Abstract—EEG imaging, the estimation of the cortical source distribution from scalp electrode measurements, poses an extremely ill-posed inverse problem. Recent work by Delorme et al. (2012) supports the hypothesis that distributed source solutions are sparse. We show that direct search for sparse solutions as implemented by the Variational Garrote (Kappen, 2011) provides excellent estimates compared with other widely used schemes, is computationally attractive, and by its separation of 'where' and 'what' degrees of freedom paves the road for the introduction of genuine prior information.

Keywords—EEG; Imaging; Variational Garrote; LASSO; Sparse Bayesian Modeling; Sparsity

I. INTRODUCTION

We are interested in real-time imaging of human brain function by electroencephalography (EEG). The EEG imaging problem is of significant theoretical interest and real-time EEG imaging has many potential applications including quality control, in-line experimental design, brain state decoding, and neuro-feedback. In mobile applications these possibilities are attractive as elements in systems for personal state monitoring and well-being, and indeed in clinical settings where proper care requires imaging under quas-natural conditions [1]. The first real-time mobile systems are based on reconstruction methods using basic Tikhonov regularization [1]. However, the computational challenges induced by the highly ill-posed nature of the EEG imaging problem escalate in mobile real-time systems and new algorithms may be necessary [2].

In recent work by Delorme et al. [3] it is argued that independent components of EEG signals are dipolar in nature. In particular it was shown that a direct dipolar fit can explain much of the spatially distributed signal measured in scalp electrodes. This is in line with a large literature, see e.g. [4] and references herein, suggesting sparse localized sources and motivates reconstruction algorithms that emphasize sparsity, thus contrasting the distributed spatial source patterns promoted in classical alternatives [5].

Unfortunately, the quest for sparse solutions to the EEG imaging problem is combinatorial and an exact solution will not be feasible in realistic real-time systems. Many promising approximation schemes have been proposed for the general problem and many have been applied to the EEG imaging problem. We here investigate a recent alternative for sparse recovery proposed by Kappen [6]. The soft active set construction is of particular interest to real-time EEG as it enables separation of the location and magnitude estimation aspects of the reconstruction task, and furthermore leads to a relative low-complexity set of non-linear equations that are iterated towards the solution.

II. THE EEG INVERSE PROBLEM

In the quasi static approximation the relation between dipolar sources placed at the cortical surface \( w_i \) and the measured potentials at multiple scalp locations \( y_i \) is instantaneous and linear \( y_i = \sum_{i=1}^{n} w_i X_{i\gamma} + \xi_i \). We have denoted the forward model by \( X_{i\gamma} \) and allowed for measurement noise \( \xi_i \), which is further assumed to be independent of the source signal. In a typical laboratory setting the number of measured scalp signals \( p \) can be \( 32 - 256 \), while the source distribution can be represented by \( n = 1000 - 10,000 \) locations. Thus we face a severely underdetermined problem and regularization is necessary to ensure a well-defined solution, see e.g., [7] for an early review. As we have noted key processes appear to be rather dipolar, thus searching for sparse localized solutions seems well-motivated.

III. THE VARIATIONAL GARROTE

The so-called Variational Garrote (VG) introduces sparseness into the regression problem by adding the binary 'location' variable \( s_i \in \{0, 1\} \) for absent/present parameters [6]. Thus, the modified linear problem reads

\[
y_i = \sum_{i=1}^{n} w_i s_i X_{i\gamma} + \xi_i.
\]

The location variable is a latent binary variable with a prior \( p(s|\gamma) = \prod_{i=1}^{n} p(s_i|\gamma) \) where \( p(s_i|\gamma) = \frac{\exp(\gamma s_i)}{1 + \exp(\gamma)} \). Parameter \( \gamma \) will in general be assumed negative \( \gamma < 0 \), reflecting a bias towards sparsity.

The optimal solution to (1) can be obtained with a variational approximation proposed in [6]. First the posterior probability of the model given the data is established based on a Gaussian noise assumption, \( \xi \sim \mathcal{N}(0, \beta^{-1}) \), \( p(s, w, \beta|\mathbf{D}, \gamma) \propto p(w, \beta)p(s|\gamma)p(D|s, w, \beta) \), with \( \mathbf{D} \) being the full data set, while the prior over sources and noise variance is assumed to be uniform \( p(w, \beta) \propto 1 \). The
discrete variable s is marginalized out, giving rise to the marginal posterior, \( p(w, \beta | D, \gamma) \). The resulting expression to maximize is now

\[
\log p(w, \beta | D, \gamma) \propto \log \sum_s p(s | \gamma)p(D | s, w, \beta).
\]

(2)

Invoking Jensen’s inequality and a variational posterior over source locations, \( q(s) \), we bound the log-likelihood in (2) from below by

\[
-\sum_s q(s) \log \frac{q(s)}{p(s | \gamma)p(D | s, w, \beta)} \equiv -F(q, w, \beta).
\]

(3)

The variational free energy \( F(q, w, \beta) \) is minimized, corresponding to maximizing the log-likelihood (2). We assume \( q(s) = \prod_{i=1}^{n} q_i(s_i) \) and factors \( q_i(s_i) = m_i s_i + (1 - m_i) (1 - s_i) \), where \( m_i \) is the probability that \( s_i = 1 \) [6].

As noted, the EEG problem is severely underdetermined, therefore we can simplify the model using a dual formulation with update rules for \( p \) Lagrange multipliers \( \lambda_{\mu}, \hat{y}_{\nu} \) [6]

\[
A_{\mu\nu} = \delta_{\mu\nu} + p^{-1} \sum_{i=1}^{n} m_i X_{i\mu} X_{i\nu}/((1 - m_i) \chi_{ii}),
\]

(4)

\[
y_\mu = \sum_{\nu=1}^{p} A_{\mu\nu} \hat{y}_{\nu}, \quad \beta^{-1} = p^{-1} \sum_{\mu=1}^{p} \hat{y}_{\mu} y_\mu,
\]

\[
\lambda_\mu = \beta \hat{y}_{\mu}, \quad w_i = \frac{1}{\beta p \chi_i (1 - m_i)} \sum_{\mu=1}^{p} \lambda_\mu X_{i\mu},
\]

\[
m_i^{-1} = 1 + \exp \left( -\frac{\beta p}{2} w_i^2 \chi_{ii} - \gamma \right), \quad v_i = m_i w_i.
\]

The computational complexity is dominated by a term \( \propto np^2 \) (4) which is much lower than the \( n^3 \) complexity of a direct implementation.

IV. EVALUATION

We investigate the Variational Garrote in a series of simulation experiments, and in a benchmark EEG data set. First we investigate a simple setup based on a random forward model, while the remaining simulations and the benchmark data are based on a high-dimensional EEG Boundary Element Method (BEM) forward model [8]. For the first set of simulations we form \( p = 50 \) measurements and \( n = 100 \) unknown sources and apply the noise precision \( \beta^{-1} = 1 \). Here we let a single source element in the ‘true’ generating model be set to unity, while the rest are set to 0. VG is run on this data set with \( \gamma = -10 \) (found in pilot experiment) and \( m \) initialized with three different strategies.

Next, VG and three currently used approximate solvers; least absolute shrinkage and selection operator (LASSO) [9], Forward selection [10], and Sparse Bayesian Modeling (SBM) [11], are tested in a more realistic EEG setting using synthetic sources. The latter consists of 10 sources set to the value 1, and the rest 0. However, now using a normalized forward model as \( X \) created using OpenMEEG [8] mapping \( n = 8196 \) sources to \( p = 128 \) electrodes.

The four methods all have a single hyper-parameter to tune, in the VG we follow [6] and tune the sparsity parameter \( \gamma \). The data set is first split into a training and test set with \( p_{\text{test}} = 10 \) and \( p_{\text{train}} = 118 \). Within the training set we further perform \( K \)-fold cross-validation to tune the four methods’ hyper-parameters. We use \( K = 2, \ldots, 15 \), i.e., the training set is subdivided to consist of a training set \(( (K - 1)/K ) \) and a validation set \(( 1/K ) \). For each \( K \), performances are reported in terms of the normalized mean
squared error (nMSE). The above procedure is repeated 50 times. Fig. 2 compares the performances of the four methods. To set a scale we also include the nMSE for the true source distribution. We find that VG outperforms the alternatives for all $K$. It is noted (not shown) that the convergence speed of VG in the applied ‘EEG setting’ is similar to that of the simple setup applied in Fig. 1. Interestingly, the performances of the methods with their respective optimized hyper-parameters are stable with respect to fold size $K$. Further, inspection of the estimates reveals that, e.g., LASSO - also referred to as minimum current estimate in the present context [12] - is less sparse than VG, and in fact has many small ‘false’ sources. Fig. 3 visualizes the spatial structure of the found sources in the context of a 3D ‘cortex’.

For the simulation we also check how well VG with optimization of sparsity using the electrode cross-validation procedure is able to identify the actual source locations. For this experiment we plant 10 sources and estimate source distributions for a range of sparsity parameters ($\gamma$). In Fig. 4 we show that the cross-validation error as function of the sparsity control parameter indeed is minimized in the same range as the source retrieval index $F_1 = \frac{2 \cdot \text{precision} \cdot \text{recall}}{\text{precision} + \text{recall}}$ [13] is maximized. For comparison we show the similar plot for SBM (where the cross-validated hyper-parameter is the noise precision). Here the test error-optimal solution has a somewhat lower source retrieval index than obtained by VG.

For a final test of the performance of VG in the context of ‘real’ EEG we turn to the SPM face recognition benchmark data [14]. We focus on reconstructing the sources and their activation in a time window $100\text{ms} < t < 200\text{ms}$, at sampling rate $f_s = 200\text{Hz}$. We make a simple extension of the model to allow for a time constant $s_i$ with time varying activation strengths $w_i$, effectively decoupling the ‘where’ ($s$) and ‘what’ ($w$) degrees of freedom which leads to only minor modifications to the inference scheme [15]. In Fig. 5 we show the resulting activation time courses and in the cortex inset arrows indicate the locations of the corresponding sources. Both time courses (N170 components) and locations are consistent with the general findings of [14] and [16].

V. DISCUSSION AND CONCLUSION

EEG imaging is a hard, underdetermined inverse problem. We hypothesize that solutions of interest are sparse and note that sparsity constraints can regularize the problem. We have shown that direct search for sparse solutions as implemented by Kappen’s Variational Garrote [6] can outperform solutions based on convex relaxations (LASSO, minimum current estimate), forward feature selection, sparse Bayesian learning, both in terms of cross-validation error on test data, and in terms of quality of the solutions. In a quasi-realistic setting with an EEG forward model we found that the VG solution provides an excellent reconstruction of the planted sources. Finally, we noted that the VG model allows separation of where and what degrees of freedom, and used this to analyze a benchmark face recognition data set assuming that the locations were constant, while activations change in time. The resulting time courses and locations for a single trial were found to be consistent with the solutions proposed earlier based on averaging over multiple epochs.
