The high-mobility two-dimensional electron gas (2DEG) confined at the interface of two insulating complex oxides provides new opportunities to explore nanoelectronic devices. So far, such oxide 2DEG is nearly exclusively created within the frame of interface polarity, such as the case of the intensively explored LaAlO$_3$/SrTiO$_3$ (LAO/STO) heterointerface. Alternatively, when building heterostructures on STO, the basis material for oxide electronics, the conductance can also originate from tunable redox reactions at the interface, i.e., the oxygen-vacancies dominated conductivity in reduced STO substrates [1]. In this presentation, the mechanism of the interface conductance in STO-based oxide heterostructures will be discussed. Moreover, our recent findings of new 2DEGs in STO-based oxide heterostructures will be also presented. Relying on redox reactions, an oxide 2DEG with electron mobilities exceeding 100,000 cm$^2$V$^{-1}$s$^{-1}$ at 2 K, 100 times higher than those of LAO/STO heterointerface, is obtained [2]. The conduction dimension and its spatial confinement will be also discussed.

Presentation Method (Invited/Regular Oral/Poster): Invited
