water (HTw) and air
147 (HTa) as well as Ecotoxicity in soil (ETs) and in water (ETw). The degree of certainty of the
148 impact potentials calculated for this group is low since the utilized methodology is still being
149 developed and tested. Furthermore the model can calculate the stored toxicity in the landfill. This
150 is an impact that has been introduced in EASEWASTE (adapted from Hansen *et al.* 2004 and
151 Hauschild *et al.* 2008). The model calculates the amount of each toxic substance (heavy metals)
152 that entered the landfill and is left at the end of the time horizon of the study, and ascribes each
153 substance the characterization factor for eco-toxicity to soil and water. In this study it was
154 decided to leave out the graphs for these impacts; this is not to say that these are not important,
155 but because the same amount of toxic substance entered each landfill and it is almost the same
156 amount that is left after the time horizon of the study, the results would be the same for all
157 landfill. Conversely, if the study had included diversion of waste streams from the landfill this
158 would have been extremely important.
159

160 2.3 Groundwater impact

161 Impact on groundwater is usually not addressed in LCA, but is here represented by Spoiled
162 Groundwater Resource (SGWR). The impact is calculated as the volume of groundwater that the
163 input to the groundwater (here leachate) can contaminate up to the drinking water criteria. This
164 impact is adapted after Birgisdóttir *et al.* (2007) where it was used on leaching from bottom ash
165 residues used in road construction. In the present study the WHO (2006) drinking water criteria
166 were used instead of the Danish drinking water criteria used in Birgisdóttir *et al.* (2007).
167 Similarly as for the other impact categories, the calculation is done for each substance and the
168 sum yields the potential impact. The impact is normalized with regards to the amount of
169 contaminated groundwater per person per year in Denmark (2900 m³/person/year (DMU & DJF,
170 2003)); the normalization reference is based on the contamination by nitrate and chloride, and

171 must be seen as a rough indicator. In previous studies with EASEWASTE*,* a normalization
172 reference of 140 m³/person/year was used which was the amount of drinking water consumption
173 per person per year. That should be kept in mind when comparing with previous studies. The
174 Spoiled Groundwater Resource impact potential is relevant only when groundwater is considered
175 a limited resource and utilized.
176

177 **3 The conventional landfill - modeling and design**

178 *3.1 Landfill types*

179 The different landfill designs have been divided into 3 archetypes under which there are a couple
180 of alternatives, giving a total of 7 different scenarios. The 3 archetypes are described briefly and
181 an overview is presented of some of the most important technical differences for each landfill, for
182 more detailed info section 3.3 contains the precise data used for each scenario.
183

184 **The dump**

185 The dump is considered in terms of an *Open dump* since this represents the theoretical worst case
186 of a landfill with no measures to control leachate or gas. Besides the emissions from leachate and
187 gas, the main environmental load comes from the diesel combusted in the specialized vehicles
188 operating on-site (compactors, dozers, etc). The diesel consumption is estimated to 0.8 L diesel
189 per tonne of waste (as cumulative value throughout 100 years).

190 Also a *Covered dump* is considered; this is a dump that is supplied with a low quality soil
191 cover and vegetation after filling of the landfill section. This results in a reduced leachate
192 generation since the soil cover can hold some water for evapotranspiration from the wet period to
193 the dry period of the year. The top cover also provides some gas oxidation in particular when the
194 gas generation is modest in the later part of the 100 year period considered. The diesel
195 consumption is here estimated to 0.9 L diesel per tonne of waste for waste compaction, soil
196 moving and for establishing the top cover. It is assumed that the soil for the cover is present at the
197 site.
198

199 **The simple conventional landfill**

200 The simple conventional landfill has introduced a bottom liner, leachate collection and leachate
201 treatment. The top cover is of higher quality than for the covered dump and therefore it is able to
202 provide a superior oxidation of gas constituents. The gas may migrate through the top cover or be
203 collected and managed by biofilters or by flares. The biofilters are only partially effective while
204 the flare is highly effective in oxidizing the gas. However, the flare produces some secondary air
205 pollutants (NSCA, 2002). The diesel consumption is here set to 2 L diesel per tonne of waste,
206 used for waste compaction, soil moving, establishing the top cover, installing leachate and gas
207 collection systems and for post-closure operations. The collected fraction of leachate is sent to a
208 treatment plant, the pollutants remaining in the treated leachate is assumed discharged to surface
209 water, while the uncollected fraction is assumed to reach the groundwater.
210

211 **The energy-recovery conventional landfill**

212 The energy-recovery conventional landfill represents the most advanced conventional landfill,
213 where the gas is collected and used for energy production. The design is similar to the simple
214 conventional landfill, but the collected gas is here used for energy production. The produced
215 energy is assumed to substitute 100% for energy production at a coal-fired power plant or a

216 power plant based on natural gas, either in pure power production or as combined heat and power
217 (CHP). The saved emissions from the power plants are credited the landfill gas utilization system.
218 The reason to choose to model both coal and natural gas substitution is that it is found that this
219 can often have a large impact in the life cycle assessment of waste management (Fruegaard *et*
220 *al.*, 2009).

221 3.2 Basic features

222 The EASEWASTE model contains a flexible landfill module as described by Kirkeby et al.
223 (2007).. It is assumed that the landfill cell is being filled within 2 years after which it is closed
224 and leachate and gas mitigation systems are installed in relevant scenarios. The annual net
225 infiltration for the vegetated top cover is set to 300 mm.

226 Energy used for operation and maintenance and excavation of the landfill is included for all
227 the landfills and considered to be identical. Emissions associated with these operations as well as
228 upstream production are accounted for as well.

229 The landfill is considered for a 100 year period. All uses of resources and all emissions during
230 this period are accounted for. It is likely that landfill gas generation is approaching a negligible
231 value within this period. The waste being landfilled is assumed to be municipal solid waste with a
232 wet weight composition of 35% organics (food waste, flowers etc.), 30% paper and cardboard,
233 10% plastics, 9% glass and 16% of other fractions. The total amount of methane generated during
234 the 100 years is calculated to 77 Nm³ CH₄ per tonne of wet waste corresponding to approximately
235 160 Nm³ landfill gas (LFG) per tonne of wet waste for this waste composition. Contaminated
236 leachate, however, is expected to appear also after 100 year. However, this circumstance is not
237 accounted for in the assessment. If the composition of waste sent to the landfill were to change,
238 this would directly impact the amount of generated methane and thereby the performance of the
239 landfill.

240 The development in leachate and gas composition and amount over the 100 year period is
241 described by defining typical values for 4 time segments within the 100 year period. The values
242 used in this study are shown in Table 2 and 3.

243 Table 2 shows the composition of the landfill gas through the 4 defined time periods; average
244 oxidation removal efficiencies relative to each period are also provided. Oxidation implies that
245 the substance is converted to a non-impacting substance. The composition is primarily based on
246 Deipser et al. (1996), Mahieu et al. (2005), NSCA (2002), Rettenberger (2005), Rettenberger and
247 Stegmann (1996), Scheutz et al. (2004), Scheutz and Kjeldsen (2005). Table 3 gives the
248 concentration of modeled compounds in the leachate composition. The composition is assumed
249 to be the same for all the different scenarios, even though there are some variations in infiltration
250 rates. However, it is assumed that the controlling parameters for the leachate formation are
251 comparable in all landfills. Removal efficiencies are here defined as the amount of substance that
252 can be removed in the leachate treatment plant, and therefore does not end up being released into
253 a freshwater source. The composition is mainly based on data from Ehrig (1983), Kjeldsen and
254 Christophersen (2001), Lee and Jones (1993), Reinhart et al. (1998). Removal efficiencies are
255 based on Knox et al. (2003), U.S. EPA (1989 and 1992)

256 The values in Table 2 and 3 are typical values aggregated from many different sources. These
257 data are the same for all the modeled landfills, and the only difference is the amount of produced
258 leachate and gas multiplied with these generation values.

259

260 3.3 *Technical measures*

261 The technical measures of the conventional landfill relates primarily to leachate and gas control.
262 Table 4 describes the technical measures applied in each scenario. The performance of these
263 measures, including any functional deterioration over time, is also described by constant
264 parameters within each of 4 time segments. The length of the segments can in EASEWASTE be
265 defined independently for each measure.

266 Typical or possible measures regarding leachate and gas controls are described below. These
267 are combined to define the various conventional landfills representing different level of
268 environmental protection. The key parameter values are presented in Table 5.

269
270 Measures for landfill gas control

- 271 • Gas measure 1 (G1): No top cover and no gas collection system are installed. All the
272 generated gas is emitted directly to air. No oxidation of the landfill gas is thus expected to
273 take place. (Open dump)
- 274 • Gas measure 2 (G2): A soil top cover is installed after the filling of the cell (2 years) and
275 provides partial oxidation of the various constituents of the gas. The oxidation of methane is
276 assumed to be low during the first 40 years where the flow rate through the top cover is high
277 (an average of 35% is oxidized), and high at the later time segments (around 80% is oxidized)
278 when the flow rate is modest. The oxidation rates used are based on numbers from a review
279 by Chanton *et al.* (2009).(Covered dump)
- 280 • Gas measure 3 (G3): A gas collection system is installed after the cell has been filled with
281 waste (2 years). Efficiencies of gas collection systems are widely discussed. Based on a study
282 by Börjesson *et al.* (2009) a rate of 75% LFG collection assuming best available technology
283 performance was decided. This gives an overall gas extraction of 58 m³ CH₄ per tonne of
284 landfilled wet municipal waste. The collected fraction is treated at the site, either by
285 biological filters (G3A), which on average oxidizes 60% (based on Gebert (2003) and
286 Scheutz (2002)) of the methane without forming any secondary gaseous products except CO₂,
287 or in flares (G3B), which oxidize 98-99.7% of the methane, while some secondary gaseous
288 products are being formed (NO_x, CO, dioxin etc.). Data for emissions from flares are based
289 on NSCA (2002) and U.S. EPA. (2000, 2008). The uncollected fraction of the LFG is partly
290 oxidized in the top soil cover, and it is assumed that 80% is oxidized in the period where
291 there is gas collection, resulting in a low flow. The oxidation rates in the last 60 years where
292 there is no gas collection were lowered. This is due to the assumption that fugitive gas
293 releases through leachate and gas collection systems may take place, which would lower the
294 overall oxidation efficiency even though the flow is lower here. (Conventional landfill)
- 295 • Gas measure 4 (G4): Similar to Gas Measure 3. The collected fraction of gas is here sent to a
296 facility producing either electricity at an efficiency of 30% (G4E) or heat at an efficiency of
297 80% (G4H). Data for emissions from boilers and combustion engines are based on NSCA
298 (2002) and U.S. EPA. (2000, 2008). The produced energy is assumed to substitute 100% for
299 energy production at a coal-fired power plant (G4EC and G4HC) or power plant based on
300 natural gas (G4EN and G4HN). The saved emissions from the power plants are credited the
301 landfill gas utilization system. Electricity consumption is assumed generated by the same
302 process as for the avoided electricity. (Conventional energy recovery landfill).

303
304

305 Measures for landfill leachate control

- 306 • Leachate measure 1 (L1): No bottom liner and no leachate collection system are installed.
307 The generated leachate migrates directly into the groundwater. (Open and covered dumps)
- 308 • Leachate measure 2 (L2): Bottom liner and leachate collection system are installed (done in
309 combination with G2-4 where the landfill is capped which also leads to a lower leachate
310 production). The efficiency of the leachate collection system is high during the first 20 years
311 (95%), assumed to fall to 80% after 20 years where there starts to be some liner failure and
312 clogging, and finally down to 60% in the aftercare period. This is a conservative estimate; the
313 liner might be lasting much longer. The collected fraction of the generated leachate is treated
314 prior to discharge to surface water (marine or fresh). The removal efficiencies of the various
315 leachate constituents are based on a range of values for each constituent(s)*remove s* and
316 has been recalculated to mean values, these give efficiencies ranging from 22% (for
317 phosphate) and up to 97-98% (for BOD and ammonia). Emissions from sludge management
318 are disregarded, and it is acknowledged this can be an issue due to the high amount of
319 contaminants in the sludge. The uncollected fraction of the generated leachate is assumed to
320 reach the groundwater.

321 **4 The conventional landfill: Cost estimates of technical measures**

322 Landfill costs are highly variable. Hogg (2002) reports that even within Europe the cost may
323 range from 25 to 150 Euro/tonne excluding landfill taxes. This variation is partially due to
324 different levels of technical measures installed at the landfill and partially due to regional
325 differences in the cost of land, wages and earnings from sale of energy from LFG. In reality, the
326 price (i.e. the gate fee) of landfilling may not directly reflect the actual cost, but merely be
327 controlled by the market and availability of alternatives to the actual landfill.

328 Table 6 presents our estimated typical unit cost for the technical measures described above
329 (based on: Bates and Haworth, 2001; Delaware Solid Waste Authority, 2006; Hogg, 2002;
330 Johannessen, 1999a, 1999b; Purdy and Shedden, 2005). The baseline cost for a dump without any
331 measures to control leachate or gas is set to 40 Euro/tonne, including capital costs and operational
332 costs. This baseline cost is used for all the landfills and in addition the costs for the technical
333 measures are added step by step.

334 The unit costs are used to evaluate the cost-effectiveness of the different measures in relation
335 to the environmental benefits that are achieved. The hypothesis is that some measures might give
336 a high environmental benefit but at a high cost, while other measures can achieve similar benefits
337 at a much lower cost.

338 The cost components are combined differently for the seven landfill scenarios. All of the
339 landfills have the same baseline cost which includes land acquisition, construction and landfill
340 operation. Most of the numbers used for the calculations are given in Euro/tonne and can simply
341 be introduced into the “per tonne” calculations. However, the gas collection, leachate collection
342 and treatment, electricity and district heating production were given in other units and therefore
343 have been calculated into Euro/tonne. This has been done with the data from the life cycle
344 assessment inventory, and these amounts are given in the table footnotes. The total costs for the
345 different landfill technologies, can be seen at the bottom of Table 6. Additionally uncertainty in
346 the allocated numbers are presented in Table 6, and this accumulated uncertainty are shown in
347 Figure 3.

348 5 Results and discussion

349 5.1 Standard impact categories

350 Through the use of the LCA model EASEWASTE significant aspects of landfill design have
351 been modeled and associated potential environmental impacts have been estimated. The main
352 results achieved are given in Figures 1, 2 and 3.

353 Figure 1 gives the normalized impact potentials for the ordinary impact categories. It can be
354 seen that global warming is significant in the dump landfills and in the landfill with the simple
355 soil cover (up to 0.1 PE per tonne wet waste corresponding to 870 kg CO₂-equivalents per tonne
356 wet waste). When a gas collection system is installed, some oxidation of the gas constituent can
357 be provided by biofilters. These do not generate any other new emissions besides carbon dioxide
358 (biogenic). Flares provide a much more efficient reduction of methane emissions, so that the
359 global warming impact is lowered to -0.026 PE per tonne wet waste. The reason for the negative
360 number is due to the fact that carbon sequestration is included in the number for all the landfill
361 (0.05 PE sequestered per tonne wet waste). This sequestration is calculated based on the biogenic
362 carbon content, which is still present in the landfill after the timeframe of the study (100 years).
363 This carbon content is based on the defined waste composition sent to the landfill. The
364 importance of this is illustrated by the “Net value – no sequestration” marks in Figure 1 where
365 the sequestration has been excluded. If the time horizon for the study was further extended the
366 amount of sequestered carbon would drop a little as a certain fraction of the remaining carbon
367 would be released (the last 4% of easily degradable carbon which is not released in the first 100
368 years where 96% is assumed released), but an amount of the carbon is also expected to be stored
369 in sequestered form in the future. When the collected gas is sent to an energy recovery facility,
370 the global warming savings are further increased, as shown in Figure 1. It can here also be seen
371 that the savings calculated when substituting coal are higher than that with natural gas. This
372 shows that it is important to evaluate what energy source would have been used if the energy had
373 not been recovered from the landfill.

374 The impact potentials calculated for the other ordinary impact categories are smaller in
375 magnitude than the impact potential estimated for global warming. The impact for photochemical
376 ozone formation is mainly due to emissions of methane and VOC's, which follows the same
377 declining trend as for global warming due to the mitigation measures for these substances. Impact
378 potentials for acidification and nutrient enrichment are very close to zero PE, and the main
379 substances of importance here, is the leaching of phosphate and ammonia to surface water
380 (marine or fresh). Stratospheric ozone depletion is the second largest impact with an impact of up
381 to 0.04 PE per tonne of wet waste. This is due to emissions of CFC11 and CFC12 and their
382 degradation products. Even though a large part of these are oxidized in the landfills as discussed
383 by Scheutz and Kjeldsen (2005), some of the substances left are still emitted as they leave the
384 landfill. In the future, this impact is expected to drop since these substances are banned in new
385 products, but the cooling agent substances that are replacing CFCs are not included, due to lack
386 of data, and it is therefore not known if this impact is still going to be of importance in future
387 environmental assessment of landfills. But in countries where electronic waste must be collected
388 separately this should not be a concern, and this is a good reason to promote separate collection
389 of electronic waste to remove this uncertainty about a potential impact.

390 5.2 *Toxic impact categories*

391 Impact potentials on toxicity-related categories are also presented in Figure 1. Leachate
392 controlling measures (bottom-liner and collection) lead to increased toxicity to the water
393 ecosystem (from 0.007 PE to 0.012 PE per tonne waste). This is due to the fact that the leachate
394 is treated at a wastewater plant, and the treated water is discharged into surface waters. There will
395 though still be a minor amount of contaminants left in the treated water (e.g. copper and zinc) that
396 will lead to an increased impact of eco-toxicity in water. The reason this impact is not as high in
397 the not lined systems (L1G1 and L1G2) is that the leachate here will end in the groundwater
398 resource and thereby will not be accredited to the surface water. As it can be seen from Figure 2,
399 it is the unlined systems that cause the largest impact, which shows that the burdens are just
400 shifted when controlling the leachate. The size in PE should not be compared directly since the
401 methodology between the two impacts is quite different, but it gives a good picture of why it is
402 necessary to collect the leachate. It is to be noted that the main contributor to spoiled groundwater
403 resources is ammonia, and the contribution and fate of this substance should be further studied to
404 establish its importance.

405 Eco-toxicity in soil is having such a small impact that it is not even noticeable on the figure,
406 but has been kept in order to show that it was calculated. The same applies to human toxicity via
407 air. The reason for the very small impact is that it is mainly caused by emissions associated with
408 the combustion from the on-site vehicles; thus, once normalized with the yearly contribution for
409 one person, this impact becomes very small.

410 Human toxicity via soil is where the largest contribution and also changes are calculated for
411 the toxic impact categories. The main reason for this is that organic compounds (benzene,
412 vinylchloride etc.), which are found to be the main contributing substances to the impact, are
413 oxidized as soon as a retention time is introduced via a cover material. By collecting the gas and
414 flaring or combusting it, the amount of substance being converted is further increased, showing
415 the benefit of recovery over passive oxidation. That these substances have such a high impact is
416 somewhat surprising, as it would have been expected that most of them would quickly degrade
417 when being released to the atmosphere. By comparing the characterization factors with those of
418 EDIP 2003 methodology (Hauschild and Potter, 2005) and USEtox methodology (Rosenbaum *et*
419 *al.*, 2008) it was found that the impact to soil from these substances is considerably lower in these
420 methodologies. If lowering the impact from these substances the overall impact fell, but the trend
421 for a large importance was the same. This does show that the uncertainty with regards to the toxic
422 methodologies should be kept in mind, and that when the USEtox methodology for metals are
423 finalized it may be better to move to this updated methodology for any future assessment.

424 For human toxicity via water there can be seen a growing trend as more measures are
425 introduced, the only exception being when there are substitution taking place based on coal. The
426 reason for the impact is mainly due to dioxin formation in the LFG combustion processes, as well
427 as fugitive releases of mercury compounds. The reason for the savings is that coal power itself
428 represents a huge mercury load to the atmosphere, and this offsets the emissions from the LFG
429 leading to a net saving.

430

431 5.3 *Economic costs*

432 In order to link economic costs to environmental performance the net sum of the impacts
433 potentials was plotted as a function of the costs for the landfill setup. The result of this is shown
434 in Figure 3. The net impact potentials are calculated by associating all impacts with a weight of

435 one, meaning all impacts are considered of similar importance. The choice of a uniform weight is
436 taken to be neutral. The reader can compare the individual columns in Figure 1 with the costs in
437 Table 6 to get a view of the disaggregated costs and impacts. Based on Figure 3 it is clear that the
438 open dump is the cheapest but also the worst performing landfill as expected. It can be seen that
439 by covering the dump the impact of the landfill can be drastically lowered for very little
440 additional cost (40 versus 42 Euro). This is due to the drop in leachate formation due to
441 evaporation in the top cover, as well as top cover oxidation of a large amount of the gas
442 constituents. Furthermore, a cover would mean that the landfill is more esthetic, odor problems
443 are minimized, blowing litter will be avoided and less vector intrusion (birds, rodents etc.) will
444 take place. All of these impacts are not measured in a traditional LCA but would still be of
445 relevance in the planning of a landfill. The installation of the leachate collection system is the
446 most costly installation besides the base costs (10 Euro per m³ leachate), but it can be seen that
447 there is still a large avoided impact from this, which is due to the drop in impact to SGR.

448 The treatment costs for the non-passive gas treatment systems are not varying very much (57-
449 63 Euro) and are mainly due to differences in cost and income for the combustion systems. The
450 difference from the worst process in this category (L2G2) and the best (G4HC) is an impact of
451 approximately 0.1PE while actually saving 5 Euro, due to the income from the energy paying for
452 the gas collection and combustion equipment. The landfills substituting heat seems to be a better
453 choice than electricity, which is due to the fact that the efficiency of the heat generation is
454 remarkably higher. It has though to be kept in mind that this option is only viable if there is a
455 customer to receive the generated heat. Electricity can on the other hand always be sold to the
456 grid and is therefore an easier default option. In general the energy recovery options are a better
457 option than the non-energy scenarios since the payment for the sold energy offsets the plant costs
458 of the generators, and at the same time the substituted energy means that the environmental
459 impact is considerably lower. This is only true as long as the studied landfill has a high methane
460 production (f.x. from household waste), whereas a low-carbon landfill would most likely not
461 generate enough methane to support energy production. The presented overall uncertainty in
462 Table 6 indicates that there is in reality not any difference between the cost for the more
463 advanced treatment technologies, as the uncertainty is as big as the largest difference between
464 these technologies. There should therefore not be any reason for not going for the optimal
465 treatment technology as long as the energy can be sold.

466 5.4 Conclusions

467 Overall, it can be observed that the efficiencies of gas and leachate collection systems are
468 crucial parameters in the assessment, since a poor collection compromises the overall
469 environmental performance. However, when good efficiencies are achieved, other circumstances
470 might affect the assessment. With respect to landfill gas, the considered combustion treatment
471 measures have demonstrated to generate emissions which are of particular concern for the
472 toxicity-related impacts. Furthermore, contaminated leachate is expected to be generated in
473 significant amounts long after the end of the collection period (70 years). As a consequence, a
474 substantial potential impact on spoiled groundwater resource still exists in those landfills
475 collecting leachate.

476 Since there is a linear correlation per tonne of waste in our calculations, between leachate
477 generation and the amount of leachate substance generated, the uncertainty with regards to the
478 leachate generation per tonne of waste will mean this uncertainty is reflected in the leachate
479 substances and hence the overall impact of the landfill. But of even more importance is the
480 geographical location of the landfill, as the precipitation rates vary considerably from region to

481 region, and a landfill in an arid versus a humid region will mean a difference in orders of
482 magnitude for the potential leachate generation. Similarly, the landfill depth when the final cap is
483 placed will determine the surface area of the landfill, and hence the leachate generation rate. The
484 same is the case for the methane and LFG generation where there is a large variability in
485 generation rates depending on the composition of the landfilled waste. It is therefore important in
486 a study to have a good knowledge of the waste fractions entering the landfill. When for instance
487 doing an integrated waste study with different diversion rates it is crucial to make sure that this is
488 updated whenever the composition changes (if this is not done automatically by the model).

489 It is therefore very important when doing an LCA study for waste management to make sure
490 that the landfill being modeled is not just an average landfill, but that it actually represents the
491 state of technology present or intended for the system.
492

493 **6 Acknowledgements**

494 We would like to thank H.C. Willumsen (LFG Consult, Viborg, Denmark) for his comments to
495 our cost estimates for the landfill designs. Also a big thank to Gitte Lemming, DTU
496 Environment, on the help with the normalization reference for groundwater contamination.

Table 4 The 7 scenarios with the technical measures (L & G) applied in each scenario.

Landfill Type	Technical Measure	Description
Dump		
Open Dump	L1 + G1	Open, no treatment
Covered Dump	L1 + G2	Covered with soil to allow for top cover oxidation.
Simple conventional		
Simple	L2 + G2	Leachate is collected and sent to treatment, no gas mitigation besides top cover oxidation
Biofilter	L2 + G3A	Leachate is collected and sent to treatment, gas collection and treatment with biofilter
Flaring	L2 + G3B	Leachate is collected and sent to treatment, gas collection and combustion in flares.
Energy recovery landfill		
Energy recovery for electricity production	L2+G4E	Leachate is collected and sent to treatment. Gas is collected and sent to a combustion engine for electricity production. Substituting electricity based on combustion of coal or natural gas
Energy recovery for heat production.	L2+G4H	Leachate is collected and sent to treatment. Gas is collected and sent to a boiler for heat production. Substituting heat based on combustion of coal or natural gas.

730 **Table 5 Key parameters describing the defined conventional landfill technologies in terms of measures for**
 731 **leachate and gas control. For each cell per period is defined the number of years, and the amount per period**
 732 **or year.**

	Time period 1	Time period 2	Time period 3	Time period 4
<i>The dump (L1, G1)</i>				
Gas generated (% of gas potential)	2y: 2%	3y: 8%	35y: 70%	60y: 16%
Gas collected (% of generated)	None	None	None	None
Gas oxidized by top cover (% of uncollected)	None	None	None	None
Leachate generated (mm/y)	2y: 500	8y: 500	40y: 450	50y: 450
Leachate collected (% of generated)	None	None	None	None
Leachate entering groundwater (% of generated)	2y: 100%	8y: 100%	40y: 100%	50y: 100%
<i>The covered dump (L1, G2)</i>				
Gas generated (% of gas potential)	2y: 2%	3y: 8%	35y: 70%	60y: 16%
Gas collected (% of generated)	None	None	None	None
Gas oxidized by top cover (% of uncollected)	2y: 0%	3y: 35%	35y: 35%	60y: 80%
Leachate generated (mm/y)	2y: 500 mm/y	8y: 250 mm/y	30y: 200 mm/y	60y: 180 mm/y
Leachate collected (% of generated)	None	None	None	None
Leachate entering groundwater (% of generated)	2y: 100%	8y: 100%	40y: 100%	50y: 100%
<i>The simple conventional landfill (L2 and, G2, G3A or G3B)</i>				
Gas generated (% of gas potential)	2y: 2%	3y: 8%	35y: 70%	60y: 16%
Gas collected (% of generated)	2y: 0%	3y: 75%	35y: 75%	60y: 0%
Gas management	None	Flared/filter	Flare/filter	None
Gas oxidized by top cover (% of uncollected)	2y: 0%	3y: 80%	35y: 80%	60y: 70%
Leachate generated (mm/y)	2y: 500 mm/y	8y: 250 mm/y	30y: 200 mm/y	60y: 180 mm/y
Leachate collected (% of generated)	20y: 95%	20y: 80%	30y: 60%	30y: 0%
Leachate entering groundwater (% of generated)	20y: 5%	20y: 20%	30y: 40%	30y: 100%
<i>The energy-recovery conventional landfill (L2, G4)</i>				
Gas generated (% of gas potential)	2y: 2%	3y: 8%	35y: 70%	60y: 16%
Gas collected (% of generated)	2y: 0%	3y: 75%	35y: 75%	60y: 0%
Gas management	None	Flared	Elec/CHP	None
Gas oxidized by top cover (% of uncollected)	2y: 0%	3y: 80%	35y: 80%	60y: 80%
Leachate generated (mm/y)	2y: 500 mm/y	8y: 250 mm/y	30y: 200 mm/y	60y: 180 mm/y
Leachate collected (% of generated)	20y: 95%	20y: 80%	30y: 60%	30y: 0%
Leachate entering groundwater (% of generated)	20y: 5%	20y: 20%	30y: 40%	30y: 100%

Table 6: Typical unit costs for technical measures included in the seven landfill configurations.

Configuration	Unit	G1	G2	G2	G3A	G3B	G4EN/G4EC	G4HN/G4HC	Uncertainty
		+ L1	+ L1	+ L2	+ L2	+ L2	+ L2	+ L2	
Baseline cost	€tonne	40	40	40	40	40	40	40	
Simple top cover	€tonne		2						
Top cover	€tonne			3	3	3	3	3	±1
Bottom liner	€tonne			4	4	4	4	4	±1
Leachate collection ^a	€tonne			2.5	2.5	2.5	2.5	2.5	±0.5
Leachate treatment	€tonne			11.2	11.2	11.2	11.2	11.2	±2
Gas collection ^b	€tonne				1	1	1	1	±0.01
Biofilter	€tonne				0.1				
Flare	€tonne					0.15			
Electricity plant	€tonne						2		± 0.5
Heat plant	€tonne							1.0	± 0.5
Electricity sold	€tonne						5.2		
District heating sold ^c	€tonne							6.9	
Total cost	€tonne	40	42	62	63	63	60	57	
Accumulated uncertainty	€tonne	0	0	±4.5	±5.6	±5.6	±6.1	±6.1	

746

^a 1.12 m³ leachate per tonne waste.

747

^b LFG collection and treatment based on 100 m³

748

^c 56m³ methane recovered for energy generation
